

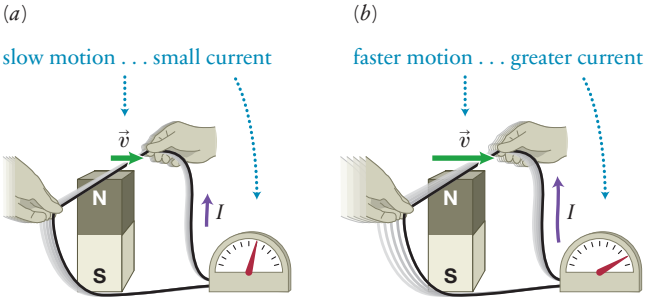

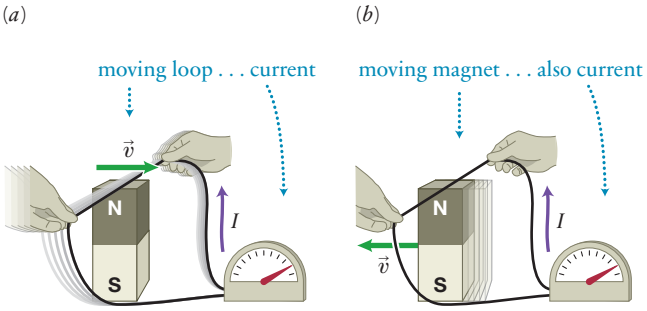

Figure 29.7 A current can be induced by moving either the loop or the magnet.

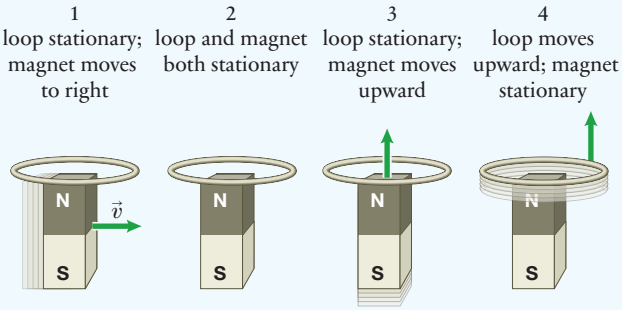
These experiments lead us to conclude:

A changing magnetic flux through a conducting loop induces a current in the loop.

This statement is called **Faraday's law.** The process by which a changing magnetic flux causes charge carriers to move, establishing a separation of charge or inducing a current, is called **electromagnetic induction.**

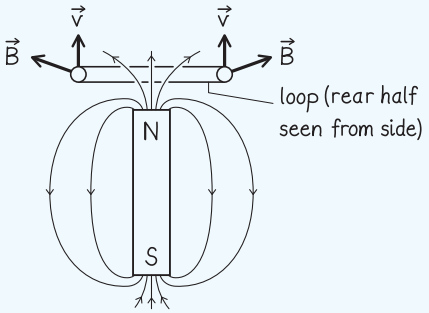
EXAMPLE 29.2 Changing magnetic flux



(*a*) In which of the four loops shown in Figure 29.8 is there a current that is caused by a magnetic force? (*b*) In which situation(s) is a current induced in the loop?

1 GETTING STARTED I begin by making a sketch of the magnetic field of the bar magnet, based on what I learned in Chapter 27 (Figure 27.13). I show a cross section of the loop placed above the north pole of the magnet (Figure 29.9).

2 DEVISE PLAN Magnetic forces are exerted on charge carriers moving relative to a magnetic field, provided there is a nonzero component of the magnetic field perpendicular to the carriers' velocity. To answer part *a*, therefore, I must determine which of the four situations satisfies those conditions. For part *b* I know that a changing magnetic flux induces a current, and so for each situation I must establish whether or not the magnetic flux through the loop is changing.



3 EXECUTE PLAN (*a*) Because the loop is stationary in situations 1 through 3, there cannot be a magnetic force in those

Figure 29.8 Example 29.2.

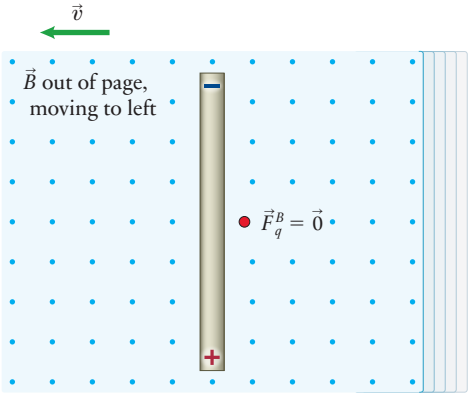
CONCEPTS

Figure 29.9

situations. For situation 4, I draw vectors in Figure 29.9 indicating the directions of the loop velocity and of the magnetic field at the position of the ring and the velocity of the loop. Because the magnetic field lines spread outward from the north pole, the magnetic field is not parallel to the velocity, and so a magnetic force is exerted on the charge carriers. According to the right-hand force rule, the force is in opposite directions on the two sides of the loop, so this magnetic force creates a current in the loop. ✔

(*b*) Because the field of a bar magnet is not uniform, any relative motion between the magnet and the loop causes the magnetic flux through the loop to change. Therefore, the magnetic flux is changing in situations 1, 3, and 4, which means current is induced in the loop in these three cases. ✔

4 **EVALUATE RESULT** That there is a current created by a magnetic force only in situation 4 makes sense because a magnetic force requires a nonzero velocity of the charge carriers and only in situation 4 is the loop moving. That there is an induced current in every situation except 2 makes sense because Faraday's law tells me that a current is induced whenever there is a changing magnetic flux through the loop—that is, whenever the loop and magnet move relative to each other.



29.3 Is a magnetic force exerted on the (stationary) charge carriers in the loop of wire held above the magnet in Figure 29.7*b*?

29.3 Electric fields accompany changing magnetic fields

Example 29.2 and Checkpoint 29.3 lead to a surprising conclusion: Although no magnetic force is exerted on the charge carriers in a stationary loop, a current is still induced! **Figure 29.10** shows this situation in more detail. Experiments show that as the source of a magnetic field moves past a stationary conducting rod, a charge separation and hence a potential difference develop between the ends of the rod even though no magnetic force is exerted on stationary charge carriers.

The potential difference that develops between the ends of the rod shown in Figure 29.10 is the same as that which would develop if the source of the magnetic

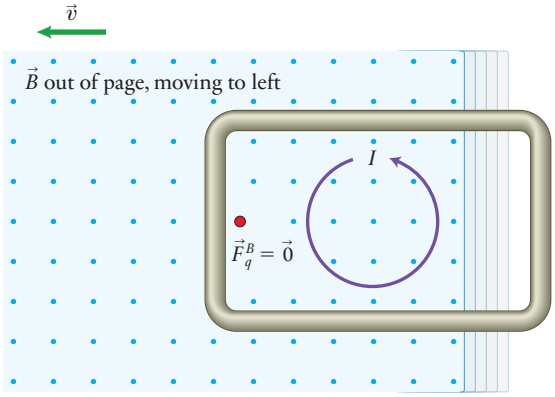


Figure 29.10 A stationary conducting rod in a moving magnetic field develops a charge separation, but no magnetic force is exerted on the charge carriers because their speed in the rod is zero, which means $\vec{v} \times \vec{B} = \vec{0}$.

field were stationary and the rod were moving to the right (recall Figure 29.1). Any motion of the rod relative to the magnetic field produces the same potential difference across the rod's ends. By the same token, a current is induced in the stationary rectangular loop of **Figure 29.11** by the moving magnetic field source, just as a current is induced in the rectangular loop moving through a constant magnetic field in Figure 29.2. In other words, whenever relative motion occurs between charge carriers and the source of a magnetic field, the resulting rearrangement of charge and potential difference is independent of the choice of inertial reference frame, as are any resulting currents.

What force causes the charge carriers to flow when the loop is stationary? We have encountered two types of forces that are exerted on charged particles: Electric and magnetic. Magnetic forces are exerted only on moving charged particles, so these forces cannot be responsible for the induced current in Figure 29.11. Only electric forces are exerted on stationary charged particles, so we must conclude that the force that causes charge to separate in Figure 29.10 is an electric force

Figure 29.11 A current is induced in a stationary conducting loop as a magnetic field source moves past it when not all of the loop is in the field, even though no magnetic force is exerted on the charge carriers.

CONCEPTS

(because it behaves like one). Because electric forces are caused by electric fields, we are led to conclude:

A changing magnetic field is accompanied by an electric field.

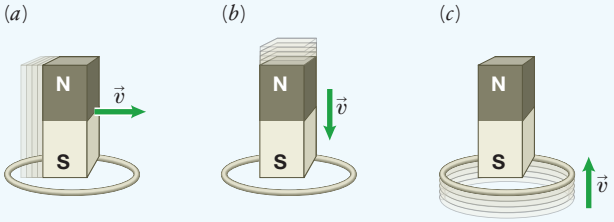
29.4 In Figure 29.1, charge accumulates at the ends of the moving rod until the amount at each end reaches an equilibrium value. Mechanical equilibrium is established when the magnetic force due to the motion of the rod counterbalances the electric force due to the charge separation. In Figure 29.10, what two forces determine the equilibrium state of the charge separation in the stationary rod?

We see that the nature of the force causing electromagnetic induction depends on the choice of reference frame. Forces that appear to be magnetic in one inertial reference frame are electric in another inertial reference frame. Indeed, the fact that our choice of reference frame affects whether a force is magnetic or electric is further evidence that electric and magnetic fields arise from fundamentally the same interaction (see Section 27.4). Because viewing the situation from a different inertial reference frame cannot alter the underlying interaction, magnetic and electric forces must be two manifestations of the same interaction.

29.5 As viewed from above, what is the direction of the induced current in situations 1 and 3 in Figure 29.8?

What do the field lines of the electric field that induces the current in Figure 29.11 look like? Electric field lines show the direction of the electric force exerted on a positively charged test particle. Because a counterclockwise current is induced in the loop (see position *d* in Example 29.1), we know that positive charge carriers in the loop experience a force directed counterclockwise all along the loop. This leads us to conclude that the field lines must form loops that close on themselves. The electric field lines that accompany a changing magnetic field are therefore very different from the electric field lines we have encountered thus far, which originate and terminate on charged objects. Returning to the loop in Figure 29.11, we see that there is no charge separation anywhere in the loop, so there is no particular place where a field line begins or ends.

CONCEPTS



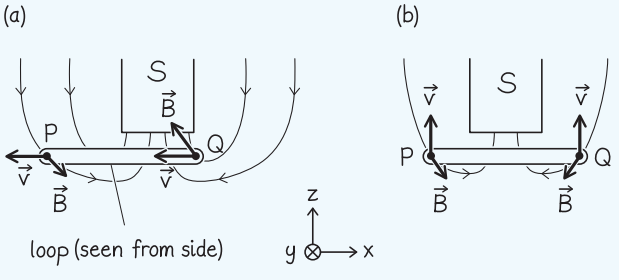
29.4 Lenz's law

What determines the direction of the current induced by a changing magnetic flux? So far, the only way we have to determine the direction of the induced current is to work out the direction of the magnetic forces by considering the situation from a frame of reference in which the magnetic field is stationary and the charge carriers are moving. As the following example illustrates, however, this procedure is cumbersome at best.

EXAMPLE 29.3 What is the current direction?

For each of the three situations shown in **Figure 29.12**, is the induced current in the loop clockwise or counterclockwise as viewed from above?

Figure 29.12 Examples 29.3 and 29.4.



1 GETTING STARTED To determine the direction of the induced current, I need to determine the direction of the electric or magnetic force exerted on the charge carriers in the loop.

2 DEVISE PLAN I can use the right-hand force rule to determine the direction of the magnetic forces (assuming positive charge carriers), and the only way I know to do this is to consider each situation from a reference frame in which the magnetic field is stationary and the loop is in motion. For (*a*) I choose a reference frame moving along with the magnet; in this reference frame the loop moves to the left (**Figure 29.13*a***). Situations (*b*) and (*c*) are equivalent, so the direction of the induced current must be the same in both. I therefore need to consider only (*c*), where the magnetic field is stationary and the loop is in motion (Figure 29.13*b*). I can then use the right-hand force rule to determine the direction of the magnetic force at a couple of locations on the loop. Once I know these force directions, I can determine the direction of the induced current.

3 EXECUTE PLAN I'll consider two locations on the loop: location P on the left and Q on the right. At each of these locations I draw arrows representing the velocity $\vec{v}$ of the (positive) charge carriers and the magnetic field $\vec{B}$. (All of the vectors I draw are in the vertical *xz* plane.)

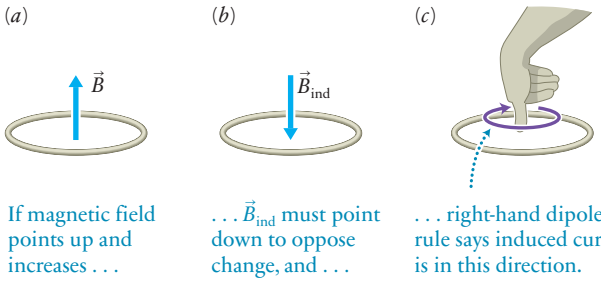
(*a*) At location P on the loop in Figure 29.13*a*, the magnetic field points down and to the right, and the charge carriers in the loop are moving to the left at velocity $\vec{v}$. If I curl the fingers of my right hand from $\vec{v}$ to $\vec{B}$ at P, my thumb points out of the page, which means the magnetic force exerted on the charge carriers at P points out of the page. Thus at P the charge carriers are moving counterclockwise as viewed from above. At Q the magnetic field is

Figure 29.13

up and to the left, and the charge carriers here are also moving to the left at velocity $\vec{v}$. When I curl the fingers of my right hand from $\vec{v}$ to $\vec{B}$, my thumb points into the page. This means the magnetic force at Q points into the page, moving the charge carriers in the loop counterclockwise as viewed from above. Thus the induced current is counterclockwise as seen from above. ✔

(*b*, *c*) At P in Figure 29.13*b*, the loop and its charge carriers are moving up at velocity $\vec{v}$, and the magnetic field has a vertical component and a component to the right in the plane of the page. Curling the fingers of my right hand from $\vec{v}$ to $\vec{B}$, I discover that the magnetic force exerted on the positive charge carriers points into the page. At Q it points out of the page, so the magnetic forces exerted on the charge carriers at P and Q induce a current that is clockwise as seen from above. ✔

4 EVALUATE RESULT Comparing Figures 29.8 and 29.12, I note that Figure 29.12*a* is similar to situation 1 in Figure 29.8, and Figure 29.12*b* and *c* are similar to situations 3 and 4. In Example 29.2, I concluded that currents are induced in situations 1, 3, and 4, so in this example, too, I should expect currents in all three situations.



A simpler approach to determining the direction of an induced current follows from experimental observation:

> **The direction of an induced current through a conducting loop is always such that the magnetic flux produced by the induced current opposes the change in magnetic flux through the loop.**

This principle is called **Lenz's law,** and the magnetic field resulting from the induced current is called the **induced magnetic field.**

Consider, for example, a conducting loop in a magnetic field that points up and is increasing in magnitude (**Figure 29.14*a***). In order for the induced magnetic field $\vec{B}_{\text{ind}}$ to oppose the change in magnetic field, $\vec{B}_{\text{ind}}$ must point down, as shown in Figure 29.14*b*. What current direction produces a downward induced magnetic field? According to the right-hand dipole rule, the current must be clockwise as seen from above (Figure 29.14*c*). Indeed, this is what we found for a loop moving into a magnetic field in Example 29.1: As the magnetic flux through the loop increases, a clockwise current is induced.

Figure 29.14 Applying Lenz's law.

EXAMPLE 29.4 Clockwise or counterclockwise?

Consider again the three situations of Figure 29.12. Use Lenz's law to determine the direction of the induced current in each loop.

1 GETTING STARTED Using Lenz's law involves determining which direction for the induced current produces an induced magnetic field opposing the change in magnetic flux through the loop. The magnetic field that passes through the loop points primarily up (toward the south pole of the magnet) and is strongest along the long axis of the magnet.

2 DEVISE PLAN According to Lenz's law, the induced current must be directed in such a way as to create an induced magnetic field $\vec{B}_{\text{ind}}$ that counteracts the change in magnetic flux. If the magnetic flux that causes the induced current decreases, $\vec{B}_{\text{ind}}$ must be in the same direction as the magnetic field of the magnet so that $\vec{B}_{\text{ind}}$ increases the magnetic flux through the loop. If the magnetic flux that causes the induced current increases, $\vec{B}_{\text{ind}}$ must be in the direction opposite the direction of the magnet's magnetic field. Once I know the direction of $\vec{B}_{\text{ind}}$, I can use the right-hand dipole rule to determine the direction of the current.

3 EXECUTE PLAN (*a*) As the magnet moves to the right, the magnitude of the magnetic field at the loop, and therefore the magnetic flux through the loop, decrease. Therefore $\vec{B}_{\text{ind}}$ is upward, in the direction of the magnet's magnetic field. To use the right-hand dipole rule, I recall from Section 28.3 that the direction of a magnetic field near the poles of a bar magnet is given by the magnetic dipole moment vector, which points from south pole to north pole. Thus I point my right thumb in this direction in Figure 29.12a and see that my fingers curl counterclockwise as viewed from above, telling me that this is the direction of the induced current. ✔

(*b*) Moving the magnet toward the loop causes the magnetic flux through the loop to increase. The induced magnetic field $\vec{B}_{\text{ind}}$ associated with the induced current must therefore point downward, opposite the direction of the field created by the magnet, to oppose the increase in magnetic flux through the loop. The induced current is therefore clockwise as viewed from above. ✔

(*c*) Moving the loop toward the magnet results in an increase in magnetic flux through the loop, as in part *b*. The induced current therefore must be clockwise as viewed from above to produce a downward-pointing induced magnetic field $\vec{B}_{\text{ind}}$ that opposes the increase in flux. ✔

4 EVALUATE RESULT My answers are the same as in Example 29.3, which gives me confidence that they are correct.

29.6 When current is induced in a conducting loop by the motion of a nearby magnet, the induced magnetic field $\vec{B}_{\text{ind}}$ exerts a force on the magnet. (*a*) In Figure 29.12*b*, what is the direction of the force exerted on the magnet by $\vec{B}_{\text{ind}}$? (*b*) Suppose Lenz's law stated that the induced current *adds to* the change that produced it instead of opposing it. What would be the direction of the force exerted by $\vec{B}_{\text{ind}}$ on the magnet?

CONCEPTS

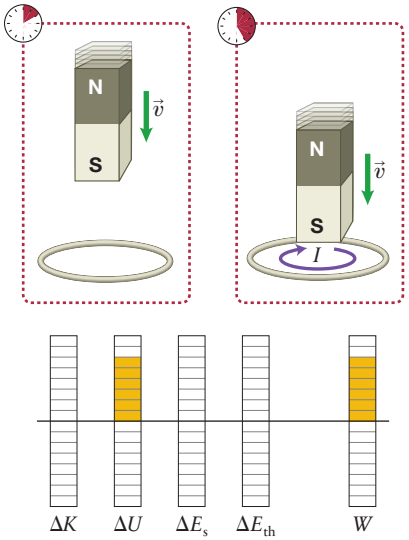
Checkpoint 29.6 gives us a clue to the reason for Lenz's law. In Figure 29.12*b*, let's consider the system made up of magnet and loop. If the induced current further increased the magnetic flux through the loop, the induced current would exert an attractive force on the magnet. This attractive force would pull the magnet closer to the loop, increasing the magnetic flux further and inducing even more current. In the process, the kinetic energy of the magnet and the energy associated with the current in the loop would increase, increasing the energy of the magnet-loop system without any work being done on it, violating the law of conservation of energy.

Conservation of energy therefore *requires* that an induced current oppose the change that created it. In Figure 29.12*b*, for example, the force exerted by the induced magnetic field $\vec{B}_{\text{ind}}$ resists the magnet moving closer to the loop. An alternative statement of Lenz's law therefore is:

An induced current is always in such a direction as to oppose the motion or change that caused it.

Because of this opposing force, an agent moving the magnet at constant speed toward the loop must do work on the magnet. Where does this energy go? As work is done on the system, the current through the loop—and therefore the induced magnetic field—increases. Just as we can associate electric potential energy with an electric field, we can associate **magnetic potential energy** with a magnetic field. In the absence of dissipation, the work done on the magnet-loop system therefore increases the magnetic potential energy of the system. The energy diagram in **Figure 29.15** illustrates the conversion of mechanical work to magnetic potential energy.

Figure 29.15 Energy diagram for a magnet-loop system when the magnet moves toward the conducting loop, inducing a current through the loop. Work must be done on the system to push the magnet at constant speed against the opposing induced magnetic field of the loop. This work causes the potential energy of the magnet-loop system to increase.



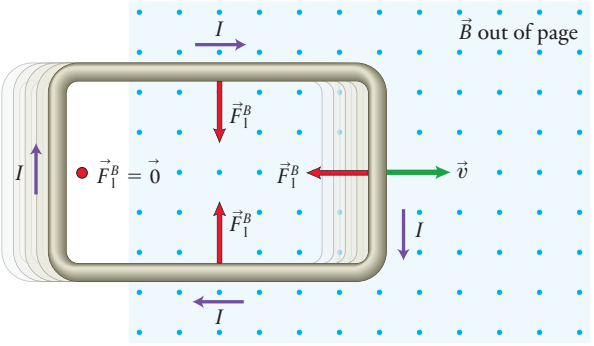


Figure 29.16 Direction of magnetic forces exerted by a magnetic field on each side of a rectangular conducting loop because of the current induced in the loop. As the loop moves into the field, the vector sum of the magnetic forces exerted on the loop resists its motion into the field.

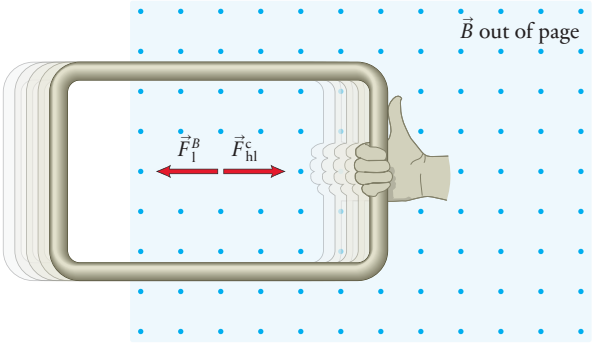
Work must also be done to move a conducting loop into a magnetic field. When current is induced in the loop by its motion in the magnetic field, the magnetic field exerts a force on the current.

Figure 29.16 shows the directions of these magnetic forces exerted on each side of a rectangular conducting loop as it enters a magnetic field from the left. The vector sum of the forces points to the left. In order to move the loop through the field at constant speed, you must exert on the loop a constant force to the right that is equal in magnitude to the magnetic force (**Figure 29.17**). In doing so, you do work on the loop.

CONCEPTS

29.7 (*a*) After the left edge of the loop in Figure 29.17 enters the magnetic field, is the work required to continue pulling the loop through the field at constant speed v positive, negative, or zero? (*b*) As the right edge emerges from the magnetic field, is the work required positive, negative, or zero?

Figure 29.17 Work must be done on a conducting loop to move it into a magnetic field because magnetic forces exerted on the loop resist its motion when there is an induced current in the loop (shown in more detail in Figure 29.16).



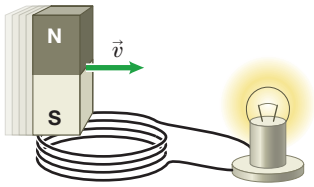


Figure 29.18 An induced current can be used to light a lamp. The work done on the magnet is converted to light and thermal energy in the filament of the lamp.

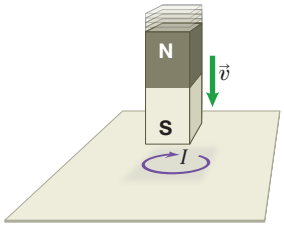
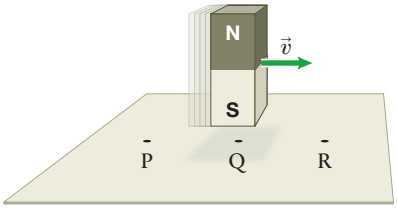


As you move a conductor relative to a magnetic field (or vice versa), the work you do transfers energy to the conductor, setting the charge carriers in motion. This energy associated with the induced current can then be converted to other forms of energy by some device placed in the current path, such as a lamp, toaster, or electric motor. In **Figure 29.18**, for example, a lamp is inserted in the current path and the work done on the system is converted to light energy and thermal energy in the lamp. Doing work by moving a loop through a magnetic field and thereby setting charge carriers in motion is the basic idea behind electric generators.

29.8 Which requires doing more work: moving a magnet toward a closed conducting loop or moving it toward a rod? Both motions are at constant speed.

It is not necessary to have a conducting object in the shape of a loop. If a bar magnet is moved toward an extended conducting object, such as a conducting sheet (**Figure 29.19**), circular currents are induced throughout the surface of the object. These currents are called **eddy currents** because they form eddy-like loops in the object's surface. (An *eddy* is the circular, whirlpool-like movement of water.)



Because eddy currents dissipate energy, they can be used to convert kinetic energy (for example, the kinetic energy associated with the motion of a conductor relative to a magnet) to thermal energy. Dissipation of energy by eddy currents is used in braking systems, especially trains and roller coasters. In contrast to conventional friction brakes, eddy current brakes involve no physical contact and so there is no wear and tear and there are no brake pads to be replaced.

Figure 29.19 The circular current loops induced in a conducting sheet by the motion of a nearby magnet are called eddy currents.

29.9 In **Figure 29.20**, a bar magnet moves parallel to a metal plate. (*a*) At the instant shown, does the magnitude of the magnetic flux increase, decrease, or stay the same through a small region around points P, Q, and R? (*b*) Are the eddy currents induced around these points clockwise, counterclockwise, or zero?

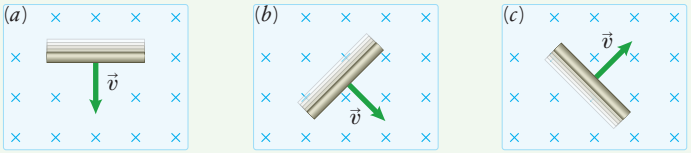


Figure 29.20 A bar magnet moves parallel to the surface of a conducting sheet, causing the local magnetic flux to change across the sheet surface and inducing eddy currents where the magnetic flux is changing (Checkpoint 29.9).

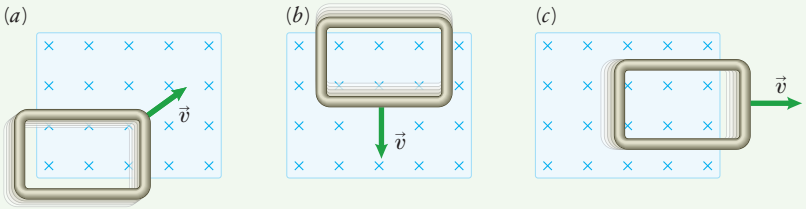
Self-quiz



1. A conducting rod moves through a magnetic field as shown in **Figure 29.21**. Which end of the bar, if any, becomes positively charged?

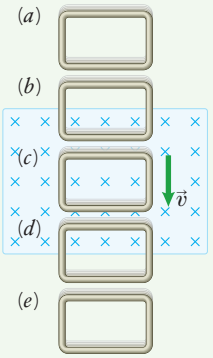
Figure 29.21

2. A conducting loop moves through a magnetic field as shown in **Figures 29.22a–c**. Which way does the current run in the loop at the instant shown in each figure?

Figure 29.22

3. A conducting loop moves through a magnetic field at constant velocity as shown in **Figure 29.23**. For each case *a*–*e*, must the work done on the loop be positive, negative, or zero to keep the loop moving?
4. Using Faraday's law, determine whether charge carriers flow in the loop for each situation shown in **Figure 29.24**.

Figure 29.23



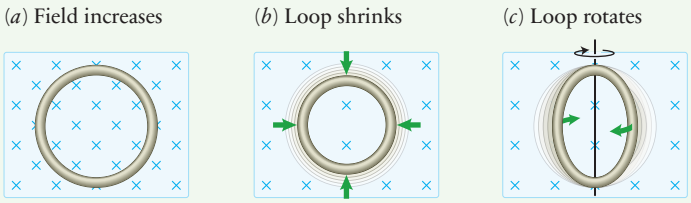


Figure 29.24

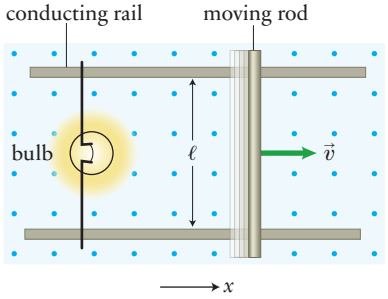
5. Using Lenz's law, determine the direction of the induced current, if any, at the instants shown in Figure 29.24.

Answers



1. The direction of the magnetic force on the positive charge carriers in the rod is given by the right-hand force rule: If you point the fingers of your right hand in the direction of $\vec{v}$ and then curl them toward $\vec{B}$ (into the page), your thumb points in the direction of the force. Applying this rule in the three situations shows that positive charge accumulates on the right end of the bar in (*a*) and (*b*) and on the left end of the bar in (*c*).
2. In (*a*) and (*b*), the magnitude of the magnetic flux through the loop increases into the page, so the induced magnetic field opposing this change must point out of the page. According to the right-hand dipole rule, an induced current must be counterclockwise to produce a magnetic field that points out of the page. In (*c*), the magnitude of the magnetic flux through the loop decreases into the page, so the induced current must be clockwise.
3. In (*a*), (*c*), and (*e*), the magnetic flux through the loop does not change and so no current is induced in the loop. The vector sum of the magnetic forces exerted on the loop is therefore zero, so no work is required to keep the loop moving at constant speed. In (*b*) and (*d*), the magnetic flux through the loop changes and a current is induced through the loop. According to Lenz's law the induced current is in such a direction as to oppose the motion or change that created it, so a positive amount of work is needed to keep the loop moving at constant speed.
4. Because the magnetic flux through the loop is changing in all three cases, charge carriers flow in all three.
5. (*a*) The magnetic field is directed into the page, and the magnitude of the magnetic flux is increasing into the page. The induced magnetic field opposing this change must therefore point out of the page, so according to the right-hand dipole rule, the induced current is counterclockwise. (*b*) Because the area of the loop decreases, the magnetic field is directed into the page and the magnitude of the magnetic flux decreases. The induced current is therefore clockwise. (*c*) At the instant shown in the figure, the magnitude of the magnetic flux through the loop decreases and so the induced current must be clockwise.

29.5 Induced emf

We first encountered the concept of emf in Chapter 26 in the context of batteries. Chemical reactions in a battery produce and maintain a separation of charge across the battery terminals; this separation results in a potential difference from one terminal to the other. If a light bulb is connected to the terminals, this potential difference drives a current through the light bulb. In Section 26.4, we defined the emf of a charge-separating device as the work done per unit charge by nonelectrostatic interactions in separating charge within the device. Because the charge separation across the ends of a rod caused by electromagnetic induction (Figure 29.10) is nonelectrostatic, we can associate an emf with this separation of charge. Emfs produced by electromagnetic induction are therefore called **induced emfs.**

Consider the setup illustrated in **Figure 29.25**. A conducting rod of length ℓ rests on two conducting rails connected to a light bulb. The rod is pulled to the right and moves at a constant speed v along the x axis. The motion of the rod changes the area of the magnetic field enclosed by the loop formed by the rod, rails, and wires attaching the bulb to the rails. Because of this area change, a current is induced through the loop. This current causes the light bulb to glow.

Figure 29.25 The emf that develops in a moving rod can be used to drive a current when that rod is part of a closed conducting loop. The rod is connected to the rest of the loop by sliding electrical contacts.

As we saw in Section 29.4, the magnetic field exerts a leftward force on the current-carrying rod. To move the rod at a constant speed v to the right, therefore, the agent pulling the rod must exert a rightward force of equal magnitude on it. In doing so, the external agent must do work on the rod, increasing the energy of the charge carriers in the loop. This energy is converted to light and thermal energy in the light bulb. We can obtain an expression for the induced emf in the loop by calculating the work done on the rod.

According to Eq. 27.4, the magnitude of the magnetic force exerted on a rod of length ℓ carrying a current I is $|I|\ell B$ when the rod is perpendicular to the magnetic field, so the contact force $\vec{F}^{\text{c}}_{\text{ar}}$ exerted by the agent on the rod required to pull it at constant speed must be of the same magnitude: $F^{\text{c}}_{\text{ar}} = |I|\ell B$. Because the work done on the rod is positive, it is equal to the product of the magnitude of the contact force exerted on it and the magnitude of the force displacement: $W_{\text{r}} \equiv F^{\text{c}}_{\text{ar}x}\Delta x_F = F^{\text{c}}_{\text{ar}}|\Delta x_F|$. In a time interval Δt, the rod is displaced a distance $\Delta x = v_x \Delta t$, so we have

$$W_{\text{r}} = F^{\text{c}}_{\text{ar}}|\Delta x_F| = B|I|\ell v \Delta t \tag{29.1}$$

or, using Eq. 27.1, $I \equiv q/\Delta t$, to simplify,

$$W_{\text{r}} = B\ell v|q|, \tag{29.2}$$

where q is the charge that passes through a given section of the rod in a time interval Δt. This result tells us how much energy is transferred to the current loop as the rod is pulled. Note that the force exerted by the magnetic field on the charge carriers in the rod transfers the mechanical work done on the rod to the charge carriers in the loop—the magnetic force itself does no work. (Because the direction of the magnetic force is always perpendicular to the motion of the charge carriers, the force cannot do any work on the carriers.)

If it bothers you that the external agent is doing the work and not the magnetic force that sets the charge carriers in motion, consider an analogy: Suppose you push yourself away from a wall starting from rest. The wall provides the force that accelerates you away from it. This force does *no work*, however, because the point of application does not move. In fact, no work at all is done on you. Internal (source) energy is converted to kinetic energy; the force exerted by the wall on you converts the internal energy to kinetic energy.

We can now calculate the magnitude of the induced emf, which is defined as the nonelectrostatic work per unit charge done on a charged particle (Eq. 26.7):

$$|\mathscr{E}_{\text{ind}}| \equiv \frac{W_{\text{r}}}{|q|} = B\ell v. \tag{29.3}$$

As shown in Figure 29.25, the induced emf in the closed conducting loop drives a current, just as a battery of the same emf would. This current has the same effect on the loop as a battery-driven current would have; in this case, it lights a light bulb. The magnitude of the resulting current—the **induced current**—depends on how much resistance the loop puts up to the motion of charge carriers. Experimentally we determine that the induced current through many conducting materials is proportional to the induced emf:

$$I_{\text{ind}} = \frac{\mathscr{E}_{\text{ind}}}{R}, \tag{29.4}$$

where the proportionality constant R is a measure of the *resistance* of the loop. The smaller the value of R, the greater the induced current for a given induced emf. We'll learn more about resistance in Chapter 31.

Equation 29.3 gives the magnitude of the induced emf in terms of v, B, and the length ℓ of the rod. In Section 29.2 we argued that the induced current—that is, the current that results from the induced emf—is due to a change in the magnetic flux enclosed by the loop. Let us therefore obtain an expression for the induced emf in terms of the magnetic flux Φ_B through the loop. In Section 27.6 we defined the magnetic flux through a loop by the surface integral (Eq. 27.10)

$$\Phi_B \equiv \int \vec{B} \cdot d\vec{A}, \tag{29.5}$$

where $d\vec{A}$ is the area vector of an infinitesimally small segment of a surface bounded by the loop.

Because the surface integral in Eq. 29.5 is independent of the choice of surface bounded by the loop (Eq. 27.15), we integrate over a flat surface bounded by the loop in Figure 29.25. Because the magnetic field is uniform, we can pull it out of the integral and so in Figure 29.25, if we let the vector $d\vec{A}$ point out of the page in the same direction as $\vec{B}$, $\Phi_B = BA$. When the moving side of the loop is displaced by Δx, the area enclosed by the expanding loop changes by $\Delta A = \ell \Delta x$. If this change occurs over a time interval Δt, the rate of change in the magnetic flux enclosed by the loop is thus

$$\frac{\Delta \Phi_B}{\Delta t} = \frac{B \Delta A}{\Delta t} = \frac{B\ell \Delta x}{\Delta t} = B\ell \frac{\Delta x}{\Delta t}, \tag{29.6}$$

so Eq. 29.3 can be written as

$$|\mathscr{E}_{\text{ind}}| = B\ell v = B\ell \left| \frac{\Delta x}{\Delta t} \right| = \left| \frac{\Delta \Phi_B}{\Delta t} \right|. \tag{29.7}$$

As we let the time interval Δt approach zero, this yields

$$\mathscr{E}_{\text{ind}} = -\frac{d\Phi_B}{dt}, \tag{29.8}$$

QUANTITATIVE TOOLS

where we have added a negative sign to indicate that the direction of the induced emf is such that it drives a current that counteracts the change in magnetic flux, in accordance with Lenz's law. Equation 29.8, which relates a changing magnetic flux to an induced emf, is a quantitative statement of **Faraday's law.**

Note that Eq. 29.8 correctly gives a zero emf when applied to the situation shown in Figure 29.4*c*, in which the entire loop (not just one side) is moving and is in the magnetic field. We derived Eq. 29.8 for the special case of one side of a rectangular conducting loop moving in a magnetic field, but it is generally valid: It gives the value of the emf no matter what causes the magnetic flux through a conducting loop to change.

29.10 Sketch how the induced emf in the loop in Figure 29.4 varies as the loop moves through the five positions.

Equation 29.8 allows us to point out an important difference between potential difference and emf, both of which are related to the work per unit charge done on charge carriers—the former by electrostatic interactions, the latter by nonelectrostatic interactions. As we established in Chapter 25, potential difference depends only on starting and ending locations. It does not depend on the path followed to get from the starting location to the ending location. In other words, potential difference is path-independent. The work per unit charge done on charged particles by *nonelectrostatic* interactions, such as the induced emf in Figure 29.25, does depend on the path taken. Consider, for example, a rectangular conducting loop containing a light bulb and placed in a changing magnetic field (**Figure 29.26*a***). The light bulb glows because the changing magnetic flux through the area enclosed by the loop causes an induced emf throughout the loop. If the area enclosed by the loop is smaller (Figure 29.26*b*), then the light bulb is less bright. The emf induced in the loop is now smaller because the smaller area causes a smaller rate of change in the magnetic flux. Had we established a potential difference across the light bulb by connecting it via wires to, say, the terminals of a battery, how much area the wires enclose would not affect the brightness of the bulb (**Figure 29.27**). We shall discuss this difference in path-dependence between potential difference and emf in more detail in the next section.

We can use an induced emf to establish a potential difference between two locations. Consider, for example, the conducting rod of Figure 29.1. As we saw in Section 29.1, the magnetic force exerted on the negative charge carriers in the moving rod drives them upward. A surplus of negative charge accumulates at the top of the rod, leaving a surplus of positive charge at the bottom. This separation of charge produces an electric field inside the rod. The negative charge carriers flow until the magnitude of the downward electric force exerted on one of them due to the electric field inside the rod is equal to the magnitude of the upward magnetic force (**Figure 29.28** on the next page):

$$F_q^E = F_q^B. \tag{29.9}$$

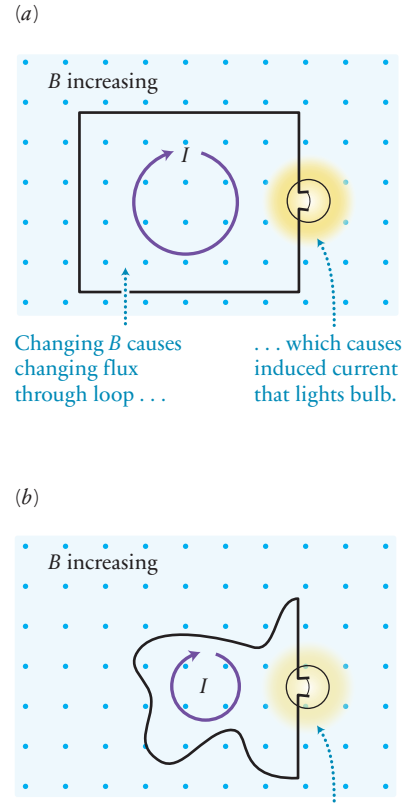
The magnitude of the magnetic force exerted on a charged particle of charge q moving perpendicular to a magnetic field is given by Eq. 27.18, $F_q^B \equiv |q|vB$, and the electric force is given by Eq. 23.6, $F_q^E = |q|E$. With this information, we can rewrite Eq. 29.9 as

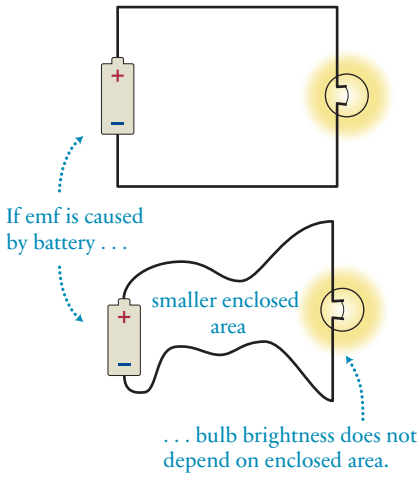
$$|q|E = |q|vB. \tag{29.10}$$

Thus E, the magnitude of the electric field inside the rod, is

$$E = vB. \tag{29.11}$$

Figure 29.26 Path-dependence of an induced emf.





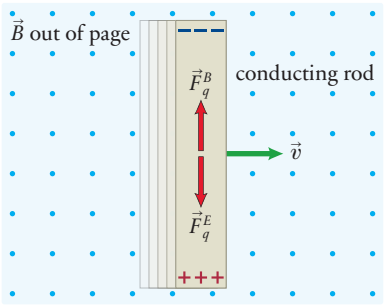


Figure 29.27 The emf produced by a battery does not depend on enclosed area.

QUANTITATIVE TOOLS

Figure 29.28 When a conducting rod moves in a magnetic field, the magnetic force exerted on the negative charge carriers in the rod causes a charge separation. This separation continues until the force exerted by the electric field resulting from the charge separation exactly counters the magnetic force exerted on the charge carriers.

This electric field causes a potential difference between the top and the bottom of the rod. For a rod of length ℓ, the potential difference is (see Eq. 25.25)

$$V_{\text{tb}} = -\int_{\text{top}}^{\text{bottom}} \vec{E}\cdot d\vec{\ell} = \int_{\text{top}}^{\text{bottom}} E\,d\ell = E\int_{\text{top}}^{\text{bottom}} d\ell = E\ell, \qquad (29.12)$$

where $\vec{E}\cdot d\vec{\ell} = -E\,d\ell$ because the electric field points from the bottom to the top of the rod whereas $d\vec{\ell}$ points in the direction of integration. In addition we have pulled E out of the integral because it is constant throughout the rod. Substituting the magnitude of the electric field from Eq. 29.11, we obtain

$$V_{\text{tb}} = vB\ell. \qquad (29.13)$$

Thus we see that the electric field in the rod establishes across the ends of the rod a potential difference that is equal in magnitude to the induced emf (Eq. 29.3).

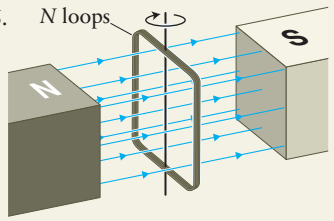
EXAMPLE 29.5 Airplane wing "battery"

A Boeing 747 with a wingspan of 60 m flies at a cruising speed of 850 km/h. What is the magnitude of the maximum potential difference induced between the two wingtips by Earth's magnetic field (the magnitude of which is roughly 0.50×10^{-4} T)?

❶ **GETTING STARTED** A Boeing 747 is made of metal and so, as the airplane flies through the magnetic field of Earth, the electrons in the metal are able to move when a magnetic force is exerted on them. This motion of the electrons causes a charge separation in the wings, and thus a potential difference is induced. To solve this problem, I must make several simplifying assumptions. I take the wings to be a 60-m conducting rod and assume the plane is flying horizontally through a vertical magnetic field. As a result, the problem reduces to a rod moving through a perpendicular magnetic field.

❷ **DEVISE PLAN** To calculate the induced potential difference between the ends of the "rod" formed by the wings, I can use Eq. 29.13.

❸ **EXECUTE PLAN**



$$V_{\text{wings}} = (8.50 \times 10^5 \text{ mh})\left(\frac{1\text{ h}}{3600\text{ s}}\right)(0.50 \times 10^{-4}\text{ T})(60\text{ m})$$
$$= 0.71\text{ T}\cdot\text{m}^2/\text{s} = 0.71\text{ V}. \checkmark$$

❹ **EVALUATE RESULT** My calculation yields a potential difference on the order of the one from an AA battery, but that should not cause any problems in the aircraft. Also, the magnetic field is unlikely to be perpendicular to the velocity of the plane, as I assumed, and therefore the actual value of the potential difference is smaller than what I obtained.

EXAMPLE 29.6 Generator

In an electric generator a solenoid that contains N windings each of area A is rotated at constant rotational speed ω in a uniform magnetic field of magnitude B (**Figure 29.29**). What is the emf induced in the solenoid?

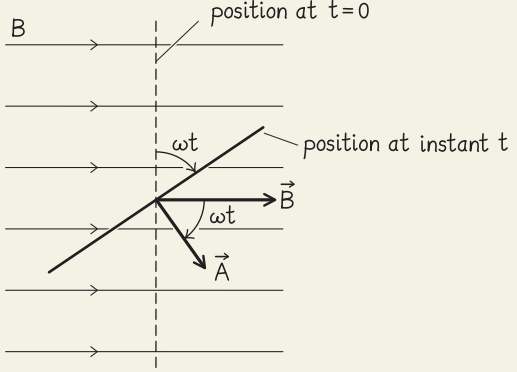


Figure 29.29 Example 29.6.

❶ **GETTING STARTED** As the solenoid rotates, the magnetic flux through it changes, and this changing flux causes an emf in the solenoid.

❷ **DEVISE PLAN** Equation 29.8 tells me that the emf induced in the solenoid equals the time rate of change of the magnetic flux through it. Therefore I must first determine how the magnetic flux varies as a function of time and then differentiate whatever expression I get to obtain the emf. I can determine the magnetic flux through the solenoid by multiplying the magnetic flux through a single winding, $\Phi_B \equiv \vec{B}\cdot\vec{A}$ (Eq. 27.9), by the number of windings N. To determine the magnetic flux through a single winding, I sketch a top view of a winding in the magnetic field, indicating the directions of the magnetic field $\vec{B}$ and the area vector $\vec{A}$ (**Figure 29.30**). I let the plane of the winding be perpendicular to the direction of the magnetic field at $t = 0$.

Figure 29.30

QUANTITATIVE TOOLS

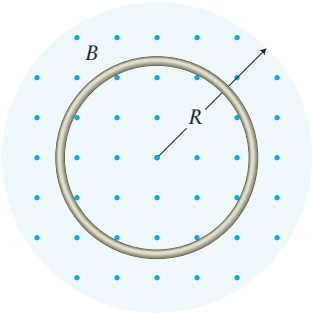
3 EXECUTE PLAN As the solenoid rotates, the scalar product $\vec{B} \cdot \vec{A}$ changes with time. At instant t shown in my sketch, the angle between $\vec{A}$ and $\vec{B}$ is ωt, and so the magnetic flux through a single winding is $\Phi_B = \vec{B} \cdot \vec{A} = BA \cos \omega t$. Through the N windings of the solenoid the magnetic flux is $\Phi_B = NBA \cos \omega t$. Substituting this value into Eq. 29.8, I get

$$\mathcal{E}_{\text{ind}} = -\frac{d}{dt}(NBA \cos \omega t) = \omega NBA \sin \omega t. \checkmark$$

4 EVALUATE RESULT My result shows that the emf oscillates sinusoidally. It is zero when $\omega t = n\pi$ $(n = 0, 1, 2, \ldots)$ and maximum when $\omega t = n\pi + \frac{\pi}{2}$ $(n = 0, 1, 2, \ldots)$. That result makes sense because the rate of change of the magnetic flux through the solenoid is zero when the area vector of the windings is parallel to the magnetic field $(\omega t = n\pi)$ and maximum when the area vector is perpendicular to the magnetic field $(\omega t = n\pi + \frac{\pi}{2})$.

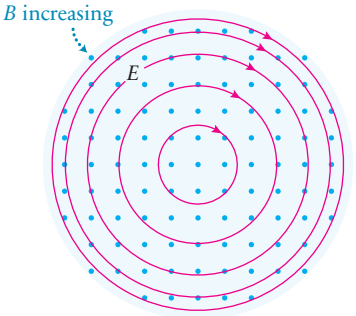
29.11 The expression I derived in Example 29.6 indicates that the emf becomes negative after the solenoid has rotated 180° and remains negative through the next 180° of rotation. However, the solenoid orientation looks the same when the solenoid has rotated 180° as when it started. Why does the emf have a different sign for half of the rotation?

29.6 Electric field accompanying a changing magnetic field



We saw in Section 29.3 that when the magnetic flux through a conducting loop changes, an electric force is exerted on the initially stationary charge carriers in the loop. This electric force is caused by the electric field that accompanies the changing magnetic field. Let's explore the properties of this electric field in more detail.

Consider the case of a conducting circular loop in a uniform magnetic field that has a circular cross section (**Figure 29.31a**). Suppose the magnitude of the magnetic field increases steadily over time. Because the conducting loop encloses an increasing magnetic flux directed out of the page, a clockwise current is induced in the loop. What do the electric field lines that are responsible for this current look like?



We found in Section 29.3 that the electric field lines that accompany a changing magnetic field form loops because there are no isolated charge carriers on which the electric field lines can begin or end. These loops must be circular and centered on the axis of the magnetic field because the electric field that accompanies the changing magnetic field must have the same cylindrical symmetry as the magnetic field (Figure 29.31*b*). Lenz's law tells us that the induced current is clockwise, and so the electric field must also be pointing clockwise. When the magnetic field does not exhibit cylindrical symmetry, the electric field lines are not circular, and in general it is difficult to determine the shape of the electric field lines.

Figure 29.31 Electric field that accompanies an increasing cylindrical magnetic field.

(*a*) Conducting ring in cylindrical uniform magnetic field

(*b*) Electric field that accompanies increasing magnetic field

29.12 What do the electric field lines look like when the magnitude of the magnetic field in Figure 29.31*b* (*a*) is held constant and (*b*) decreases steadily?

To determine the magnitude of the electric field that accompanies the changing magnetic field, let's think about its effect on charge carriers in the conducting loop. A current is induced in the loop because the electric field does work on the charge carriers in the loop. We can calculate the work done by the electric field using Eq. 25.1, which gives the work done by an electric field $\vec{E}$ on a particle carrying a charge q in moving it from point A to point B:

$$W_q(\text{A} \to \text{B}) = \int_{\text{A}}^{\text{B}} \vec{F}_q^E \cdot d\vec{\ell} = q \int_{\text{A}}^{\text{B}} \vec{E} \cdot d\vec{\ell}. \qquad (29.14)$$

QUANTITATIVE TOOLS

(Note that the electric field accompanying the changing magnetic field is *not* an electrostatic field, and thus the quantity calculated in Eq. 29.14 is *not* electrostatic work.)

The work done on a particle carrying a charge q as it travels around the closed path formed by the conducting loop is then

$$W_q \text{ (closed path)} = q \oint \vec{E} \cdot d\vec{\ell}. \tag{29.15}$$

The work done by the electric field per unit charge is thus

$$\frac{W_q}{q} = \oint \vec{E} \cdot d\vec{\ell}. \tag{29.16}$$

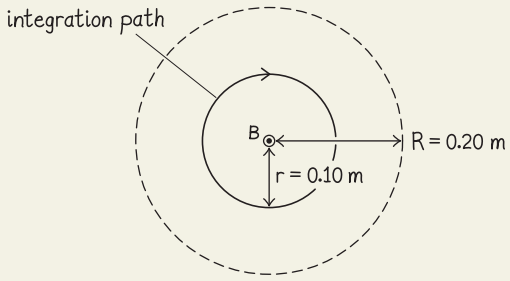
This work per unit charge is the induced emf (Eq. 26.7), and so combining Eq. 29.16 with Eq. 29.8 gives us an expression that contains the electric field accompanying the changing magnetic field:

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt}. \tag{29.17}$$

Equation 29.17 is an alternative statement of Faraday's law. Note that the magnetic flux appearing in this equation is a signed quantity. In order to obtain the correct direction of the electric field in Eq. 29.17, the magnetic flux must be taken to be positive when the magnetic field points in the direction of your right-hand thumb as you curl the fingers of your right hand in the direction of the integration path.

Keep in mind that the electric field in Eq. 29.17 is not an electrostatic field. Electrostatic fields originate directly from static charge distributions. Rather than originating from static charged objects, the electric field in Eq. 29.17 appears with a changing magnetic field and the electric field lines close on themselves. As we saw in Chapter 25, the work done by an electrostatic field on a charged particle moving around a closed path is zero, which means the line integral around a closed path on the left in Eq. 29.17 is always zero for an electrostatic field (see Eq. 25.32). However, as Eq. 29.17 shows, in a region where the magnetic field is changing, the line integral of an electric field around a closed path is not necessarily zero. This means that the electric field accompanying the changing magnetic field can do work on charged particles that travel along a closed path and the amount of work depends on the choice of path. We cannot define a potential difference between two points for such an electric field because it would have different values for different paths between those points.

EXAMPLE 29.7 Electric field magnitude



Let the uniform cylindrical magnetic field in Figure 29.31 have a radius $R = 0.20$ m and increase at a steady rate of 0.050 T/s. What is the magnitude of the electric field at a radial distance $r = 0.10$ m from the center of the magnetic field?

❶ **GETTING STARTED** The changing magnetic field is accompanied by an electric field that has circular field lines pointing clockwise (Figure 29.31). Because of the circular symmetry, I know that the magnitude E of the electric field cannot vary along any given electric field line.

❷ **DEVISE PLAN** To solve this problem, I can use Eq. 29.17 to work out the relationship between E and the rate of change of the magnetic field magnitude dB/dt. Because E is constant along any electric field line, it must be constant on *any* circular path centered on the axis of the cylindrical magnetic field. I therefore choose as my path of integration a clockwise circular path of radius $r = 0.10$ m centered on the long central axis of the magnetic field (**Figure 29.32**). Because $\vec{E}$ is always parallel to $d\vec{\ell}$, $\vec{E} \cdot d\vec{\ell} = E\,d\ell$ on the left side of Eq. 29.17, and because the magnitude of the electric field is the same everywhere on the path, I can take E out of the integral. To evaluate the right side, I must first calculate the magnetic flux through the circular integration path. Because the magnetic field is uniform, the magnetic flux is given by Eq. 27.9.

QUANTITATIVE TOOLS

Figure 29.32

❸ **EXECUTE PLAN** The left side of Eq. 29.17 becomes

$$\oint \vec{E} \cdot d\vec{\ell} = 2\pi r E. \tag{1}$$

The magnetic flux through the area enclosed by the integration path is negative (curling the fingers of my right hand in the direction of the integration path makes my thumb point in the direction opposite the direction of $\vec{B}$), and so

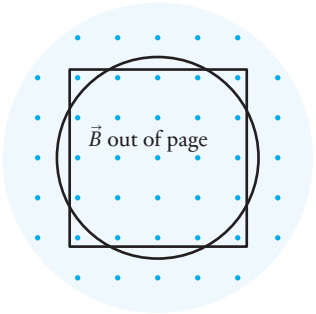
$$\Phi_B = -BA = -\pi r^2 B.$$

Thus the right side of Eq. 29.17 becomes

$$-\frac{d\Phi_B}{dt} = +\pi r^2 \frac{dB}{dt}. \tag{2}$$

Substituting Eqs. 1 and 2 into Eq. 29.17 then yields

$$2\pi r E = \pi r^2 \frac{dB}{dt}$$



$$E = \tfrac{1}{2} r \frac{dB}{dt} = \frac{(0.10\ \text{m})(0.050\ \text{T/s})}{2}$$

$$= 2.5 \times 10^{-3}\ \text{T} \cdot \text{m/s} = 2.5 \times 10^{-3}\ \text{N/C}. \checkmark \tag{3}$$

❹ **EVALUATE RESULT** Equation 3 shows that the magnitude of the electric field increases with radial distance r from the center of the magnetic field. Given the cylindrical symmetry of the situation, that's exactly what I expect.

Although the electric field lines and the conducting loop pictured in Figure 29.31 are circular, our derivation of Eq. 29.17 does not depend on the shape of the path of integration. This means we can use Eq. 29.17 to determine the line integral of the electric field around any closed path. For example, **Figure 29.33** shows a square path of integration that encloses the same area (and hence the same magnetic flux) as the circular path I used to solve Example 29.7. Because the enclosed magnetic flux is the same, we know that the integral of the electric field around the square path must yield the same result as the integral around the round path, even though the electric field is no longer tangent to the path and no longer of the same magnitude all along the path.

Figure 29.33 Square and circular paths of integration that enclose the same area and therefore enclose the same magnetic flux.

29.13 In Example 29.7 what is the magnitude of the electric field at a distance of 0.30 m from the center of the magnetic field?

29.7 Inductance

An interesting consequence of Faraday's law is that when a current through a conducting loop changes, the change induces an emf *in the loop itself*. To understand why this happens, consider **Figure 29.34*a*** on the next page, in which a battery drives a current I through a solenoid. Because the current creates a magnetic field, a nonzero magnetic flux passes through the loops of the solenoid.

Now imagine the battery is suddenly disconnected, as in Figure 29.34*b*. Without the battery to supply an emf, the current, the magnitude of the magnetic field, and the magnitude of the magnetic flux all start to decrease. Faraday's law tells us, however, that the changing flux induces in the solenoid an emf that opposes the change in flux. Consequently, as the magnetic flux is decreasing, the induced emf causes an induced current that has the same direction as the original current. The magnetic flux associated with this induced current opposes the change in the magnetic flux.

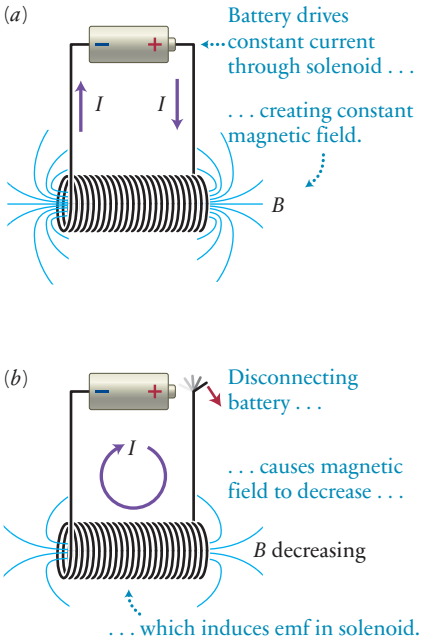


Figure 29.34 Disconnecting a battery from a solenoid induces in the solenoid an emf that opposes the decrease in current through it.

The induced emf is proportional to the rate of change in the magnetic flux through the solenoid (Eq. 29.8). The magnetic flux is proportional to the magnitude B of the magnetic field, which is proportional to the current through the loop (Eq. 28.6, $B = \mu_0 nI$). Thus the faster the current changes, the greater the magnitude of the induced emf:

$$\mathcal{E}_{\text{ind}} \propto \frac{d\Phi_B}{dt} \propto \frac{dB}{dt} \propto \frac{dI}{dt}. \tag{29.18}$$

We can define the **inductance** L of a loop or solenoid as the constant of proportionality between the emf and the rate of change of current:

$$\mathcal{E}_{\text{ind}} = -L\frac{dI}{dt}. \tag{29.19}$$

A large inductance leads to a large induced emf. The derived SI unit of inductance is the **henry:**

$$1\ \text{H} \equiv 1\ \text{V}\cdot\text{s/A} = 1\ \text{kg}\cdot\text{m}^2/\text{C}^2. \tag{29.20}$$

A device that has an appreciable inductance is called an **inductor.** Inductors are used widely in electric circuits to slow down the timing of variations in current.

The inductance describes how much change in magnetic flux is associated with a change in current for a particular loop or solenoid, as we can see by substituting Eq. 29.8 in the left side of Eq. 29.19:

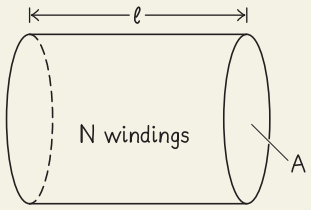
$$\frac{d\Phi_B}{dt} = L\frac{dI}{dt}. \tag{29.21}$$

The inductance of a current-carrying device or circuit depends only on its geometry, but for most real devices, calculating the inductance is not simple. The general procedure for determining the inductance is described in the Procedure box "Calculating inductances" on this page. In a few particularly simple cases, it is possible to derive an algebraic expression for the inductance, as in Example 29.8.

PROCEDURE: Calculating inductances

The inductance of a current-carrying device or current loop is a measure of the emf induced in the device or loop when current is changed. To determine the inductance of a particular device or current loop, follow these four steps.

1. Derive an expression for the magnitude of the magnetic field in the current-carrying device or current loop as a function of the current. Your expression should depend only on the current I and possibly—but not necessarily—the position within the device or current loop.
2. Calculate the magnetic flux Φ_B through the device or current loop. If the expression you derived in step 1 depends on position, you will have to integrate that expression over the volume of the device or circuit. Use symmetry to simplify the integral and divide the device into segments on which B is constant.
3. Substitute the resulting expression you obtained for Φ_B into Eq. 29.21. As you take the derivative with respect to time, keep in mind that only the current varies with respect to time, so you should end up with an expression that contains the derivative dI/dt on both sides of the equal sign.
4. Solve your expression for L after eliminating dI/dt.



QUANTITATIVE TOOLS

EXAMPLE 29.8 Inductance of a solenoid

What is the inductance of a solenoid (Section 28.6) of length ℓ that has N windings, each of cross-sectional area A, when the current through the device is I?

❶ **GETTING STARTED** I begin by making a sketch of the solenoid (**Figure 29.35**). If I treat the solenoid as being infinitely long, I know from Section 28.6 that the magnetic field is uniform inside the solenoid and zero outside of it. To calculate the inductance of the solenoid, I follow the steps in the Procedure box on the previous page.

Figure 29.35

❷ **DEVISE PLAN** I first need to obtain an expression for the magnetic field magnitude B in terms of the current I. We derived this expression in Section 28.6 and found $B = \mu_0 nI$ (Eq. 28.6), where n is the number of windings per unit length $n = N/\ell$, and so $B = \mu_0 NI/\ell$. Knowing B, I can calculate the magnetic flux, substitute this result into Eq. 29.21, and then solve for the inductance L.

❸ **EXECUTE PLAN** The magnetic flux through one winding is the area A enclosed by the winding multiplied by the magnetic field B inside the solenoid: $\Phi_B = BA$. For the solenoid, the magnetic flux is then

$$\Phi = NBA = \frac{\mu_0 N^2 IA}{\ell}.$$

Substituting this expression for the magnetic flux into Eq. 29.21 yields

$$\frac{d}{dt}\frac{\mu_0 N^2 IA}{\ell} = L\frac{dI}{dt}.$$

The only part of the left side that is time-dependent is the current I, so differentiating with respect to time and simplifying give me

$$L = \frac{\mu_0 N^2 A}{\ell}. \checkmark$$

❹ **EVALUATE RESULT** My result shows that the inductance of a solenoid increases as the square of the number of windings N. This makes sense because both the magnetic field inside the solenoid and the magnetic flux increase with N. That inductance also depends on the area A enclosed by each winding also makes sense because increasing A increases the magnetic flux. Finally, that the inductance is inversely proportional to the length ℓ of the solenoid makes sense because the magnetic field is proportional to the number of turns per unit length.

29.14 A solenoid has 2760 windings of radius 50 mm and is 0.60 m long. If the current through the solenoid is increasing at a rate of 0.10 A/s, what is the magnitude of the induced emf?

29.8 Magnetic energy

We saw in Section 26.6 that work must be done to charge a capacitor and that this work increases the electric potential energy stored in the electric field of the capacitor. Likewise, work must be done on an inductor to establish the current through it because the change in current causes an induced emf that opposes this change; this work increases the **magnetic potential energy** stored in the magnetic field of the inductor.

In Chapter 26, we saw that electric potential energy can be attributed either to the configuration of charge in a system or to the electric field of this charge configuration. Likewise we can attribute the potential energy in an inductor either to the current through it or to the magnetic field caused by the current.

How much potential energy is stored in an inductor in which the current is I? To work this out, we calculate the work required to create a current I in an inductor. We begin by writing the work dW done on the inductor when an amount of charge dq moves through it. This work is the negative of the work done by the induced emf of the inductor:

$$dW = -\mathscr{E}_{\text{ind}}\, dq. \tag{29.22}$$

Using the definitions of current and Eq. 29.19, we obtain for the rate at which work is done

$$\frac{dW}{dt} = -\mathscr{E}_{\text{ind}}\frac{dq}{dt} = -\mathscr{E}_{\text{ind}} I = LI\frac{dI}{dt}, \tag{29.23}$$

and so $dW = LI\,dI$. We can then integrate both sides to obtain the work W done on the inductor to create a current I in it:

$$W = \int dW = L\int I\,dI = \tfrac{1}{2}LI^2. \tag{29.24}$$

To determine how much potential energy is stored in the magnetic field of an inductor, let's choose the zero of magnetic potential energy to be when there is no current through the inductor, and therefore no magnetic field. The magnetic potential energy stored in the inductor when there is a current through it is then equal to the work done to increase the current from zero to I:

$$U^B = \tfrac{1}{2}LI^2. \tag{29.25}$$

This is analogous to Eq. 26.4 for the electric potential energy stored in a capacitor, $U^E = \frac{1}{2}CV_{\text{cap}}^2$, with L taking the place of C and I taking the place of V_{cap}. Because this energy in the inductor is stored in the magnetic field, let's express the energy in terms of the magnetic field. We'll do this for the case of a long solenoid, but the result turns out to be generally applicable. Substituting the expression worked out in Example 29.8 for L into Eq. 29.25, we obtain

$$U^B = \tfrac{1}{2}\frac{\mu_0 N^2 A}{\ell}\,I^2, \tag{29.26}$$

where, as in Example 29.8, N is the number of windings, A is the area of each winding of the solenoid, and ℓ is the length of the solenoid.

In Chapter 26, we used the expression for the electric potential energy U^E to arrive at an expression for the energy density in an electric field: $u_E = \frac{1}{2}\epsilon_0 E^2$ (Eq. 26.6). Let us now use Eq. 29.26 to obtain an expression for the energy density in the magnetic field. Equation 28.6, $B = \mu_0 nI$, where $n = N/\ell$ is the number of windings per unit length, gives us the magnitude of the magnetic field inside a solenoid, and taking the square of this equation yields

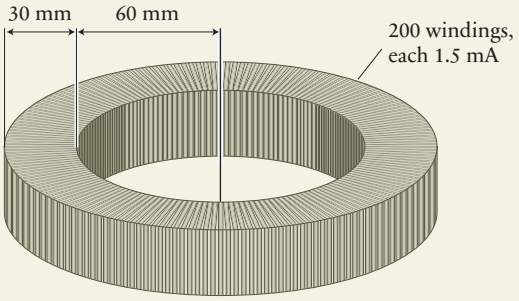
$$B^2 = \frac{\mu_0^2 N^2 I^2}{\ell^2}. \tag{29.27}$$

Multiplying the right side of Eq. 29.26 by the factor $\mu_0\ell/\mu_0\ell$ gives

$$U^B = \tfrac{1}{2}\frac{\mu_0 N^2 A I^2}{\ell}\frac{\mu_0\ell}{\mu_0\ell} = \tfrac{1}{2}\frac{\mu_0^2 N^2 I^2}{\mu_0\ell^2}A\ell = \tfrac{1}{2}\frac{B^2}{\mu_0}A\ell. \tag{29.28}$$

Because $A\ell$ is the volume of the region of magnetic field inside the solenoid, dividing the energy U^B by this volume gives us the **energy density** of the magnetic field:

$$u_B \equiv \tfrac{1}{2}\frac{B^2}{\mu_0}. \tag{29.29}$$



This expression is analogous to the expression for the energy density u_E in the electric field (Eq. 26.6), with B appearing instead of E and $1/\mu_0$ replacing ϵ_0. If the magnetic field is nonuniform, we must subdivide the volume of interest into small enough segments that B can be considered uniform within each segment, then apply Eq. 29.29 to each segment and take the sum of all the contributions. This amounts to integrating the energy density of the magnetic field over the volume containing the magnetic field:

$$U^B = \int u_B\,dV. \tag{29.30}$$

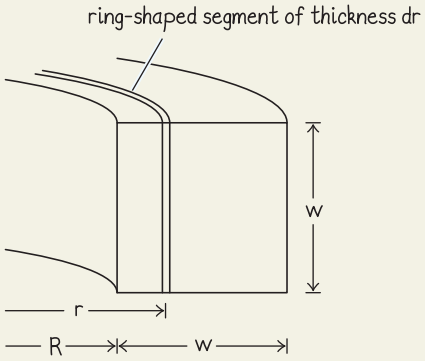
EXAMPLE 29.9 Magnetic energy stored in a square toroid

Consider a toroid with square windings (**Figure 29.36**). The inner radius is $R = 60$ mm, each winding has width $w = 30$ mm, and there are 200 windings, each carrying a current of 1.5 mA. What is the magnetic potential energy stored in this toroid?

Figure 29.36 Example 29.9.

❶ **GETTING STARTED** The current through the toroid causes a magnetic field inside the toroid. This magnetic field stores magnetic potential energy. I note that the width of the windings is not negligible relative to the toroid radius, and this tells me that I must assume a nonuniform magnetic field magnitude across the width of the windings. I therefore must use Eq. 29.30 to determine the amount of magnetic potential energy stored.

❷ **DEVISE PLAN** Before I can use Eq. 29.30, I must obtain the energy density of the magnetic field, which is given by Eq. 29.29. To calculate this energy density, I need to know the magnitude B of the magnetic field. Because the magnetic field is nonuniform, I must determine B by using Eq. 28.9, $B = \mu_0 NI/2\pi r$, where r is the radial distance from the center of the ring formed by the toroid. So to determine the magnetic potential energy stored, I must integrate Eq. 29.29 over the volume of the space enclosed by the windings of the toroid.



❸ **EXECUTE PLAN** Equation 29.29 gives me

$$U^B = \int u_B\,dV = \frac{1}{2\mu_0}\int B^2 dV = \frac{\mu_0 N^2 I^2}{8\pi^2}\int \frac{dV}{r^2}. \qquad (1)$$

To integrate over the volume of the toroid, I divide the volume into ring-shaped segments (**Figure 29.37**) of height w, radius r, and thickness dr. The volume dV of each segment is equal to the product of the ring's circumference $2\pi r$, height w, and thickness dr: $dV = 2\pi r w\,dr$. Substituting this expression into Eq. 1 and integrating over r from the inner radius of the toroid, $r = R$, to the outer radius, $r = R + w$, I get

$$U^B = \frac{\mu_0 N^2 I^2}{8\pi^2}\int_R^{R+w}\frac{2\pi w r\,dr}{r^2} = \frac{\mu_0 N^2 I^2 w}{4\pi}\int_R^{R+w}\frac{dr}{r}.$$

Figure 29.37

Working out the integration over r yields

$$U^B = \frac{\mu_0 N^2 I^2 w}{4\pi}\ln\left[1 + \frac{w}{R}\right]. \qquad (2)$$

Substituting in the values for μ_0, N, I, R, and w, I obtain for the magnetic potential energy stored in the toroid

$$U^B = (10^{-7}\,\mathrm{T\cdot m/A})(200)^2(1.5\times10^{-3}\mathrm{A})^2 \times (30\cdot10^{-3}\,\mathrm{m})\ln\left(1 + \frac{30\ \mathrm{mm}}{60\ \mathrm{mm}}\right)$$

$$= 1.1\times10^{-10}\,\mathrm{T\cdot m^2\cdot A} = 1.1\times10^{-10}\,\mathrm{J},\ \checkmark$$

where I have used $1\ \mathrm{T\cdot m^2\cdot A} = 1\ [\mathrm{N/(A\cdot m)]\cdot m^2\cdot A} = 1\ \mathrm{N\cdot m} = 1\ \mathrm{J}$ (Eq. 27.6).

❹ **EVALUATE RESULT** The result I obtained is a very small amount of energy, but I have no idea (yet) how much energy is stored in a magnetic field. I can, however, compare my result with the result I would obtain in the limit where the width of each winding is much less than the toroid radius, $w \ll R$. In that limit the magnetic field is uniform inside the toroid, and its magnitude is given by Eq. 28.9, $B = \mu_0 NI/2\pi R$. The volume inside the windings of the toroid is equal to the toroid circumference, $2\pi R$, times the area of a winding, w^2: $V = 2\pi R w^2$. Substituting this expression for B in Eq. 29.29 and multiplying the energy density of the magnetic field by the volume V, I then get for the magnetic potential energy stored in the toroid

$$U^B = \tfrac{1}{2}\frac{\mu_0^2 N^2 I^2/(2\pi R)^2}{\mu_0}(2\pi R w^2) = \frac{\mu_0 N^2 I^2 w^2}{4\pi R}$$

$$= \frac{\mu_0 N^2 I^2 w}{4\pi}\frac{w}{R}. \qquad (3)$$

Because $\ln(1+\epsilon) \approx \epsilon$ for $\epsilon \ll 1$, Eq. 2 is equal to Eq. 3 in the limit that $w \ll R$, giving me confidence in my integration result.

29.15 How does the energy density of a 1.0-T magnetic field compare with the energy density of an 1.0-V/m electric field?

QUANTITATIVE TOOLS

Chapter Summary

Induced emf and current (Sections 29.1, 29.2, 29.4, 29.5)

Concepts A changing magnetic flux through the area enclosed by a conducting loop causes an **induced current** through the loop. This process is called **electromagnetic induction.**

According to **Lenz's law**, the direction of an induced current is always such that the magnetic flux produced by the induced current opposes the change in the magnetic flux that induces the current.

Quantitative Tools If a straight rod of length ℓ moves with speed v perpendicular to a magnetic field of magnitude B, the magnitude of the **induced emf** across the ends of the rod is

$$|\mathscr{E}_{\text{ind}}| = B\ell v. \tag{29.3}$$

According to **Faraday's law,** the induced emf in a closed path due to a changing magnetic flux through the area enclosed by the path is

$$\mathscr{E}_{\text{ind}} = -\frac{d\Phi_B}{dt}, \tag{29.8}$$

where $d\Phi_B/dt$ is the rate at which the magnetic flux changes. The **induced current** in a conducting loop of resistance R is

$$I_{\text{ind}} = \frac{\mathscr{E}_{\text{ind}}}{R}. \tag{29.4}$$

Reminder: The **magnetic flux** Φ_B through a surface is

$$\Phi_B \equiv \int \vec{B} \cdot d\vec{A}, \tag{27.10, 29.5}$$

where the integral is taken over the surface. Magnetic flux is measured in **webers** (Wb), where $1\ \text{Wb} \equiv 1\ \text{T} \cdot \text{m}^2$.

The electric field accompanying a changing magnetic field (Sections 29.3, 29.6)

Concepts A changing magnetic field is accompanied by an electric field. Unlike an electrostatic field, this electric field does not necessarily do zero work on a charged particle that travels around a closed path.

Quantitative Tools The integral around any closed path of the electric field that accompanies a changing magnetic field is given by

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt}, \tag{29.17}$$

where the line integral is around a closed path, and the magnetic flux is through a surface bounded by that same closed path.

Inductance (Section 29.7)

Quantitative Tools If an emf $\mathscr{E}_{\text{ind}}$ is induced in a loop when the current through it changes at the rate dI/dt, the **inductance** L of the loop is given by

$$\mathscr{E}_{\text{ind}} = -L\frac{dI}{dt}. \tag{29.19}$$

See the Procedure box on page 1028 for guidance on how to calculate L. The SI unit of inductance is the **henry** (H):

$$1\ \text{H} \equiv 1\ \text{V} \cdot \text{s/A} = 1\ \text{kg} \cdot \text{m}^2/\text{C}^2. \tag{29.20}$$

The inductance of a solenoid of length ℓ and cross-sectional area A with N turns is

$$L = \frac{\mu_0 N^2 A}{\ell}.$$

Magnetic energy (Section 29.8)

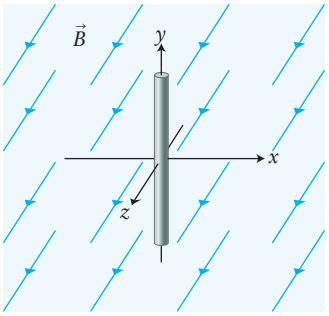
Quantitative Tools The **magnetic potential energy** U^B stored in the magnetic field of an inductor that has inductance L and carries a current I is

$$U^B = \tfrac{1}{2}LI^2. \tag{29.25}$$

The **energy density** u_B of the potential energy stored in a magnetic field of magnitude B, defined as the magnetic potential energy per unit volume, is

$$u_B \equiv \tfrac{1}{2}\frac{B^2}{\mu_0}. \tag{29.29}$$

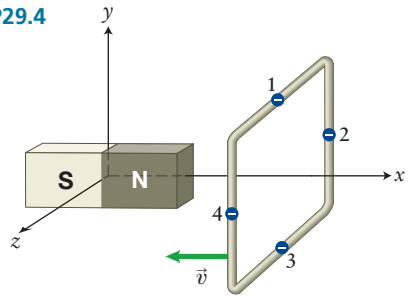
Questions and Problems



For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • *= easy,* •• *= intermediate,* ••• *= hard;* CR *= context-rich problem.*

29.1 Moving conductors in magnetic fields

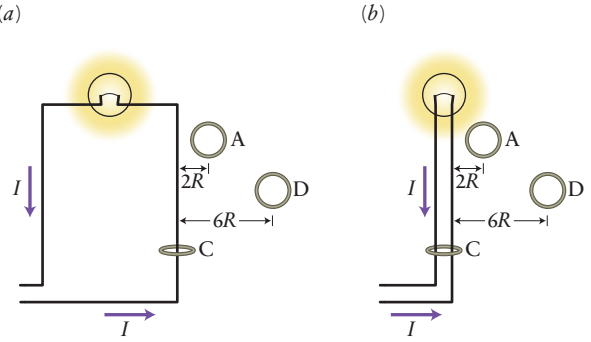


1. What happens if the conducting rod in Figure P29.1 moves (*a*) in either direction along the z axis and (*b*) in either direction along the y axis? •

Figure P29.1

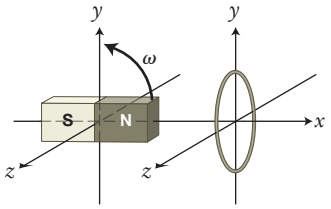
2. The Air Force Thunderbirds aerial demonstration team is performing at an air show located on Earth's magnetic equator. In what directions can the airplanes fly so that there is no charge separation on their metal surfaces? •
3. How should any one of the airplanes described in Problem 2 fly in order to produce the maximum charge separation between its wing tips? (Consider both the direction of motion and the orientation of the wings.) ••
4. Figure P29.4 shows a square conducting loop centered on the x axis, with its sides parallel to the y and z axes. The loop moves with constant velocity in the negative x direction toward a small bar magnet that is centered on the origin and has its polar axis aligned along the x axis. At the instant shown, what is the direction of the magnetic force exerted on an electron sitting at the midpoint of each side? Does the motion of the loop cause any separation of the charge carriers in the loop? Does the motion induce a current in the loop? If so, what is the direction of that current? ••

Figure P29.4



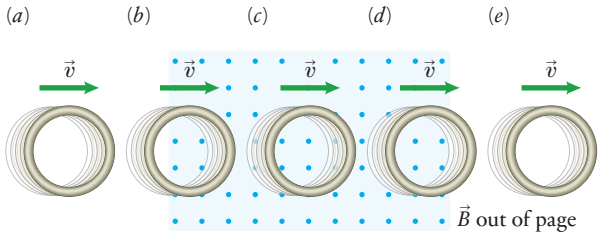
5. What happens if the conducting rod in Figure P29.1 rotates (*a*) clockwise about the z axis as viewed looking down the positive z axis toward the origin, (*b*) clockwise about the x axis as viewed looking down the positive x axis toward the origin, and (*c*) clockwise about the y axis as viewed looking down the positive y axis toward the origin? ••

29.2 Faraday's law



6. The large loop of wire in Figure P29.6*a* carries into and out of a lamp an electric current whose direction alternates back and forth with time. A circular ring of wire of radius R is at one of the three positions labeled A, C, and D. (*a*) At which position is the induced current in the ring greatest? At which position is it smallest? (*b*) Instead of being spread out in large loops, the actual wiring in houses and other buildings has the wires entering and leaving the lamp close and parallel to each other, as shown in Figure P29.6*b*. How is the induced current in the ring affected by this geometry? •

Figure P29.6



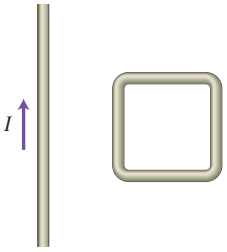
7. The bar magnet in Figure P29.7 is rotated about an axis that runs perpendicular to the page and passes through the center of the magnet. The magnet rotates with rotational speed ω. A loop of wire is placed alongside the magnet as shown. The loop is positioned so that the axis that runs perpendicular to the face of the loop and that passes through the center of the loop lies in the plane in which the magnet rotates. (*a*) Is a current induced in the loop? (*b*) If so, is the induced current constant, or does it vary with time? •

Figure P29.7

8. Suppose that in Example 29.1 you used a circular loop rather than a rectangular loop of the same area. What similarities and differences would you observe in each portion of Figure P29.8 parts *a*–*e*? ••

Figure P29.8

9. A large region of space contains a uniform magnetic field that is increasing with time. You have a piece of wire of length ℓ and want to form a coil from it. What shape should you use for your windings and how many windings should you have to generate the maximum induced current in the coil when it is placed in the changing magnetic field? ••
10. A 1.00-m length of wire is shaped into a rectangle, and another 1.00-m length of identical wire is shaped into a circle. Both wires then move at the same speed into and then out of a region of uniform magnetic field. Is the induced current in the rectangle greater than, smaller than, or the same as the induced current in the circle? •••



29.3 Electric fields accompany changing magnetic fields

11. You observe a small charge separation between the ends of a conducting rod that is lying on the table in front of you. This is puzzling because the rod is not connected to a battery or other power source; it is at rest on the nonconducting table, pointed toward a nearby window. You call your friend, who calmly asks where you are. You reply that you are riding the high-speed train between Paris and Avignon. Your friend offers explanations for the charge separation in two different inertial reference frames. What are those explanations? •
12. A flat conducting plate is centered in the *xy* plane of an *xyz* coordinate system in which the *xy* plane is horizontal. A bar magnet is lowered vertically toward the plate. If the magnet is oriented so that its north pole faces the origin as the magnet moves toward the plate, what do the electric field lines in the plate look like? What do the field lines look like if the south pole faces the origin as the magnet moves? •
13. A metal pipe is held vertically, and a bar magnet is dropped into it. What do the electric field lines in the pipe look like as the magnet falls through it? ••
14. You have a bar magnet and a circular conducting loop, and you wish to induce a current in the loop that changes direction regularly: clockwise, counterclockwise, clockwise, and so on. Explain how to do this while the loop remains at rest on a wooden table. ••

29.4 Lenz's law

15. You have a bar magnet and a loop of wire. The loop lies in the plane of this page, and we define a positive current as one for which the current direction is clockwise around the loop as viewed from above. How can you move the magnet so as to induce a positive current in the loop? (There are several answers to this question; provide as many as you can.) •
16. If you drop a magnet through a length ℓ of copper pipe, the time interval needed for the magnet to travel through the pipe (even if the magnet never touches the sides of the pipe) is much greater than the time interval the magnet takes to drop the same distance ℓ in air. Why? •
17. The long straight wire in Figure P29.17 carries a current I that varies in time as $I = I_0 \sin(\omega t)$, and a loop of wire is held stationary near the straight wire. When is the induced current in the loop clockwise? When is it zero? When is it counterclockwise? ••

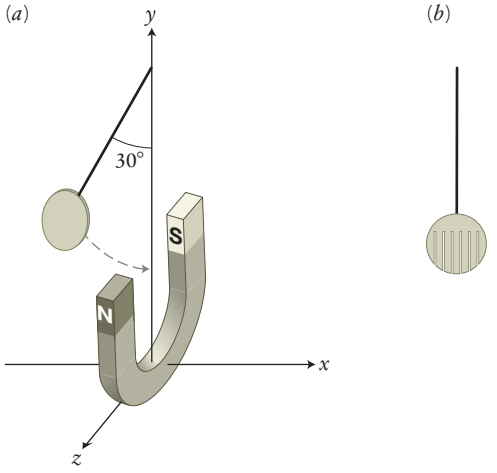


Figure P29.17

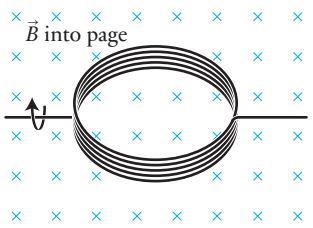
18. A pendulum consists of a rod with an aluminum disk attached, suspended from a pivot. First the pendulum is held at a 30° angle to the vertical and released so that it begins to swing. The disk passes between the poles of a powerful magnet on each swing (Figure P29.18*a*). Next a series of vertical slits are cut completely through the disk (Figure P29.18*b*). The pendulum is again held at a 30° angle and released, and the disk again passes between the magnet's poles on each swing. Describe the motion of

the pendulum in each case and explain your answer. Ignore any frictional force exerted at the pivot. ••

Figure P29.18

29.5 Induced emf

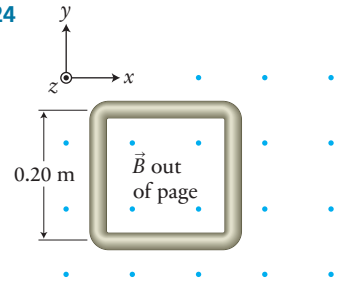
19. To measure the magnitude of Earth's magnetic field B_E, you use a single conducting coil with an area $A = 10\ \text{cm}^2$ rotating at an angular speed ω, and measure the peak emf induced on the coil. You know that $B_E \simeq 50\ \mu\text{T}$. What should the minimum value of ω be if you cannot measure emfs below 1 mV? •



20. A conducting loop having radius 20 cm is held fixed, and there is a magnetic flux of 0.6 T.m^2 through the loop. When the magnetic field is turned off, the magnetic flux through the loop becomes zero in 4 s. What is the average magnitude of the induced emf in the loop during the 4.0 s time interval? •

21. A rectangular loop of length $\ell = 4$ cm, width $w = 3$ cm, and internal resistance $R = 0.5$ V/A is located so that the normal to the loop is parallel to a uniform magnetic field. Suddenly, the loop is turned upside down. A galvanometer measures the total amount of charge flowing through the loop in this time interval to be 1.5 mC. What is the magnitude of the magnetic field? •

22. Suppose you are fabricating a device to measure the orientation of the Erath's magnetic field (i.e., 50 μT). The device can accommodate a single conducting coil attached to a motor that can make it rotate at a speed of 12000 rotations/minute. If the maximum limit of peak induced emf that can ideally be measured by the device is 2×10^{-5} V, then what must be the area A enclosed by the conducting coil that you have to manufacture? •



23. A circular coil of radius $R = 50$ mm rotates about an axis that is perpendicular to a uniform magnetic field of magnitude $B = 0.50$ T (Figure P29.23). If the coil completes 60 rotations each second, how many windings must the coil have in order to power an appliance that requires an emf that varies as $\mathcal{E}_{\text{ind}}(t) = V_{\text{max}} \sin(\omega t)$, where $V_{\text{max}} = 155$ V? ••

Figure P29.23

24. The square conducting loop in Figure P29.24 lies in the xy plane of an xyz coordinate system. The loop is in a uniform magnetic field that points in the positive z direction and is decreasing at a rate of 0.070 T/s. What are (*a*) the magnitude of the induced emf in the loop and (*b*) the direction of the induced current in the loop? ••

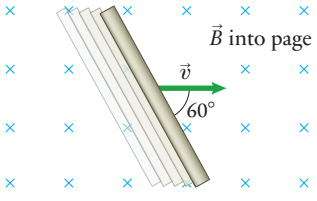


Figure P29.24

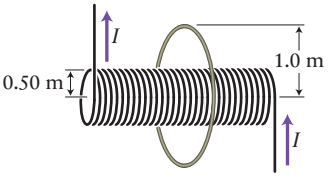
25. An increasing number of products, such as passports and credit cards, contain an embedded radio-frequency identification chip that both stores and transmits information. The chips do not have their own power sources. Instead, they receive their power through induction from the device used to read the stored information. The reading device generates a magnetic field, and the passport or credit card containing a coil is passed through this field. If a certain chip needs a peak induced emf of 4.0 V to operate and the magnetic field varies with time as $B(t) = B_{\text{peak}} \sin(\omega t)$, where $B_{\text{peak}} = 5.0$ mT is the maximum magnetic field and $\omega = 8.52 \times 10^7\ \text{s}^{-1}$, what value must the product AN have in order for the chip to operate, where A is the coil's surface area and N is number of turns in the coil? Assume that the magnetic field is perpendicular to the plane of the coil. ••



26. A 50-cm-long metal rod is placed in a uniform magnetic field with the rod length perpendicular to the field direction (Figure P29.26). The rod moves at 0.10 m/s, and its velocity vector makes an angle of 60° with the rod length. If the magnitude of the magnetic field is 1.0 T, what is the potential difference between the two ends of the rod? ••

Figure P29.26

27. The very long cylindrical solenoid of Figure P29.27 has a radius of 0.50 m and 1200 windings per meter along its length. A circular conducting loop of radius 1.0 m, and

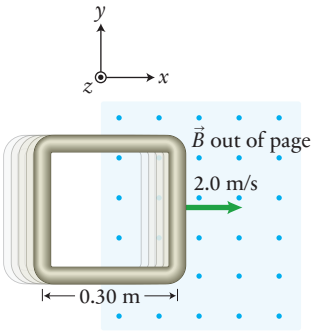


Figure P29.27

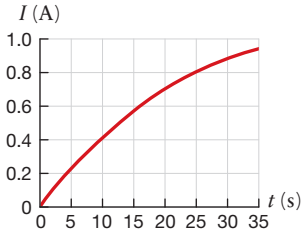
resistance 0.5 V/A encircles the solenoid, with the long central axis of the solenoid passing through the center of the loop, and coinciding with the axis of the loop. The solenoid initially carries a steady current $I = 2$ A. If the connection between the solenoid and the battery providing the steady current is interrupted all of a sudden, what will be the total amount of charge flowing in the loop? ●●

28. The space to the right of the y axis in Figure P29.28 contains a uniform magnetic field of unknown magnitude that points in the positive z direction. As a conducting square loop placed in the xy plane (oriented with its horizontal and vertical sides parallel to the x and y axes) moves to the right across the y axis at a constant speed of 2.0 m/s, a 0.24-V emf is induced in the loop. (*a*) If the side length of the loop is 0.30 m, what is the magnitude of the magnetic field? (*b*) What is the direction of the induced current in the loop? ●●

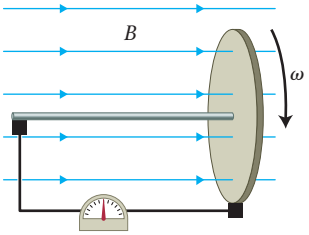
Figure P29.28



29. A region of space contains a changing magnetic field given by $\vec{B}(t) = B_0 e^{-t/\tau}\hat{k}$, and a circular conducting loop of radius R lies in this region in the xy plane. (*a*) Calculate the upward magnetic flux through the loop as a function of time. Is the flux increasing or decreasing as time passes? (*b*) Calculate the induced emf in the loop as a function of time, where upward is in the $\hat{k}$ direction. (*c*) Determine the current direction in the loop. ●●

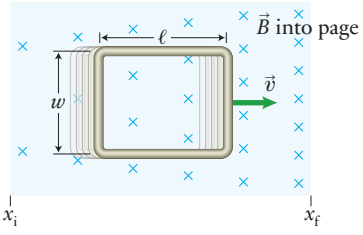
30. The coil in a generator has 100 windings and a cross-sectional area of 0.0100 m^2. (*a*) If the coil turns at a constant rotational speed and the magnetic field in the generator is that of Earth ($B = 0.500 \times 10^{-4}$ T), how many 360° rotations must the coil complete each second to generate a maximum induced emf of 1.00 V? (*b*) Based on this calculation, does it seem practical to use Earth's magnetic field in electric generators? ●●

31. You have two cylindrical solenoids, one inside the other, with the two cylinders concentric. The outer solenoid has length $\ell_{\text{outer}} = 400$ mm, radius $R_{\text{outer}} = 50$ mm, and $N_{\text{outer}} = 1000$ windings. The inner solenoid has length $\ell_{\text{inner}} = 40$ mm, radius $R_{\text{inner}} = 20$ mm, and $N_{\text{inner}} = 150$ windings. The inner solenoid is centered within the outer solenoid. When the outer solenoid carries a current given by $I(t) = I_0 \sin(\omega t)$, with $I_0 = 600$ mA and $\omega = 100$ s^{-1}, what is the peak emf in the inner solenoid? ●●



32. A rectangular wire loop enclosing an area $A = 0.40$ m^2 is inside a long cylindrical solenoid with two windings per mm. The area vector of the loop is aligned with the axis of the solenoid, and the current in the solenoid varies according to the graph shown in Figure P29.32. What is the induced emf in the loop at $t = 10$ s? ●●

Figure P29.32



33. A circular metal disk with a shaft through its center rotates about a central axis as shown in Figure P29.33. The unit is placed in a uniform magnetic field of magnitude 1.5 T, directed parallel to the shaft. Two small sliding contacts are placed against the unit, one touching the edge of the disk and the other touching the end of the shaft. (*a*) If the disk radius is 100 mm and the disk completes 300 rotations per minute, what is the value of the emf induced between the two contacts? (*b*) Which contact is at the greater potential? ●●

Figure P29.33

34. The dimensions of the rectangular loop of wire in Figure P29.34 are $\ell = 50$ mm and $w = 40$ mm. The loop moves at speed $v = 30$ mm/s through the magnetic field shown. The field magnitude increases linearly from $B_i(x_i) = 10$ mT at $x_i = 300$ mm to $B_f(x_f) = 60$ mT at $x_f = 900$ mm. The area vector of the loop is parallel to the magnetic field direction. What is the induced emf in the loop? ●●●

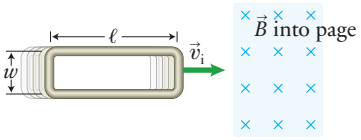


Figure P29.34

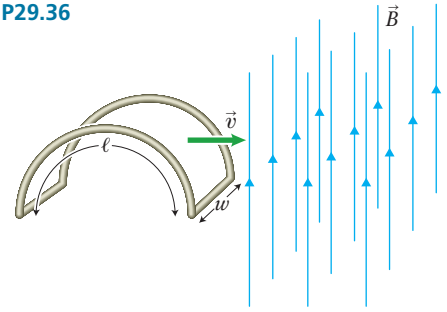
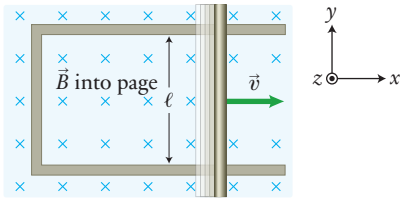
35. The dimensions of the rectangular loop of wire in Figure P29.35 are $\ell = 400$ mm and $w = 120$ mm. The mass of the loop is 10 g, its resistance is 5.0 V/A, and before entering the magnetic field shown the loop is moving at a constant speed v_i. The magnetic field magnitude is



5.0 T, and the loop's area vector is parallel to the field direction. How many seconds after the leading edge of the loop enters the magnetic field is the loop's speed half its initial value? Ignore any friction effects. •••

Figure P29.35

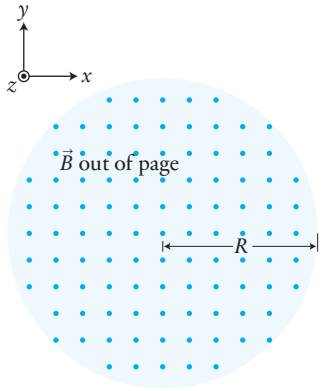


36. (*a*) A rectangular loop of wire is $\ell = 800$ mm long and $w = 500$ mm wide. You bend the ℓ sides into a semicircle while keeping the w sides straight, as shown in Figure P29.36, and then move the curved loop at speed $v = 0.800$ m/s into a uniform magnetic field of magnitude $B = 0.600$ T. One of the sides labeled w is the leading edge of the moving loop, and the magnetic field direction is perpendicular to those sides. What is the value of the emf induced in the loop? (*b*) What is the induced emf if the loop is rotated 90° so that the side leading into the magnetic field is one of the curved sides? •••

Figure P29.36

37. A bar is sliding along a set of connected conducting rails as shown in Figure P29.37. The bar is given an initial velocity $\vec{v}_i$ to the right and then allowed to move freely. The bar has mass m, and the distance between the rails (which is also the bar length) is ℓ. The resistance of the conducting loop comprising the bar and conducting rails is R. Show that the speed of the bar decreases exponentially with time, and determine the time constant. •••

Figure P29.37



38. The area vector of a rectangular loop that is initially $\ell_i = 300$ mm long and $w_i = 200$ mm wide is aligned with the direction of a uniform magnetic field that has initial magnitude $B_i = 500$ mT. You want to increase the field magnitude smoothly to $B_f = 700$ mT in 10 s, but you want to have zero induced current in the loop. You plan to accomplish this by changing the loop's length ℓ as you increase the magnetic field. In order to have $I_{ind} = 0$, what must the loop length be after 3.00 s and after 10.0 s? •••

29.6 Electric field accompanying a changing magnetic field

39. A uniform magnetic field exists in a circular area. A particle carrying charge $q = 3.0\ \mu$C is placed in the field a distance $r_p = 5$ cm from the center of the circular area. If the magnetic field drops at a constant rate of 0.2 T/s, what its the magnitude and direction that an external force should have so that the particle remains fixed in its position? •

The next four problems are based on the situation illustrated in Figure P29.40. A uniform magnetic field pointing in the positive z *direction fills a cylindrical volume of space of radius* R *whose central axis is the* z *axis. Outside this region, there is no magnetic field.*

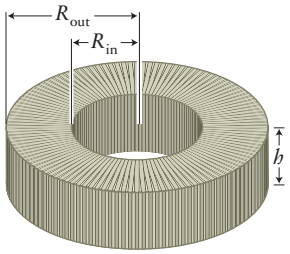
Figure P29.40

40. In Figure P29.40, $R = 0.12$ m and a changing magnetic field creates an electric field that has magnitude $E = 10$ V/m at a radial distance $r = 0.060$ m from the center of the magnetic field. What is the instantaneous magnitude of the time rate of change of the magnetic field? •

41. If in Figure P29.40 $R = 0.25$ m and the magnetic field magnitude is decreasing at a rate of 0.30 T/s, what is the magnitude of the electric field created by this changing magnetic field (*a*) at radial distance $r = 0.20$ m from the magnetic field center and (*b*) at $r = 0.50$ m from the center? (*c*) Do the electric field lines encircle the z axis clockwise or counterclockwise, when viewed looking down the positive z axis toward the origin? ••

42. If the magnitude of the magnetic field in Figure P29.40 changes with time as $B = B_{max} \sin(\omega t)$, calculate the magnitude of the electric field that accompanies this changing magnetic field as a function of time t and radial distance r from the center of the magnetic field for (*a*) $r < R$ and (*b*) $r > R$. (*c*) At $t = 0$, what is the direction of the electric field? ••

43. The magnitude of the magnetic field in Figure P29.40 changes with time, and the magnitude of the accompanying electric field inside the magnetic field is given by $E(r, t) = 3Crt^2$, where C is a positive constant and r is the radial distance from the center of the magnetic field. For the case where $B = 0$ at $t = 0$, derive an expression for the magnitude of the magnetic field as a function of time for $t > 0$. ●●
44. A uniform magnetic field fills a cylindrical volume of radius R, and the field magnitude changes with time at an unknown rate. At a certain instant, the electric field magnitude at a radial distance $r_1 < R$ from the magnetic field center is E_1. At this instant, at what radial distance r from the magnetic field center is the electric field magnitude E equal to $E_1/3$ (*a*) if $r < R$ and (*b*) if $r > R$? ●●
45. It takes an electric field magnitude of about 10^6 V/m to ionize atoms in the air and produce a spark. Is it possible to increase the magnetic field inside a long solenoid quickly enough to generate a spark inside? Take the solenoid radius to be 30 mm. ●●●



29.7 Inductance

46. An emf of −0.75 V is induced in an inductor of 1.25 H. Find the rate of change of current. Suggest if the current increases or decreases through the inductor. ●
47. If the magnitude of the emf produced in an inductor is 4.0 V when the current through it decreased at a constant rate of 0.2 A/s, calculate the inductance of the inductor. ●
48. A friend of yours needs an inductance of 2 H for one of the circuits he is building. You offer him a cylindrical piece of insulating material of length 30 cm and radius 2 cm to use as a core. How many loops of wire will he need to wrap around this core? ●
49. The current through an inductor of inductance L is given by $I(t) = I_{max} \sin(\omega t)$. (*a*) Derive an expression for the induced emf in the inductor as a function of time. (*b*) At $t = 0$, is the current through the inductor increasing or decreasing? (*c*) At $t = 0$, is the induced emf opposing or aiding the flow of the charge carriers? (Remember that the direction of a positive induced emf is the same as the current direction and the direction of a negative induced emf is opposite the current direction.) (*d*) How are the answers to parts *b* and *c* consistent with the behavior of inductors discussed in the text? ●●
50. The induced emf in an inductor of inductance L varies with time according to $\mathscr{E}_{ind}(t) = -2Ct$, where C is a positive constant. (*a*) If there is no current through the inductor at $t = 0$, calculate the current as a function of time for $t > 0$. (*b*) Is the current increasing or decreasing when $t > 0$? (*c*) Discuss how your answer to part *b* is consistent with the sign of $\mathscr{E}_{ind}$ and what you know about the behavior of inductors. ●●
51. You and a friend have a 0.65-m length of copper wire that has a diameter of 4.115 mm and a wooden rod that is 85 mm long and has a diameter of 10 mm. You're aiming to wind the wire around the rod about 40 times to form an inductor. (*a*) What is the maximum inductance you can achieve with this device? (*b*) Your friend solves this problem by reasoning that a cylindrically wound wire whose length greatly exceeds its radius is a solenoid, and therefore he can use the equation from Example 29.8 to determine the inductance:

$$L = \frac{\mu_0 N^2 A}{\ell}$$
$$= \frac{(4\pi \times 10^{-7}\ \text{T}\cdot\text{m/A})(40^2)\pi(0.0020575\ \text{m})^2}{0.65\ \text{m}}$$
$$= 4.1 \times 10^{-8}\ \text{H}.$$

Evaluate your friend's work. ●●
52. The toroid in Figure P29.52 has 200 rectangular windings, and the toroid radii are $R_{in} = 160$ mm and $R_{out} = 240$ mm. The height of each winding is $h = 20$ mm, such that the rectangular cross section of each winding is $(R_{out} - R_{in}) \times h = (80\ \text{mm}) \times (20\ \text{mm})$. What is the inductance of the toroid? ●●●

Figure P29.52

29.8 Magnetic energy

53. Estimate the amount of magnetic potential energy stored in a 1.50 H inductor when the current through it is 3.0 A. ●
54. If 24 J of magnetic potential energy is stored in a 3.0 H inductor, calculate the current in the inductor. ●
55. A cylindrical solenoid, of radius 0.5 cm and length 30 cm has 1200 windings and carries a current of 0.5 A. (*a*) What is the inductance of the solenoid? (*b*) What is the total magnetic potential energy inside the solenoid? (*c*) What is the magnetic energy density inside the solenoid? ●●
56. When you unplug a coffee maker that plugs into the utility outlet of your car, you notice a spark. Worried that the coffee maker might be broken, you take it apart and find that the heating element is a tungsten wire that, according to the label, is wound 600 times around what appears to be a nonmagnetic core. The core has radius $R = 2.0$ mm and length $\ell = 200$ mm. On the outside of the coffee maker, it says 12 V, 3.2 A. Where does the spark come from? ●●
57. The magnitude of the magnetic field in a magnetic resonance imaging (MRI) machine can be as great as $B = 3.0$ T. Under normal circumstances, this field cannot be shut off by just flipping a switch. Instead the magnitude needs to be carefully decreased to zero. In an emergency, however, the magnet can be "quenched" so that B reduces to zero in 20 s. Such a quench can cost thousands of dollars and likely damages the magnets. Assume that the magnetic field exists inside a cylinder of radius $R = 300$ mm and length $\ell = 200$ mm. How much magnetic potential energy is dissipated when the

magnetic field is quenched in this way, and what is the average rate at which energy is dissipated? ••

58. What is the magnetic potential energy stored in a cylindrical volume of height $h_{\text{cylin}} = 50$ mm and radius $R_{\text{cylin}} = 24$ mm that symmetrically surrounds an infinitely long wire that has radius $R_{\text{wire}} = 2.1$ mm and carries current $I = 2.3$ A? •••

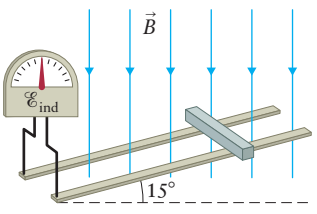
59. A cylindrical solenoid of length ℓ and radius R has n windings per unit length and carries a current I. (*a*) Use the inductance expression $L = (\mu_0 N^2 A)/\ell$ from Example 29.8 and Eq. 29.25, $U^B = LI^2/2$, to derive an expression for the magnetic potential energy in the solenoid as a function of the current and the solenoid's dimensions. (*b*) Derive this same expression by beginning with Eq. 29.30, $U^B = \int u_B \, dV$. •••

Additional Problems

60. Calculate the length of the cylindrical solenoid that has 900 windings, such that the radius of each winding is 2 cm, that shows an inductance of 8.5×10^{-2} H. •

61. The current in a cylindrical solenoid is increased smoothly from $I_i = 0.40$ A at $t_i = 3.0$ s to $I_f = 1.20$ A at $t_f = 5.0$ s. What is the induced emf during this time interval if the solenoid length is $\ell = 150$ mm, the radius of each winding is $R = 20$ mm, and there are 400 windings? •

62. A uniform magnetic field exists in a cuboidal volume of space with $l = 3$ cm, $b = 2$ cm, and $h = 1$ cm. If the magnetic energy stored in the volume is 10 J, what is the magnitude of the magnetic field? •



63. A cylindrical electromagnet produces a uniform 1.5-T magnetic field between the poles. If the north and south poles of the electromagnet have circular cross-section having radius 60 mm and separation 50 mm, then calculate the magnetic potential energy stored in the magnetic field of the electromagnet. •

64. The rate at which the magnetic flux inside a wire loop decays is given by $\Phi_B(t) = \Phi_{B,i} e^{-\beta t}$, where $\beta = 0.50/\text{s}$ and $\Phi_{B,i} = 4.0$ Wb. What is the magnitude of the induced current at $t = 10$ s if the resistance of the wire is $R = 2.0$ V/A? ••

65. To construct a solenoid having cross-sectional area 1.256×10^{-3} m^2 and 500 windings that can produce a magnetic field of 10×10^{-3} T, (*a*) calculate the length of the solenoid if the current in the device is 5 A. Calculate (*b*) the inductance of the solenoid, (*c*) considering the cross-sectional area and given magnetic field, the amount of magnetic potential energy stored in the solenoid. (*d*) Using the value of L obtained in part (*b*) estimate the magnetic potential energy stored within the solenoid. ••

66. A conducting bar that is $\ell = 40$ mm long can slide with negligible friction on two parallel conducting rails positioned at an incline of $\theta = 15°$ (Figure P29.66). Initially, the bar is at rest in a magnetic field of magnitude $B = 0.60$ T. What is the emf between the rails 0.20 s after the bar starts sliding while it is still inside the magnetic field? ••

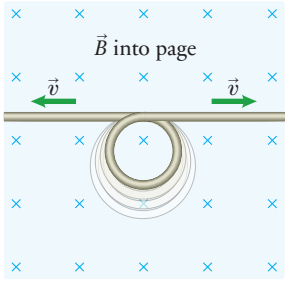


Figure P29.66

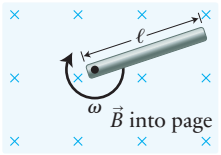
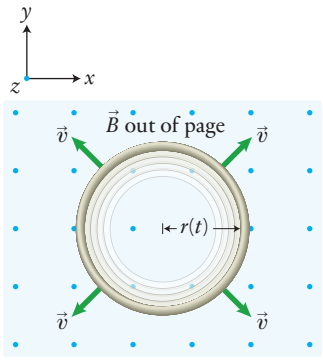
67. You have a circular wire loop of radius $a = 20$ cm. It carries a current that increases linearly from 0 to 5 A in 0.01 s. At the center of this loop is a wire loop of radius $b = 1$ mm and resistance $R = 1.8$ mV/A. The loops are coplanar. What is the current induced in the smaller loop? ••



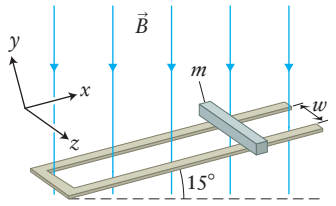
68. You shape a flexible wire into a loop of initial radius $r_i = 30$ mm. You then place the loop in a uniform magnetic field and pull the two ends of the wire in opposite directions at $v = 6.0$ mm/s so that the loop starts closing up (Figure P29.68). If the field magnitude is $B = 0.70$ T, what is the emf between the ends of the wire 2.0 s after you begin pulling? ••

Figure P29.68



69. A rod of length ℓ rotates about one end at a constant rotational speed ω. The rod is in a uniform magnetic field $\vec{B}$, and the axis of rotation is parallel to $\vec{B}$ (Figure P29.69). (*a*) In terms of ℓ, B, and ω, what potential difference develops between the two ends of the rod? (*b*) Which end of the rod has a greater potential? (*c*) If $\ell = 0.15$ m, $B = 1.0$ T, and $\omega = 377$ s^{-1}, what is the potential-difference value? ••

Figure P29.69

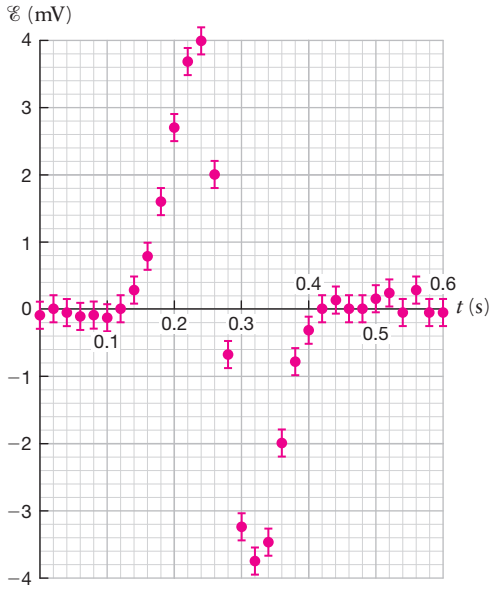


70. A uniform magnetic field of magnitude B fills all space and points in the positive z direction (Figure P29.70). A circular conducting loop in the xy plane is growing larger, with its radius as a function of time given by $r(t) = vt$, where v is a positive constant. (*a*) Derive an expression for the magnitude of the emf induced in the loop as a function of time. (*b*) What is the direction of the induced current? ••

Figure P29.70

71. A conducting bar of width $w = 0.12$ m and mass $m = 8.0$ g can slide freely on two parallel conducting rails positioned at an incline of $\theta = 15°$ (Figure P29.71). The rails are connected at their base by a piece of conducting material. The distance between the rails is w, and the resistance in the rails is $R = 0.20\ \Omega$/A. A uniform magnetic field $\vec{B}$ is exactly vertical as indicated in the drawing, with $B = 0.50$ T. At what constant (terminal) speed does the bar slide down the incline? Ignore friction. ●●

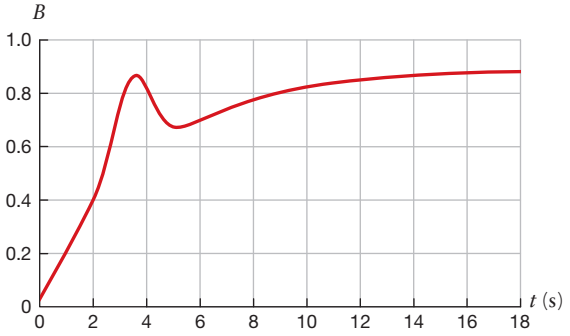
Figure P29.71



72. For the system described in Problem 71, you measure a constant speed of 1.0 m/s. Because this is not the value you calculated when you ignored friction in the system, you conclude that the friction in the rails is too great to be ignored. What value for the coefficient of kinetic friction μ_k yields the 1.0-m/s speed you measured? ●●●

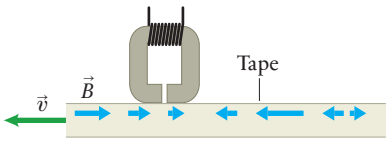
73. A square loop of wire of side length a and resistance R lies a distance x to the right of a long, straight wire that carries a current I. The straight wire lies in the plane defined by the loop, parallel to one side of the square, and the current direction in the wire is upward. The loop is held stationary, and the current in the wire varies sinusoidally as $I = I_{max} \sin(\omega t)$. Derive an expression for the emf induced in the loop as a function of I_{max}, ω, a, x, and t. ●●●

74. You are working for a company that is interested in mapping geological formations in Earth's crust by examining variations in the magnitude of the magnetic field at Earth's surface. Your assignment is to design a device that can detect small variations in this magnetic field at ground level. Deciding on a system that uses a rotating coil, you realize that the design (number of windings, winding cross-sectional area, rotational speed, and so forth) must give a 1-mV signal in Earth's magnetic field in order to be useful. ●●● CR



75. On the fifth floor of the physics building, you are in a laboratory class studying induction. You are using a computer to measure emf values from a solenoid when suddenly a thunderstorm breaks out. You see a large blip on the computer screen and 2.0 s later hear a loud thunderclap. Looking out the window, you see that straight ahead a tree was struck by lightning. You quickly save the data on your computer (plotted in Figure P29.75) and note that the solenoid happens to be oriented at an angle of $\theta = 40°$ with respect to your line of sight to the tree. The solenoid windings have cross-sectional area $A = 0.10\ m^2$, and there are $N = 100$ windings. You wonder about the current involved in the lightning flash that struck the tree. ●●● CR

Figure P29.75



76. An electromagnet in a physics laboratory is damaging electronic apparatus in its vicinity. You suspect that the damage is due to unusually large induced currents created each time the electromagnet power supply is turned on, so you decide to monitor the magnet's magnetic field. Figure P29.76 shows the field magnitude as a function of time during the first 18 s after you connect the magnet to a power supply. Instead of smoothly increasing to its designed value of 0.90 T, the field magnitude starts to decrease after about 3.0 s, very likely due to fluctuations in its power supply. What is not clear is whether these fluctuations can account for the damage, because the electronic apparatus is designed with the expectation that the change in magnetic field strength will be linear with time. ●●● CR

Figure P29.76

77. Analog tape players read sound recorded on magnetic tape. The sound is recorded by magnetizing the tape longitudinally (magnetization parallel to the tape's length) with varying magnetic field magnitudes in either direction. The tape is usually divided into longitudinal tracks so that different signals can be recorded in parallel. In the player, as the tape is pulled across the reading head, a varying emf is induced in a coil wound around the C-shaped metal core of the head (Figure P29.77). This emf is then amplified and sent to the speakers. Trying to learn more about the physics of this technology, you read that the recorded signal magnitude is usually given in terms of *fluxivity*, which is the peak magnetic flux per track width. In particular, you find a paper that gives a fluxivity of 320 nWb/m for a 1000-Hz sine wave recorded on a track 6.3 mm wide [O. Schmidbauer, *J. Audio Eng. Soc.*, 46(10), 859 (1998)]. Naturally, not all of the flux generated threads through the coil, but your search shows that reading heads can have a "flux efficiency" of 98% [J. G. McKnight, B. E. Cortez, and J. A. McKnight, *J. Audio Eng. Soc.*, 46(10), 845 (1998)] and that 250 coil windings are typical. You begin to wonder about the emf induced in the coil and how the frequency of the recorded sound relates to the speed v with which the tape runs. ●●● CR

Changing Electric Fields

CONCEPTS

30.1 Magnetic fields accompany changing electric fields
30.2 Fields of moving charged particles
30.3 Oscillating dipoles and antennas

QUANTITATIVE TOOLS

30.4 Displacement current
30.5 Maxwell's equations
30.6 Electromagnetic waves
30.7 Electromagnetic energy

As we have seen in Section 29.3, electric fields accompany changing magnetic fields. Is the reverse true, too—do magnetic fields accompany changing electric fields? In this chapter we see that magnetic fields do indeed accompany changing electric fields. Consequently, a changing electric field can never occur without a magnetic field, and a changing magnetic field can never occur without an electric field. The interdependence of changing electric and magnetic fields gives rise to an oscillating form of changing fields called *electromagnetic waves*.

Electromagnetic waves are familiar to us as a wide range of phenomena: visible light, radio waves, and x rays are all electromagnetic waves, the only difference being the frequency of oscillation of the electric and magnetic fields. We see our world by means of these waves, whether by using our eyes to observe our surroundings or by using x-ray diffraction to construct an image of a molecule or a material. Modern communications, from radio and television to mobile telephones, also make extensive use of electromagnetic waves. As we shall see, all these electromagnetic waves consist of changing electric and magnetic fields.

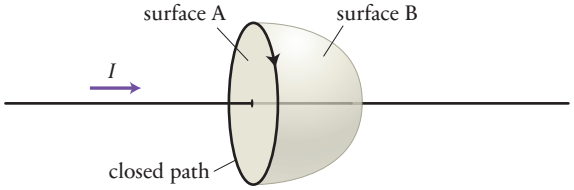
30.1 Magnetic fields accompany changing electric fields

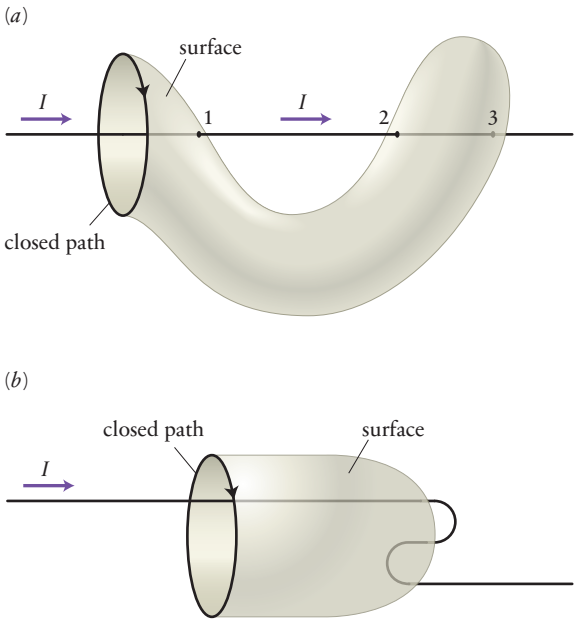
In order to see that a magnetic field accompanies a changing electric field, let's revisit Ampère's law (Section 28.5), which states that the line integral of the magnetic field along a closed path is proportional to the current encircled by the path (Eq. 28.1, $\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I_{\text{enc}}$).

Figure 30.1 shows a current-carrying wire encircled by a closed path. The current encircled by the path is equal to the current through the wire, I. Another way to determine the encircled current is to consider any surface spanning the path and determine the current intercepted by that surface. For example, Figure 30.1 shows two different surfaces spanning the path. The current intercepted by either surface is I, the current encircled by the path.

30.1 Is the current intercepted by the surface equal to the current encircled by the closed path (*a*) in **Figure 30.2*a*** and (*b*) in Figure 30.2*b*?

Figure 30.1 Current-carrying wire encircled by a closed path. Surfaces A and B both span the path. Surface A lies completely in the plane of the path. Surface B extends as a hemisphere whose rim is the path.





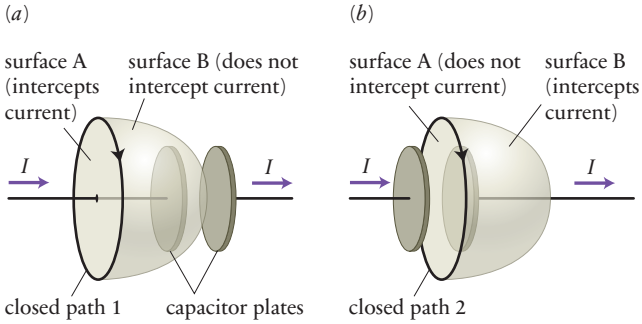


Figure 30.2 Checkpoint 30.1.

Checkpoint 30.1 shows that the current encircled by a closed path is equal to the current that is intercepted by any surface that spans the path, provided we keep track of the directions in which each interception takes place. Ampère's law can equally well be applied to the current encircled by a closed path and to the current intercepted by any surface spanning that closed path.

Now consider inserting an uncharged capacitor into our current-carrying wire while continuing to supply a constant current I to the wire. (That is, the capacitor is being charged.) **Figure 30.3*a*** shows two surfaces A and B spanning the same closed path. The line integral of the magnetic field around the closed path does not depend on the choice of surface spanning the path. However, while the capacitor is charging, surface A is intercepted by a current I but surface B, which passes

Figure 30.3 Capacitor being charged by a current-carrying wire. (*a*) The closed path of interest encircles the wire. Surface A intercepts the current, but surface B passes between the capacitor plates and does not intercept the current. (*b*) The closed path of interest lies between the capacitor plates. Surface A also lies between the plates and does not intercept the current, but surface B intercepts the current.

CONCEPTS

between the capacitor plates, is not intercepted by any current. If we choose a closed path that lies between the capacitor plates (Figure 30.3*b*), a similar difficulty arises. Surface A intercepts no current, while surface B intercepts the current I.

In the case of a capacitor, therefore, the equivalence between encircled current and current intercepted by a surface spanning the encircling path doesn't hold. Surface B in Figure 30.3*a* would lead us to conclude that the line integral of the magnetic field around closed path 1 is zero. Because symmetry requires the magnetic field to always be tangent to the path and have the same magnitude all around the path, the line integral being zero means there is no magnetic field at the location of closed path 1 (even though the path encircles a current). Conversely, surface B in Figure 30.2*b* suggests there is a magnetic field at the location of closed path 2, even though that path encircles no current. Experiments do indeed confirm that there *is* a magnetic field in and around the gap between the plates of the charging capacitor. So only the surfaces that intersect the wires leading to the capacitor appear to provide the correct value of I_{enc} in Ampère's law for both closed paths in Figure 30.3.

Why must there be a magnetic field in and around the gap between the plates of the charging capacitor? Although there is no flow of charged particles between the plates of the capacitor, there *is* an electric field (**Figure 30.4**). Let us examine this electric field in more detail in the next checkpoint.

30.2 (*a*) While the capacitor of Figure 30.4 is being charged, is the current through the wire leading to or from the capacitor zero or nonzero? Is the electric field between the plates zero or nonzero? Is it constant or changing? (*b*) Answer the same questions for the capacitor fully charged.

CONCEPTS

The answers to Checkpoint 30.2 suggest that the magnetic field between the plates of the charging capacitor arises from the *changing* electric field. The current to the capacitor causes the electric field between the plates to change, and the changing electric field between the capacitor plates acts in a way similar to the current that causes this change:

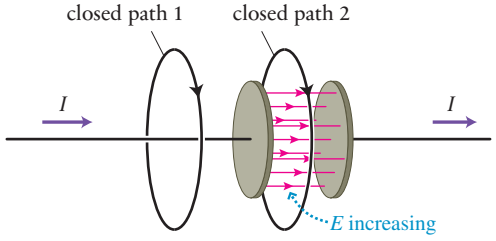
A changing electric field is accompanied by a magnetic field.

When the capacitor is fully charged, the current I into and out of the capacitor is zero, and there is no magnetic field surrounding the wires to the capacitor. Between the capacitor plates, the electric field is no longer changing, and the magnetic field is zero.

There are strong parallels between the electric field that accompanies a changing magnetic field and the magnetic field that accompanies a changing electric field, as **Figure 30.5** illustrates. Experiments show that the electric field lines that accompany a changing magnetic field form loops encircling the magnetic field, just as the magnetic field lines that accompany a changing electric field form loops encircling the electric field.

As we discussed in Section 27.3, the magnetic field surrounding a current-carrying wire forms loops that are clockwise when viewed looking along the direction of the current. The direction of these loops can be described by the right-hand current rule: Point the thumb of your right hand in the direction of the current, and your fingers curl in the direction of the magnetic field. Similarly, the direction of the loops formed

Figure 30.4 Capacitor being charged by a current-carrying wire. The electric field between the plates is shown. Closed path 1 encircles the current through the wire; closed path 2 encircles the electric field between the capacitor plates.



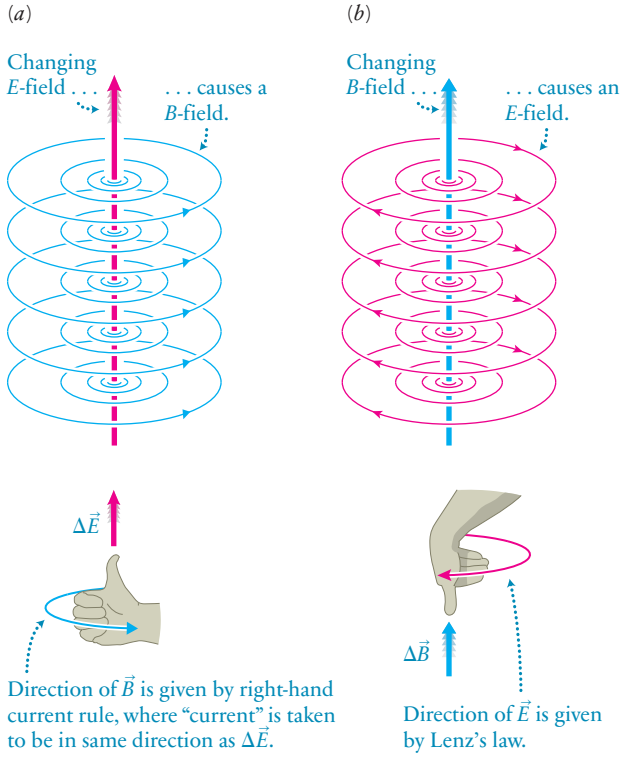


Figure 30.5 Parallels between (*a*) the electric field that accompanies a changing magnetic field and (*b*) the magnetic field that accompanies a changing electric field.

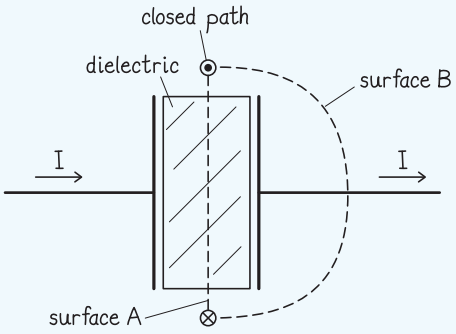
by the magnetic field lines that accompany a changing electric field are given by the right-hand current rule, taking the change in the electric field, $\Delta\vec{E}$, as the "current." If we take this change in the electric field into account in Figure 30.3, treating $\Delta\vec{E}$ as though it were a current, the inconsistency we encountered before is resolved: Either a current or a change in the electric field, $\Delta\vec{E}$, is intercepted by the surface, and so for all surfaces spanning the paths we conclude that there is a magnetic field.



30.3 Consider disconnecting a charged capacitor from its source of current and allowing it to discharge (to release its charge into an external circuit). During discharge, the current reverses direction (relative to its direction when the capacitor was charging), but the electric field between the plates does not change direction. How does the direction of the magnetic field between the plates compare to the direction when the capacitor was charging? Does the right-hand current rule apply?

EXAMPLE 30.1 Capacitor with dielectric

Consider a capacitor being charged with a constant current I and a dielectric between the plates. Is the magnitude of the magnetic field around a closed path spanning the capacitor (such as closed path 2 in Figure 30.4) any different from what it would be without the dielectric? Why or why not?

❶ **GETTING STARTED** I begin by making a two-dimensional sketch of the capacitor, indicating the position of the closed path (**Figure 30.6**).

Figure 30.6

❷ **DEVISE PLAN** To determine the magnetic field magnitude at any position along the closed path, I need to examine the current and the changing electric field intercepted by a surface spanning the closed path.

❸ **EXECUTE PLAN** If I consider a flat surface through the closed path (surface A in Figure 30.6), the surface intersects the dielectric. While the capacitor is charging, the dielectric is being polarized: Negative charge carriers in the dielectric are displaced in one direction, and positive charge carriers are displaced in the opposite direction. This displacement of charge carriers corresponds to a current. Surface A also intercepts a changing electric field. However, without further information about the capacitor, I can determine neither the current nor the electric field between the capacitor plates, which is affected by the presence of the dielectric. Surface A therefore doesn't permit me to compare the magnetic field magnitude to what it would be without the dielectric. I therefore draw another surface, making this surface loop around one of the capacitor plates (surface B in Figure 30.6). This surface intercepts only the wire leading from the capacitor, and I know that the current through the wire is unchanged by the presence of the dielectric. The fact that the current through this wire is unchanged tells me that the effective current in the region containing the dielectric is also unchanged. Therefore, the magnetic field must be the same as it would be without the dielectric. ✔

❹ **EVALUATE RESULT** Intuitively I expect the magnetic field magnitude around my closed path to be unchanged when the magnetic field magnitude around the wires attached to the capacitor is unchanged. The electric field between the capacitor plates gives rise to a displacement of charge carriers within the dielectric and thus affects the electric field between the capacitor plates, but apparently everything adds up to yield, for a given current through the capacitor, the same magnetic field magnitude outside the capacitor for a given current to the capacitor regardless of the presence or absence of the dielectric.

We now have a complete picture of what gives rise to electric and magnetic fields and on what kind of charged particle these fields exert forces. **Table 30.1** summarizes the properties of electric and magnetic fields. Note the remarkable symmetry between the two. Each type of field is produced by charged particles and accompanies a changing field of the other type. Electric fields are produced by charged particles either at rest or in motion, but magnetic fields are produced only by charged particles in motion. Likewise, any charged particle—at rest or in motion—is subject to a force in the presence of an electric field, but only charged particles in motion are subject to forces in a magnetic field.

Table 30.1 Properties of electric and magnetic fields

	Electric field	Magnetic field
associated with	charged particle	moving charged particle
	changing magnetic field	changing electric field

CONCEPTS

Table 30.2 Electric and magnetic field lines

	Electric field	Magnetic field
lines emanate from or terminate on	charged particle	–
loops encircle	–	moving charged particle
	changing magnetic field	changing electric field

Table 30.2 summarizes what we know about the field lines for electric and magnetic fields. The most striking difference between electric and magnetic fields is that magnetic field lines always form loops but electric field lines do not always form loops. This is a direct consequence of the difference in the sources of these fields. Magnetic field lines must form loops because there is no magnetic equivalent of electrical charge—no magnetic monopole (see Section 27.1). Instead, magnetic fields arise from current loops that act as magnetic dipoles.

Electric and magnetic field lines that represent changing fields both form loops around the changing field. When particles serve as the field sources, however, the difference between magnetic and electric fields is evident: Electric field lines emanate or terminate from charged particles, while magnetic field lines always form loops around moving charged particles (currents).

We shall return to these ideas quantitatively in Section 30.5.

30.4 The neutron is a neutral particle that has a magnetic dipole moment. What does this nonzero magnetic dipole moment tell you about the structure of the neutron?

CONCEPTS

30.2 Fields of moving charged particles

We have seen that capacitors generate changing electric fields when charging or discharging. What else produces changing electric fields? One answer to this question is: changes in the motion of charged particles.

Before examining the electric fields of accelerating charged particles, let's consider the electric fields generated by charged particles moving at constant velocity. **Figure 30.7** shows the electric field of a stationary charged particle and of the same particle moving at constant high speed. (By high speed, I mean a speed near enough the speed of light for relativistic effects to become important.)

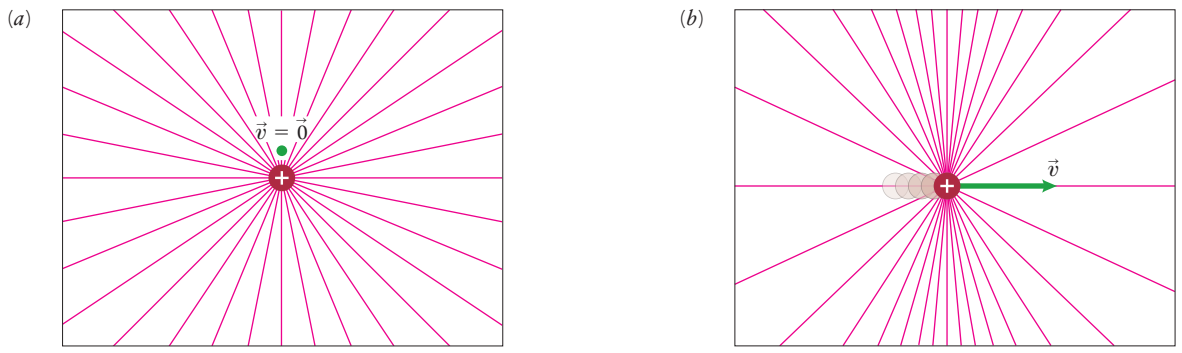
The electric field of the stationary particle is spherically symmetrical; the electric field of the moving particle is still radial but definitely not spherically symmetrical. In this electric field, the field lines are sparse near the line along which the particle travels and are clustered together in the plane perpendicular to the motion. (This clustering is a relativistic effect and takes place for the same reason that objects moving at relativistic speeds appear shorter along the direction of motion, as discussed in Sections 14.3 and 14.6.) Consequently, the electric field created by the moving particle is strongest in that perpendicular plane. The faster the particle moves, the more the electric field lines bunch up in the transverse direction.

Keep in mind that as the particle moves at constant speed, the electric field lines move with it. At any instant, the electric field lines point directly away from the position of the particle *at that instant*. This means that as the particle moves, the electric field at a given position changes.

Because the particle in Figure 30.7*b* is moving, it is like a tiny current; it has a magnetic field that forms loops around its direction of travel, as shown in Figure 28.2*b*. The particle in Figure 30.7*a* does not produce a magnetic field because it is at rest.

Now let's consider a particle that is initially at rest and then is suddenly set in motion. The electric field of this particle is shown at three successive instants in **Figure 30.8**. Figure 30.8*b* and *c* show something we have not seen before: electric field lines that do not point directly away from the charged particle that is their source but instead are disrupted by sharp kinks. What is more, these kinks, which appear when the particle accelerates (just after Figure 30.8*a*), do not

Figure 30.7 Electric field line pattern of a charged particle (*a*) at rest and (*b*) moving to the right with speed v (v is a significant fraction of the speed of light). For the moving particle, the electric field lines cluster around the plane perpendicular to the direction of motion.



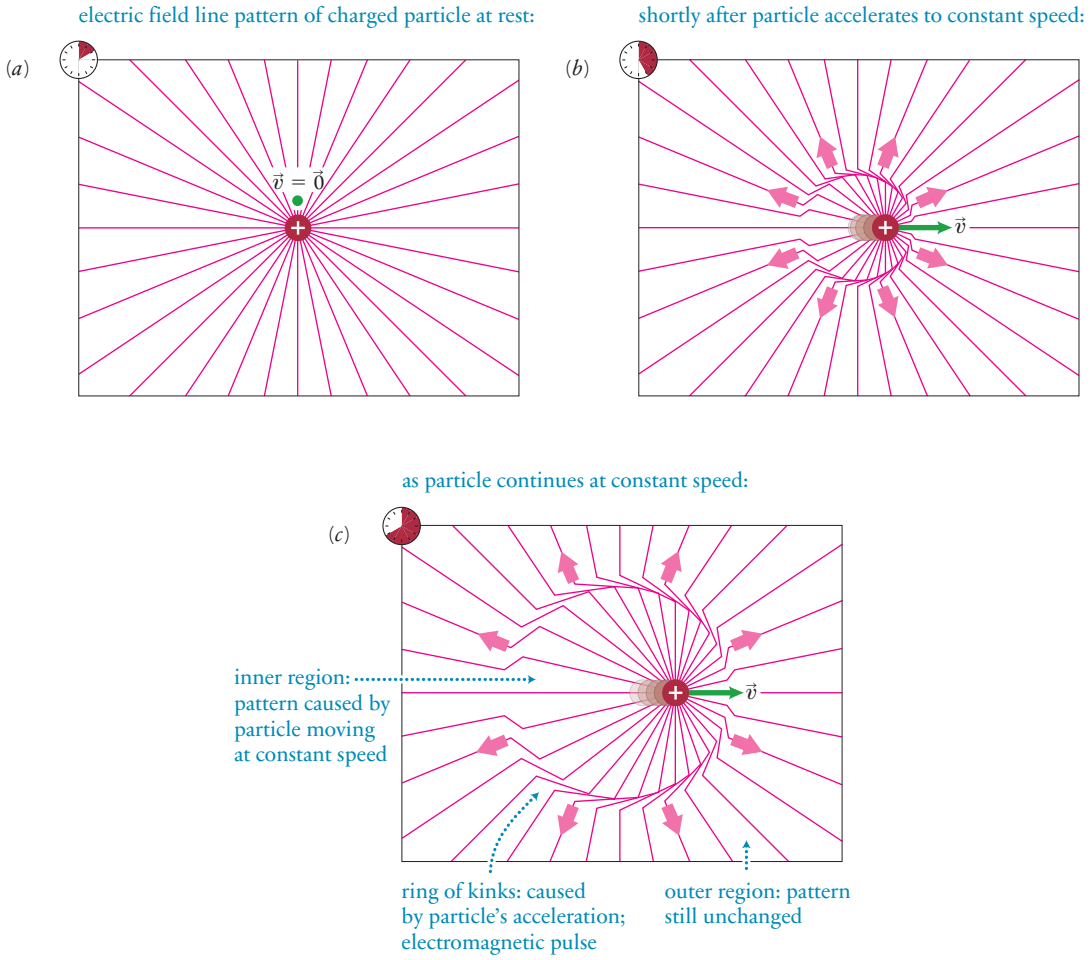


Figure 30.8 Electric field line pattern of a particle (*a*) initially at rest, (*b*) accelerating to speed v, and (*c*) moving at constant speed v. In (*b*) and (*c*), the ring of kinks in the electric field lines traveling outward from the particle corresponds to an electromagnetic wave pulse. Note that the speed v is smaller than the speed of the particle in Figure 30.7, indicated by the shorter arrow. Consequently, the electric field lines here are less sharply bunched around the vertical.

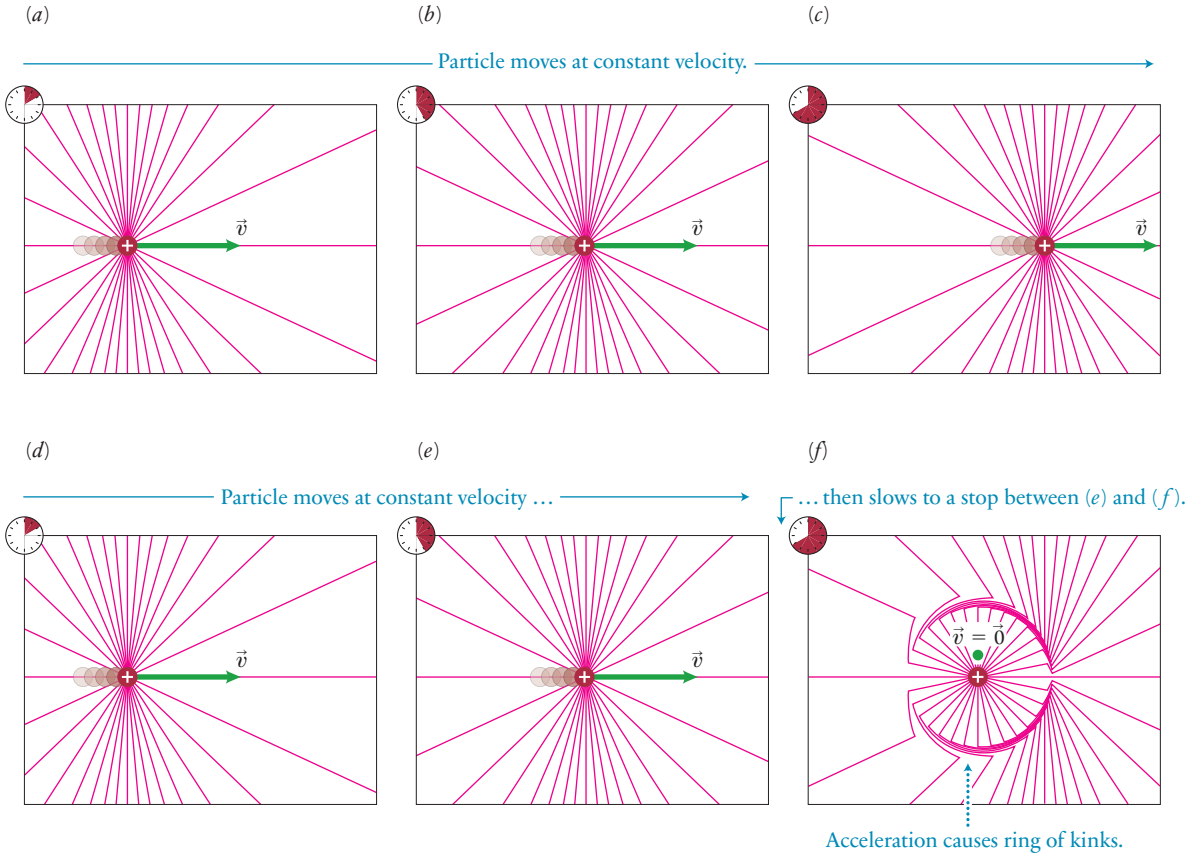
go away once the particle reaches its final constant speed. Instead, they travel radially out from the location where the particle was when it started moving.

Where do these kinks in the electric field pattern come from? They arise because the electric field cannot change instantaneously everywhere in space to reflect changes in the source particle's motion. Remember that field lines extend infinitely far away from the particles that are their sources. If the electric field associated with a particle could change immediately everywhere in the universe when that particle changes its motion, then information about the change in motion would also be transmitted instantaneously throughout the entire universe. As we saw in Chapter 14, however, experiments show that such an instantaneous transmission of information does not happen. Changes in the electric field, and the information that these changes carry, travel at a finite (though very great) constant speed. In fact, in vacuum such changes always travel at the same speed regardless of the details of the motion of the particles that produce them.



At distances that are too great for changes to reach in the time interval represented in Figure 30.8, the electric field line patterns in Figures 30.8*b* and *c* are still the same as the pattern of the stationary particle of Figure 30.8*a*. At distances that can be reached in that time interval, the electric field line patterns in parts *b* and *c* are those of the moving particle. Kinks form in order to connect these two patterns.

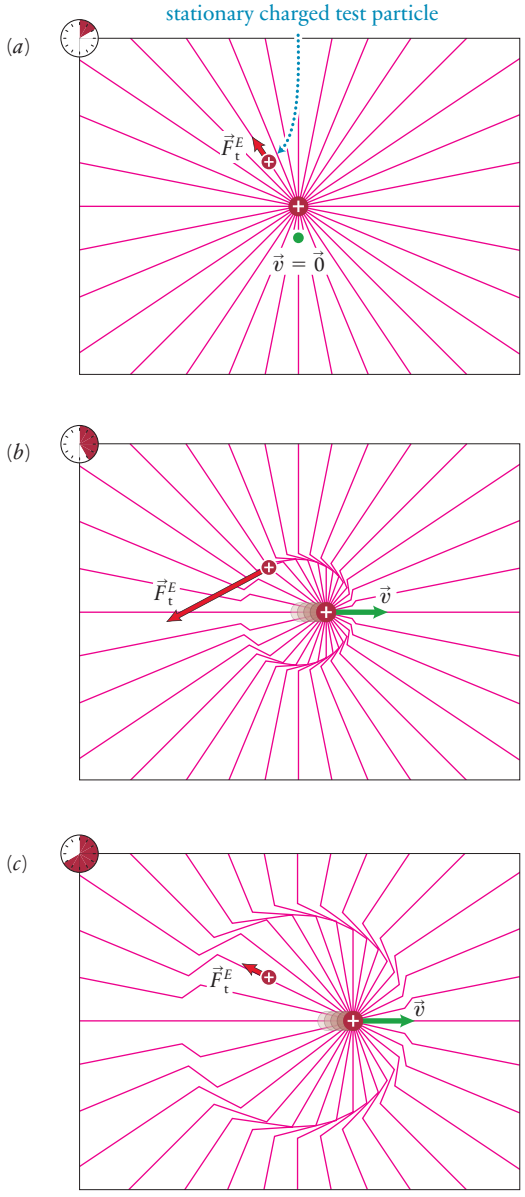
These kinks also form when a particle initially moving at constant velocity $\vec{v}$ abruptly comes to a stop (**Figure 30.9** on the next page). The particle stops just after the instant shown in Figure 30.9*e*. Part *f* shows the electric field line pattern of the stationary particle after some time interval has elapsed.

The electric field line density and consequently the magnitude of the electric field are much greater in the kinks than elsewhere. The energy density in the kinks region is therefore greater than the energy density in

CONCEPTS

Figure 30.9 Electric field line pattern of a charged particle moving at some relativistic speed v. The upper diagrams show successive instants as the particle moves at constant velocity. The lower diagrams show the same instants, but the particle slows down to a stop between (*e*) and (*f*).

other parts of the electric field. As the kinks move, they carry energy away from the particle. These kinks (and the energy carried by them) are one of the two parts of *electromagnetic waves*. As you might guess, kinks in magnetic field lines are the other part. Because changing electric fields are accompanied by changing magnetic fields (and vice versa), the two are always found together. An **electromagnetic wave** is thus a combined disturbance in an electric and a magnetic field that is propagating through space. Because a single isolated propagating disturbance is called a wave pulse (see Section 16.1), the kinks that appear in Figures 30.8 and 30.9 are *electromagnetic wave pulses*.



CONCEPTS

30.5 Estimate the final speed v of the charged particle in Figure 30.8 in terms of the speed of propagation c of the electromagnetic wave pulse produced by the particle's acceleration.

Let us now look at what effect an electromagnetic wave pulse has on a charged particle. **Figure 30.10** shows the force exerted on a stationary charged test particle by the electric field of an accelerated charged particle. At the first instant shown (Figure 30.10*a*), before the particle at the center of the panel is accelerated, the force exerted by the electric field on the test particle acts in the direction of the electric field line joining the two particles and points away from the center particle. At the second instant shown (Figure 30.10*b*), the center particle has been accelerated, and the wave pulse created by the acceleration has just reached the test particle. The electric force exerted on the test particle is no longer directed along the line joining the two particles but is directed along the kinks in the electric field lines. The force therefore has a component tangential to a circle centered on the original position of the accelerated particle at the center of the panel. (The exact direction depends on the magnitude and duration of the acceleration of the accelerated particle.) Moreover, because the electric field line density is large in the region of the kinks, the electric force is large in magnitude.

At the final instant shown (Figure 30.10*c*), the wave pulse has traveled beyond the test particle and the electric force once again points away from the particle. The electric field line density is much smaller again, and so the magnitude of the electric force exerted on the test particle is again much smaller.

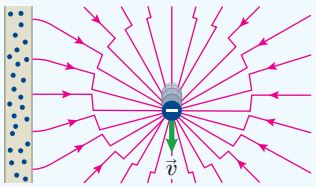


Figure 30.10 Electric force exerted on a stationary charged test particle by the electric field of an accelerated charged particle.

EXAMPLE 30.2 Electromagnetic wave pulse

A particle carrying a negative charge is suddenly accelerated in a direction parallel to the long axis of a conducting rod, producing the electric field pattern shown in **Figure 30.11**.

Figure 30.11 Electric field of an accelerated particle near a conducting rod, before the wave pulse reaches the rod. (The electric field lines bend in near the conducting rod due to the rearrangement of charge carriers at the surface of the rod.)

Does the electric field of the negatively charged particle create a current through the rod (*a*) at the instant shown in the figure, before the electromagnetic wave pulse created by the acceleration reaches the rod, and (*b*) at the instant the pulse reaches the rod? If you answer yes in either case, in which direction is the current through the rod?

❶ **GETTING STARTED** A current is created when charge carriers in the rod flow through the rod. For the carriers to flow, a force needs to be exerted on them.

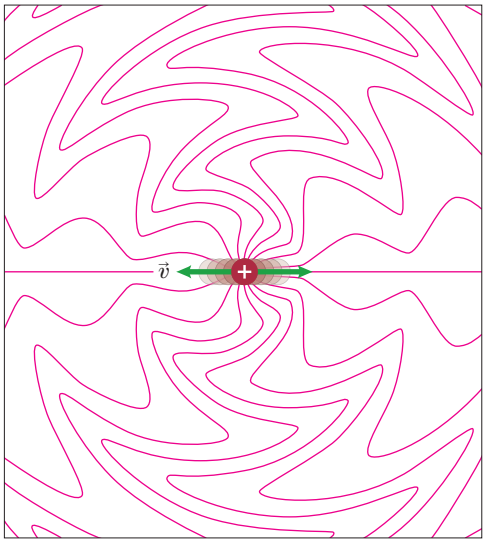
❷ **DEVISE PLAN** To determine whether there is a current through the rod, I must determine if the electric field is oriented in such a way as to cause a flow of charge carriers through the rod. Even though in a metallic rod only electrons are free to move, I can pretend that only positive charge carriers are free to move because as I saw in Section 27.3, my answer is independent of the sign of the mobile charge carriers.

❸ **EXECUTE PLAN** (*a*) No. Before the pulse reaches the rod, the electric field is constant and so the rod is in electrostatic equilibrium. Therefore the electric field magnitude inside the rod is zero, so no charge carriers in the rod flow at the instant shown. ✔

(*b*) Yes. Once the pulse arrives at the rod, the electric field in the rod points downward, accelerating positively charged particles downward and causing a downward current. ✔

❹ **EVALUATE RESULT** Because the particle being accelerated is negatively charged, it makes sense that it pulls positive charge carriers in the rod along (with a delay caused by the time interval it takes the wave pulse to travel to the rod). In practice, electrons in the rod are accelerated upward, but the result is the same as what I describe for positive charge carriers.

30.6 In Figure 30.10, in which regions of space surrounding the accelerating particle does a magnetic field occur?



30.3 Oscillating dipoles and antennas

The wave pulse we have just considered is a brief, one-time, propagating disturbance in the electric field, analogous to the disturbance created when the end of a taut rope is suddenly displaced (as in Figure 16.2, for instance). Just as a harmonic wave can be generated on a rope by shaking the end of the rope back and forth in a sinusoidal fashion, a harmonic electromagnetic wave can be generated when a charged particle oscillates sinusoidally. **Figure 30.12** on the next page shows the electric field of a charged particle undergoing sinusoidal oscillation. This electric field consists of periodic kinks traveling away from the particle in a wavelike fashion.

In practice, isolated charged particles are not common. More often, positive and negative charged particles are present together, whether in individual atoms or in solid or liquid materials. Thus, displacing a positive particle leaves a negative particle behind, forming an electric dipole. Let us therefore consider the electric field pattern of an oscillating electric dipole.

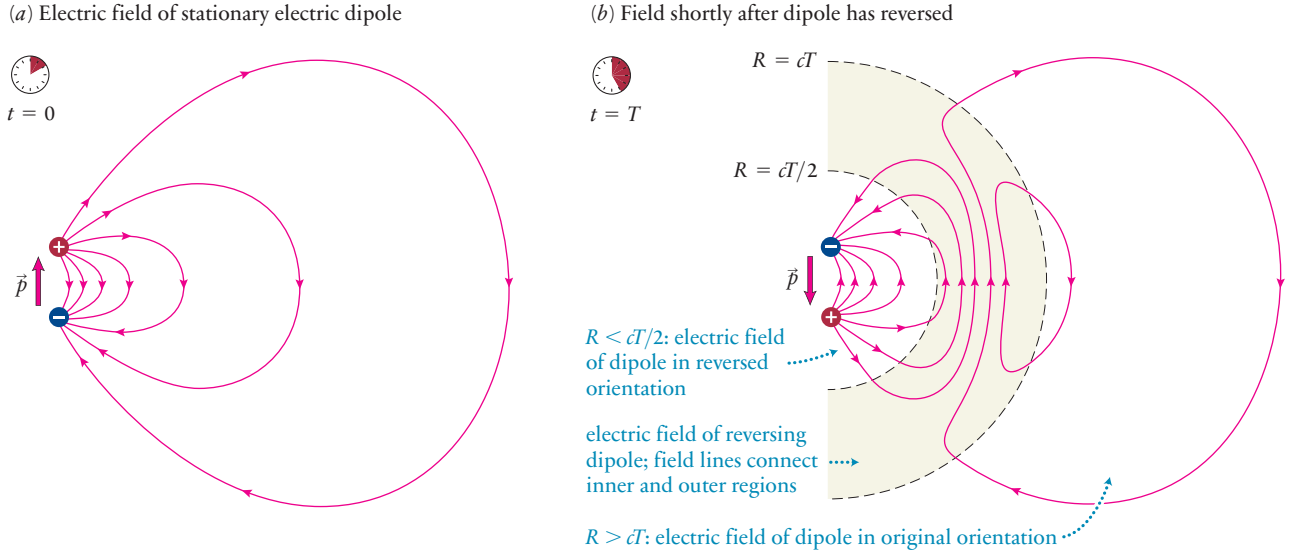
CONCEPTS

Figure 30.12 Electric field of a sinusoidally oscillating charged particle.

The electric field pattern of a stationary electric dipole with the positive charged particle above the negative charged particle is shown in **Figure 30.13*a***. What about the electric field pattern of a stationary dipole made up of the same charged particles but with their positions switched, so that the dipole moment $\vec{p}$—which points from the negatively charged end to the positively charged end (see Section 23.4)—has reversed? The corresponding pattern of electric field lines has the same shape as shown in Figure 30.13*a*, but the directions of all the electric field lines are reversed.

Now let's work out the electric field pattern of an oscillating dipole, in which the two particles oscillate back and forth with a period T. We begin by considering the electric field of a dipole that undergoes only a single reversal of its dipole moment (that is, one-half of a single oscillation) rather than oscillating continuously. The dipole starts out as shown in Figure 30.13*a* at instant $t = 0$. The charged particles that constitute the dipole then switch places in a time interval $T/2$ (half a cycle) and remain there.

Figure 30.13*b* shows the electric field pattern at instant $t = T$, after the dipole has been at rest in its new orientation for a time interval $T/2$. We can divide the space surrounding the dipole into the three regions shown. First consider the region sufficiently close to the dipole that the electric field is just the electric field of the stationary dipole in its new orientation. If we denote the speed at which changes in the electric field travel outward by c and the dipole has been stationary for a time interval $T/2$, this innermost region occupies a circle of radius $R = cT/2$. (The origin of our coordinate system is the center of the dipole, midway between the two particles.) Inside this circle, the electric field is that of the stationary dipole, the same shape as shown in Figure 30.13*a* but with the electric field line directions reversed.



Now consider the region sufficiently far away that no information about the motion of the dipole has reached it yet. This region lies outside a circle of radius $R = cT$. In this region, the electric field pattern is identical to that shown in Figure 30.13*a*, the electric field of the original dipole before it flipped over.

In the highlighted region of Figure 30.13*b* between these two circles, the electric field pattern is not dipolar. Because there are no charged particles in this region, the electric field lines cannot begin or end here. Instead, they must be connected to the electric field lines in the inner and outer regions. Consequently the electric field lines split into two disconnected sets: a set that emanates from the ends of the dipole and a set of loops detached from the dipole.

This electric field line pattern can be generalized to the case of a sinusoidally oscillating dipole (one that doesn't stop after half a cycle). **Figure 30.14** shows snapshots

CONCEPTS

Figure 30.13 (*a*) Electric field of a stationary electric dipole in which the positive particle lies above the negative particle. (*b*) Electric field of the same dipole after the dipole moment has reversed and the charged particles have returned to rest.

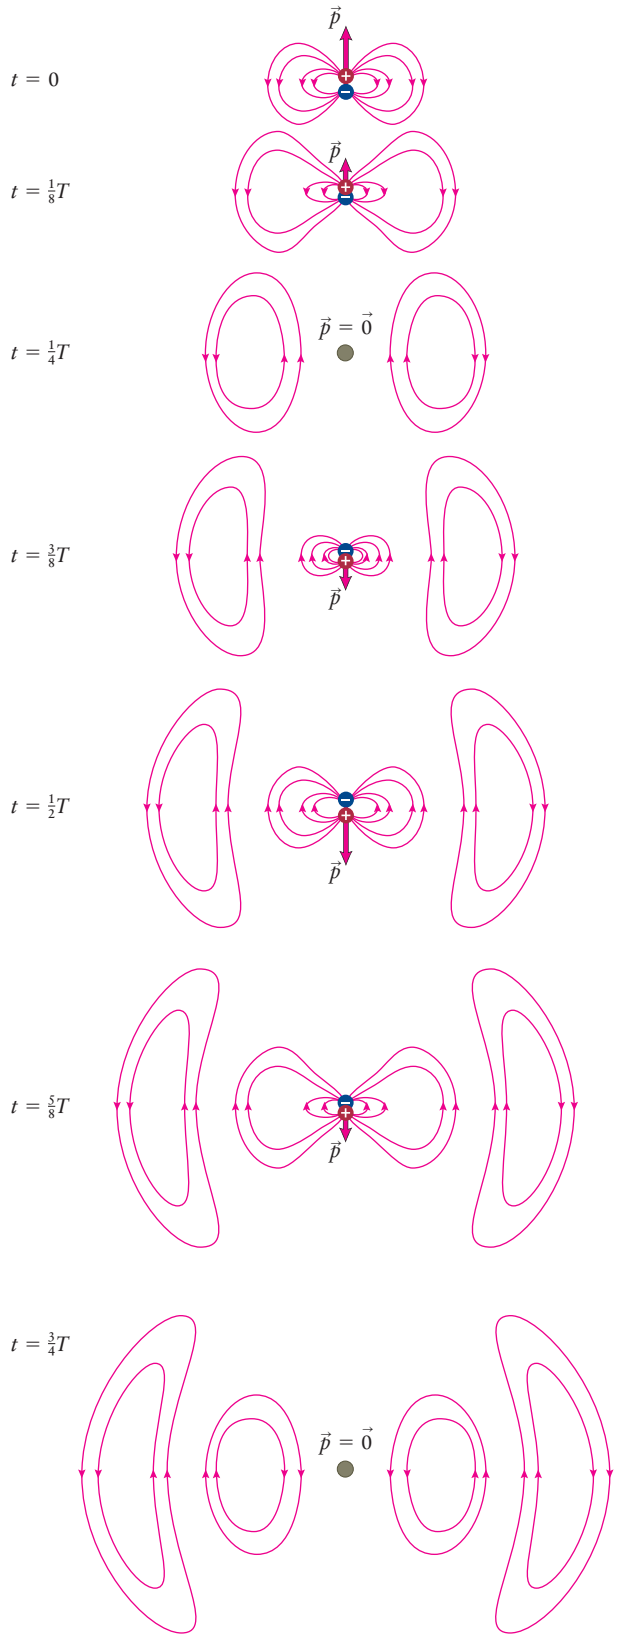


Figure 30.14 Snapshots of the electric field pattern of a sinusoidally oscillating electric dipole at time intervals of $T/8$ (where T is the period of oscillation).

of the electric field pattern of such a dipole at time intervals of $T/8$. Just as with the single half-oscillation, we see a dipolar electric field near the dipole. Farther away, the electric field lines form loops.

Notice how these loops form every half-cycle (that is, at $t = T/4$ and $t = 3T/4$): As the charged particles of the dipole reach the origin during each oscillation, the electric field lines pinch off and the loops travel outward like puffs of smoke. This regular emission of looped electric field lines is a harmonic electromagnetic wave that travels away from the electric dipole horizontally left and right.

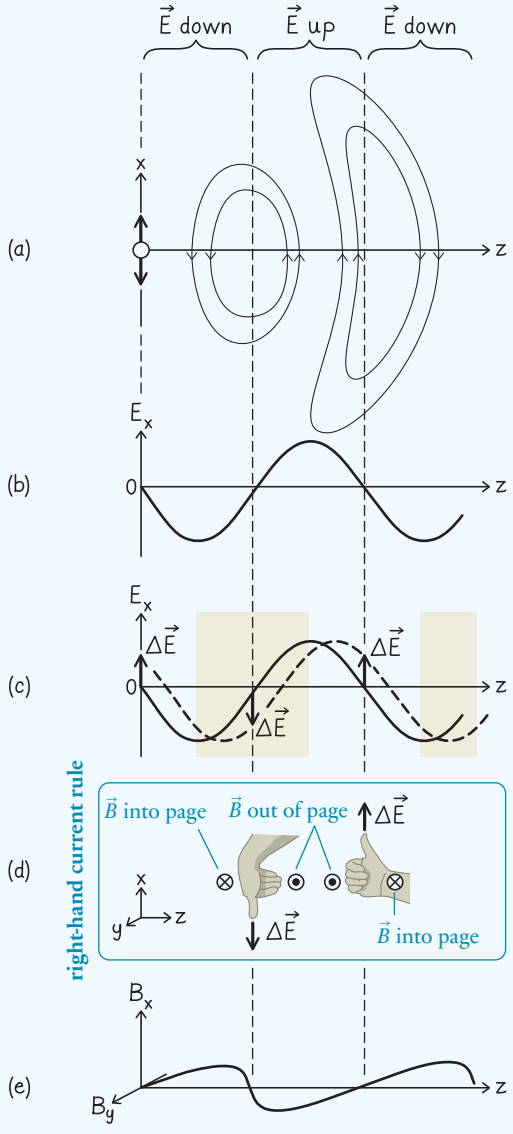
30.7 (*a*) If Figure 30.14 shows the oscillating electric field pattern at its actual size, estimate the wavelength of the electromagnetic wave. (*b*) If the wave is traveling at speed $c = 3 \times 10^8$ m/s, what is the wave frequency? (*c*) What is the period of oscillation?

So far we have focused on the electric field pattern of this electromagnetic wave because it is natural to think about the electric field of a dipole. However, the changing electric field of the oscillating dipole is accompanied by a magnetic field. Consequently, the oscillation produces not only an electric field but also a magnetic field.

EXAMPLE 30.3 Magnetic field pattern

Consider the electric field pattern of a sinusoidally oscillating dipole in Figure 30.14. (*a*) At $t = \frac{3}{4}T$, where along the horizontal axis bisecting the straight line connecting the two poles is the electric field increasing with time? Where is it decreasing? (*b*) Based on your answer to part *a*, what pattern of magnetic field lines do you expect in the horizontal plane that bisects the straight line connecting the two poles?

1 GETTING STARTED Because the dipole oscillates sinusoidally, I expect the electric field to be a sinusoidally oscillating outward-traveling wave. The wave is three-dimensional, but the problem asks only about the electric field along the dipole's horizontal axis, so a one-dimensional treatment of this wave suffices. Because the wave is three-dimensional, the amplitude decreases as $1/r$ as the wave travels outward (see Section 17.1), but I'll ignore the decrease over the small distance over which the wave propagates in the figure.



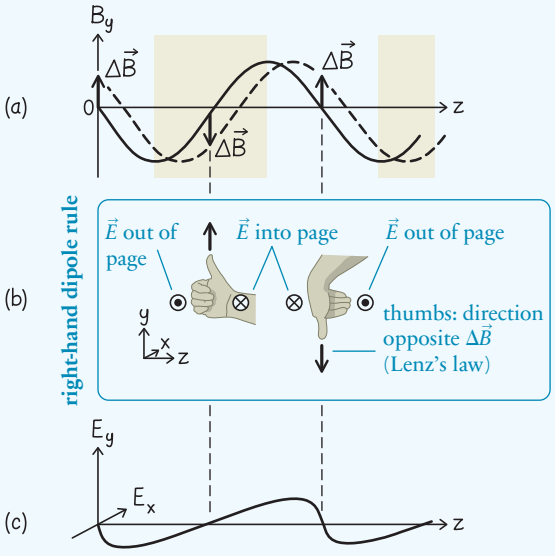
2 DEVISE PLAN I know from Chapter 16 that a one-dimensional sinusoidal wave can be represented by a sine function both in space and in time. (The wave function shows the value of the oscillating quantity as a function of position at a given instant in time, and the displacement curve shows the oscillating quantity as a function of time at a given position.) I can use the information shown in Figure 30.14 to draw the wave function for the electric field at $t = \frac{3}{4}T$. Once I have the wave function and know which way the wave is traveling, I can determine where the electric field increases. Because a changing electric field causes a magnetic field, I can use the information from part *a* to solve part *b*.

(Continued)

CONCEPTS

3 EXECUTE PLAN (*a*) Because the problem asks for information at the instant $t = \frac{3}{4}T$, I begin by copying the right half of the bottom electric field pattern of Figure 30.14 (**Figure 30.15*a***). (The left half is simply the mirror image of the right half.) I draw a rightward-pointing horizontal axis through the center of the dipole and denote this as the z axis. I see that the electric field points downward parallel to the vertical axis (which I take to be the x axis) in the region between the dipole and the center of the first set of electric field loops. In the region between the centers of the first and the second set of loops, the electric field points upward. Because the electric field must vary sinusoidally, I can now sketch how its x component varies with position along the horizontal axis (Figure 30.15*b*).

Figure 30.15



As the wave travels outward, the wave function of Figure 30.15*b* moves to the right (dashed curve in Figure 30.15*c*). The difference between the dashed and solid curves is the change in the electric field $\Delta\vec{E}$ (black arrows); $\Delta\vec{E}$ points down when the derivative of E_x with respect to z is positive (shaded regions) and up when it is negative (unshaded regions). ✔

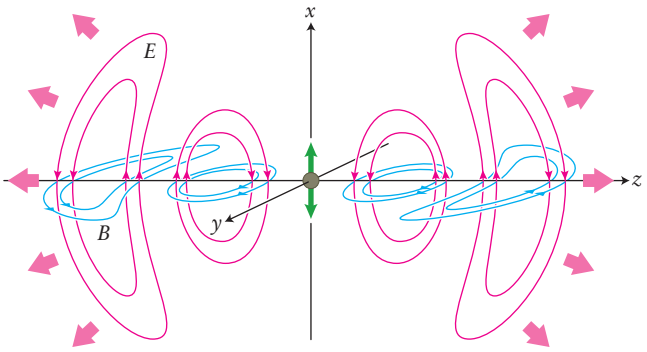
(*b*) The direction of the magnetic field is determined by the right-hand current rule, taking the direction of the change in the electric field $\Delta\vec{E}$ as the "current." Pointing the thumb of my right hand down in the region where $\Delta\vec{E}$ points down and up where $\Delta\vec{E}$ points up (Figure 30.15*d*), I see from the way my fingers curl that the magnetic field lines form loops in the horizontal (yz) plane that are centered on the vertical black dashed lines, just like the electric field lines do. Consequently the magnetic field points out of the page when E_x is positive and into the page when E_x is negative. If I let the y axis point out of the page, the y component of the magnetic field must be positive when E_x is positive and negative when E_x is negative. I therefore draw a sinusoidally varying function for B_y as a function of position (Figure 30.15*e*). ✔

4 EVALUATE RESULT My answer shows that the electric and magnetic fields have the same dependence on time but are oriented perpendicular to each other. Because the magnetic field changes, Faraday's law tells me that it is accompanied by an electric field. To analyze this electric field I can use an approach similar to the one I used to determine the magnetic field. **Figure 30.16*a*** shows the magnetic wave traveling outward. The difference between the dashed and solid curves is the change in the magnetic field $\Delta\vec{B}$. According to what I learned in Section 29.4, the direction of the electric field accompanying my changing magnetic field is given by Lenz's law and the right-hand dipole rule (Figure 30.16*b*). Consequently the electric field points into the page when B_y is positive and out of the page when B_y is negative. Because the x axis points into the page in this rendering (compare Figures 30.15*d* and 30.16*b*), the x component of the electric field must be positive when B_y is positive and negative when B_y is negative, as shown in Figure 30.16*c*. The electric field shown in Figure 30.16*c* is exactly the electric field I started out with in Figure 30.15*b*. In other words, the electric field yields the magnetic field and the magnetic field yields the electric field, and the two are entirely consistent with one another.

Figure 30.16

CONCEPTS

Figure 30.17 Electric and magnetic field pattern of oscillating dipole. The pink arrows indicate the direction of propagation of the electromagnetic wave pulse. For simplicity, only the fields in the *xz* and *yz* planes are shown.



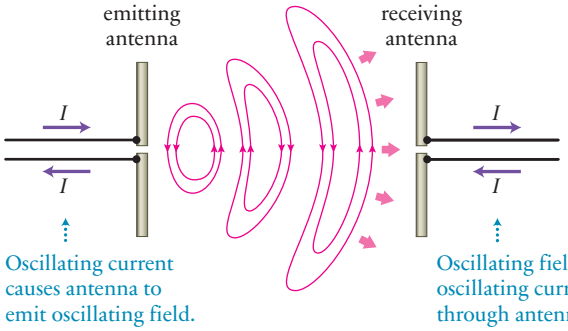


Figure 30.18 System of two antennas, one that emits electromagnetic waves and one that receives them. The emitting antenna is supplied with an oscillating current created by a source of alternating potential difference. An oscillating current is induced in the receiving antenna by the arriving electromagnetic wave.

The solution to Example 30.3 suggests that the magnetic field line pattern is similar to the electric field line pattern, but perpendicular to it. **Figure 30.17** shows the combined electric and magnetic field pattern of an oscillating dipole. Traveling electromagnetic waves, like the one shown in Figure 30.17, are transverse waves (see Section 16.1) because both the magnetic field and the electric field are perpendicular to the direction of propagation. Also, the electric and magnetic fields propagate at the same frequency, and both reach their maxima (or minima) simultaneously; the electric and magnetic fields are therefore in phase with each other.

30.8 (*a*) At the origin of the graphs in Figure 30.15, the electric field is zero, but there is a current due to the motion of the charged particles that constitute the dipole. Is this current upward, downward, or zero at the instant shown in Figure 30.15? (*b*) Is this current (or the absence thereof) consistent with the magnetic field pattern shown in Figure 30.17?

In the wave shown in Figure 30.17, not only are the electric and magnetic fields perpendicular to each other, but throughout the entire wave the electric field has no component perpendicular to the *xz* plane. (The magnetic field, in contrast, is always perpendicular to this plane.) By convention the orientation of the electric field of an electromagnetic wave as seen by an observer looking in the direction of propagation of the wave is called the **polarization** of the wave. An observer looking at the dipole in Figure 30.17 would say that the wave from the dipole is polarized along the *x* axis. Because the electric field oscillation from the dipole in Figure 30.17 retains its orientation as it travels in any given direction, the wave is said to be *linearly polarized*. In certain cases the polarization of an electromagnetic wave rotates as it propagates, and the wave is said to be *circularly* or *elliptically polarized*.

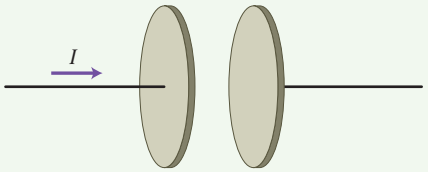
We have seen that oscillating dipoles generate electromagnetic waves by accelerating the oppositely charged particles that make up the dipole in a periodic manner. Practically speaking, how can we cause charged particles, in a dipole or anything else, to accelerate periodically? One common approach is to apply an alternating potential difference to an *antenna*, which is a device that either emits or receives electromagnetic waves. The alternating potential difference drives charge carriers back and forth through the antenna, thereby producing an oscillating current through the antenna.

Antennas that emit electromagnetic waves are designed in many ways to produce a variety of electric and magnetic field patterns. The simplest design is two conducting rods connected to a source of alternating potential difference (**Figure 30.18**). Because of the alternating potential difference, the ends of the antenna are oppositely charged and cycle between being positively charged, neutral, and negatively charged.

When the top end of the antenna is positively charged and the bottom end is negatively charged, the electric field of the antenna points down. When the charge distribution is reversed, the electric field points up. As the charge distribution oscillates, the electric field adjacent to the emitting antenna also oscillates. This changing electric field is accompanied by a changing magnetic field, and the disturbance in the fields travels away from the emitting antenna in the same manner as the electromagnetic wave of Figures 30.14, 30.15, and 30.17.

If the length of each rod in an emitting antenna is exactly one-quarter of the wavelength of the electromagnetic wave emitted, the electric fields produced strongly resemble the dipole fields of Figure 30.17. Such an antenna is often called a *dipole antenna;* it is also called a *half-wave antenna* because the length of the two rods is equal to half a wavelength.

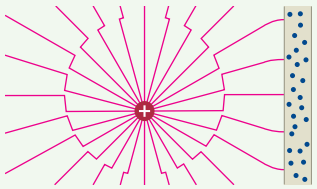
In antennas that receive electromagnetic waves, the oscillating electric field of the wave causes charge carriers in the antenna to oscillate, as discussed in Example 30.3. This produces an oscillating current (shown schematically in Figure 30.18) that can be measured. When operated in this mode, the antenna is said to be *receiving* a signal.



30.9 To maximize the magnitude of the current induced in a receiving antenna, should the antenna be oriented parallel or perpendicular to the polarization of the electromagnetic wave?

CONCEPTS

Self-quiz



1. Suppose the current shown in **Figure 30.19** discharges the capacitor. What are the directions of $\vec{E}$, $\Delta\vec{E}$, and $\vec{B}$ between the plates of the discharging capacitor?

Figure 30.19

2. A positively charged particle creates the electric field shown in **Figure 30.20**. When the kinks in the electric field lines reach the rod, what is the direction of the current induced in the rod?

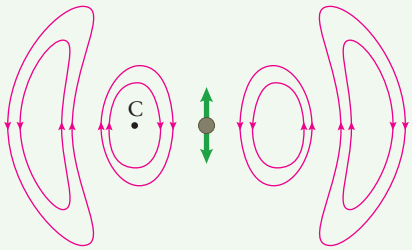


Figure 30.20

3. For the oscillating dipole of Figure 30.14, sketch the electric field pattern at $t = \frac{5}{4}T$.

4. In the electric field pattern for a sinusoidally oscillating dipole shown in **Figure 30.21**, what are (*a*) the direction of the change in the electric field $\Delta\vec{E}$ at point C as the electric field propagates and (*b*) the direction of the magnetic field loop near C?

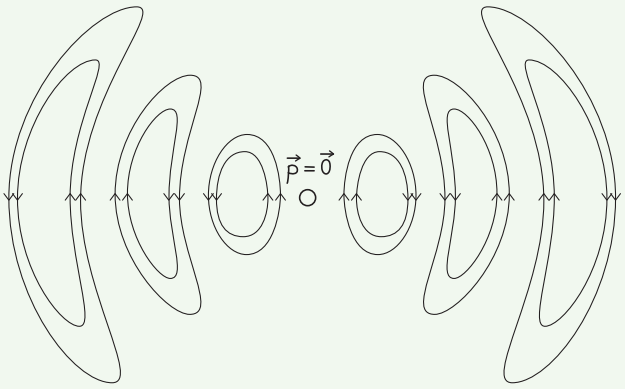

Figure 30.21

Answers

1. The current brings positive charge carriers to the left plate and removes them from the right plate. For the capacitor to discharge, the left plate must be negatively charged and the right one positively charged; this means $\vec{E}$ points left. The electric field decreases as the capacitor discharges, so $\Delta\vec{E}$ is to the right (just as the current is). The magnetic field lines are circular and centered on the axis of the capacitor in a direction given by the right-hand current rule with the thumb along the direction of $\Delta\vec{E}$. That is, the magnetic field lines are clockwise looking along the direction of the current.
2. Because the particle carries a positive charge, the electric field lines radiate outward. The electric field in the kinks therefore points up, and so the kinks induce an upward current through the rod.
3. See **Figure 30.22**. Because the loops move outward and a new pair of loops forms every half-period, the pattern now has three loops. Note in Figure 30.14 that the loops closest to the dipole at $t = \frac{1}{4}T$ and $t = \frac{3}{4}T$ have the same shape but opposite directions. Half a period after $t = \frac{3}{4}T$, at $t = \frac{5}{4}T$, the loops closest to the dipole again have the same shape (and the same direction as at $\frac{1}{4}T$). Likewise, at $t = \frac{5}{4}T$ the second closest loops curl in the direction opposite the direction at $\frac{3}{4}T$.

Figure 30.22

4. (*a*) The loops passing at C travel to the left. At the instant shown, the electric field is close to zero, but as the pattern moves to the left, the electric field lines point downward at C, so $\Delta\vec{E}$ is down. (*b*) The thumb of your right hand aligned in the direction of $\Delta\vec{E}$ makes your fingers curl in the direction of the magnetic field: clockwise viewed into the plane of the page.

30.4 Displacement current

The work we did with Ampère's law in Sections 28.4 and 28.5 dealt only with the magnetic field associated with an electric current. As we saw in Section 30.1, though, magnetic fields also accompany changing electric fields, a phenomenon not covered by our Chapter 28 form of Ampère's law. Let us now see how the quantitative formulation of Ampère's law must be modified to account for the magnetic fields that accompany changing electric fields.

To do this, consider the charging capacitor in **Figure 30.23**. Ampère's law relates the integral of the magnetic field around a closed path to the current intercepted by a surface spanning the path (Eq. 28.1). Applying Ampère's law to surface A in Figure 30.23, we have

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I. \tag{30.1}$$

For surface B, however, the right-hand side of Eq. 30.1 is zero because the current is zero in the gap between the capacitor plates. As we discussed in Section 30.1, there is a change in the electric field between the capacitor plates, so surface B does not intercept a current, but it does intercept a change in electric flux. Let us therefore generalize Ampère's law by adding to the right side a term that depends on this change in electric flux.

We choose this term so that when we apply the generalized version of Ampère's law to the capacitor shown in Figure 30.23, for example, the magnetic field around the designated path is the same whether we calculate it from the current intercepted by surface A or from the change in electric flux $d\Phi_E/dt$ through surface B.

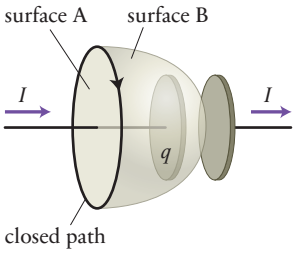
To obtain this generalizing term, let's determine a mathematical relationship between $d\Phi_E/dt$ through surface B and the current to the plates. First, note that the change in electric flux is related to the change in the charge q on the plates, which, in turn, is related to the current I to the plate. Consider the closed surface surrounding the left capacitor plate in Figure 30.23 made up by surfaces A and B combined. Applying Gauss's law to this closed surface, we find that the electric flux through it is

$$\oint_{\text{A+B}} \vec{E} \cdot d\vec{A} = \frac{q}{\epsilon_0}, \tag{30.2}$$

where q is the charge on the capacitor plate. Because the electric field is confined to the region between the plates, the electric flux through surface A is zero (Figure 30.23) and so

$$\oint_{\text{A+B}} \vec{E} \cdot d\vec{A} = \int_{\text{A}} \vec{E} \cdot d\vec{A} + \int_{\text{B}} \vec{E} \cdot d\vec{A} = \int_{\text{B}} \vec{E} \cdot d\vec{A} = \frac{q}{\epsilon_0}. \tag{30.3}$$

If we denote the electric flux through surface B by Φ_E, we see from Eqs. 30.3 that $q = \epsilon_0 \Phi_E$. The rate of change of the charge on the capacitor plates, dq/dt, is equal to the current supplied to the capacitor, so



$$I \equiv \frac{dq}{dt} = \epsilon_0 \frac{d\Phi_E}{dt}, \tag{30.4}$$

which is the relationship we were looking for.

If we substitute Eq. 30.4 in the right side of Eq. 30.1, we obtain

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.5}$$

Figure 30.23 Capacitor being charged by a current-carrying wire. Because surfaces A and B both span the closed path shown, either surface can be used to calculate the magnetic field around the path. Ampère's law must be the same in either case.

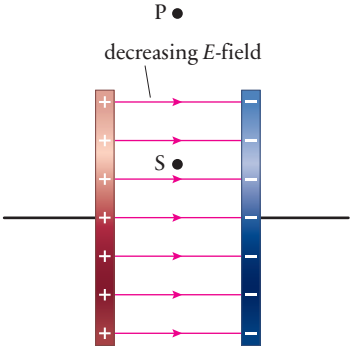
We can now use this expression to determine the line integral of the magnetic field around the closed path in Figure 30.23 by evaluating the change in electric flux through surface B. Because the right side of Eq. 30.5 is equal to $\mu_0 I$, we obtain for $\oint \vec{B} \cdot d\vec{\ell}$ the same value we found using the original form of Ampère's law with the current intercepting surface A.

To account for both a current and a changing electric flux, we generalize Ampère's law as follows:

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I_{\text{int}} + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.6}$$

This equation holds for any surface spanning a closed path and is sometimes called the *Maxwell-Ampère law*, in honor of the Scottish physicist James Clerk Maxwell (1831–1879), who first introduced the additional term in Eq. 30.6. To reflect the fact that we must only include the current intercepted by the surface, not the current encircled by the integration path, we write I_{int} rather than I_{enc}.

The quantity on the right side of Eq. 30.4 is called the **displacement current:**



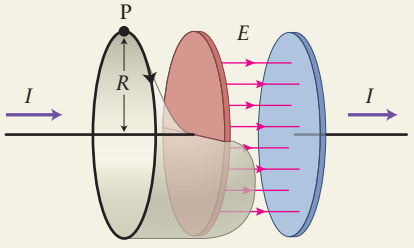
$$I_{\text{disp}} \equiv \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.7}$$

As you can see from Eq. 30.4, the SI units of the displacement current are indeed those of a current. The name is somewhat misleading because the derivation holds for a capacitor in vacuum where no charged particles are present in the space between the plates. Even if the term is somewhat of a misnomer, it is still useful to associate the change in the electric field with a "current" to determine the direction of the magnetic field accompanying a changing electric field. As we argued in Section 30.1, the direction of this displacement current is the same as that of the change in the electric field $\Delta\vec{E}$. We can then use the right-hand current rule to determine the direction of the magnetic field from the displacement current (see, for example, Figure 30.5).

Using Eq. 30.7, we can write Eq. 30.6 in the form

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 (I_{\text{int}} + I_{\text{disp}}). \tag{30.8}$$

Figure 30.24 Checkpoint 30.10.



30.10 The parallel-plate capacitor in **Figure 30.24** is discharging so that the electric field between the plates *decreases*. What is the direction of the magnetic field (*a*) at point P above the plates and (*b*) at point S between the plates? Both P and S are on a line perpendicular to the axis of the capacitor.

EXAMPLE 30.4 A bit of both

The parallel-plate capacitor in **Figure 30.25** has circular plates of radius R and is charged with a current of constant magnitude I. The surface is bounded by a circle that passes through point P and is centered on the wire leading to the left plate and perpendicular to that wire. The surface crosses the left plate in the middle so that the top half of the plate is on one side of the surface and the bottom half is on the other side. Use this surface and Eq. 30.6 to determine the magnitude of the magnetic field at point P, which is a distance $r = R$ from the capacitor's horizontal axis.

Figure 30.25 Example 30.4.

QUANTITATIVE TOOLS

❶ **GETTING STARTED** The surface intercepts both a current (through the wire) and a changing electric field (between the plates). To apply Eq. 30.6, I must therefore determine both the current and the electric flux intercepted by the surface.

There also is a simple way to obtain the answer to this question: Ampère's law (Eq. 30.1). If I take the circle through point P centered on the wire and perpendicular to it as the integration path, then the integral on the left side of Eq. 30.1 is equal to the magnitude of the magnetic field times the circumference of the circle: $2\pi RB$. The path encircles the current I, so Ampère's law gives me $2\pi RB = \mu_0 I$ and $B = \mu_0 I/(2\pi R)$. Because the magnetic field magnitude cannot depend on the approach used to calculate it, I should obtain the same result using Eq. 30.6 and the surface in Figure 30.25.

❷ **DEVISE PLAN** The left side of Eq. 30.6 is identical to the left side of Eq. 30.1 and therefore equal to $2\pi RB$. To evaluate the right side of Eq. 30.6, I must determine both the ordinary current and the displacement current intercepted by the surface.

❸ **EXECUTE PLAN** If the surface intercepted the entire electric flux between the plates, the displacement current term on the right side of Eq. 30.6 would be equal to $\mu_0 I$. The surface intercepts only half of the electric flux, however, so the displacement current is

$$\epsilon_0 \frac{d\Phi_E}{dt} = \tfrac{1}{2} I.$$

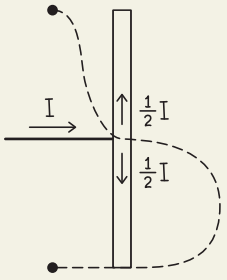
Next I need to determine how much current is intercepted by the surface. To charge the plate uniformly, the current must carry charge carriers evenly to the two halves of the plate—half of the charge carriers go to the top half of the plate and the other half go to the bottom half of the plate (**Figure 30.26**). Because the top half of the plate is to the right of the surface, the current going to the top half of the plate must cross the surface. The current intercepted by the surface is thus $\frac{1}{2}I$, and the right side of Eq. 30.6 becomes

$$\mu_0 I_{\text{int}} + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt} = \mu_0 \left(\tfrac{1}{2} I\right) + \mu_0 \left(\tfrac{1}{2} I\right) = \mu_0 I. \quad (1)$$

Substituting the right side of Eq. 1 into the right side of Eq. 30.6, I have $2\pi RB = \mu_0 I$ and so $B = \mu_0 I/(2\pi R)$, which is the same value I got using Eq. 30.1. ✔

❹ **EVALUATE RESULT** It's reassuring to see that the magnetic field magnitude at P does not depend on the choice of surface spanning the integration path. I can easily modify the argument above to show that any other surface that intercepts the left plate gives the same result. For example, a surface that intercepts one-quarter of the plate, as in **Figure 30.27**, intercepts one-quarter of the electric flux, and so the displacement current is only $I/4$. This surface intercepts the current twice: Where the surface intersects the wire, the current I crosses the surface from left to right, and where the surface intersects the plate, one-quarter of the current crosses the surface in the other direction, for a total contribution of $\frac{3}{4}I$. Again the sum of the ordinary and displacement currents intercepting the surface is I.

Figure 30.26



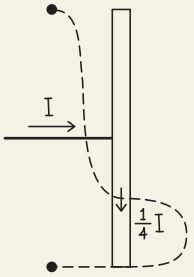


Figure 30.27

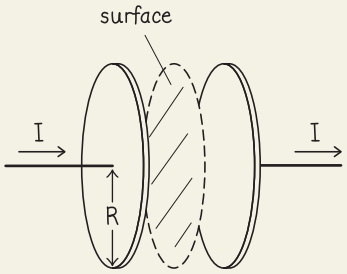
EXAMPLE 30.5 Magnetic field in a capacitor

A parallel-plate capacitor has circular plates of radius $R = 0.10$ m and a plate separation distance $d = 0.10$ mm. While a current charges the capacitor, the magnitude of the potential difference between the plates increases by 10 V/μs. What is the magnitude of the magnetic field between the plates at a distance R from the horizontal axis of the capacitor?

❶ **GETTING STARTED** As the capacitor is charging, there is a changing electric flux between the plates, so the electric field between the plates is changing. This changing electric field is accompanied by a magnetic field.



❷ **DEVISE PLAN** Equation 30.6 relates the magnetic field to a changing electric flux. To work out the left side of Eq. 30.6, I chose a circular integration path centered on the horizontal axis of the capacitor so that I can exploit the circular symmetry of the problem. To work out the right side of Eq. 30.6, I need to determine the rate of change of the electric flux through an appropriate surface spanning the integration

(Continued)

QUANTITATIVE TOOLS

path. I choose the simplest possible surface: a flat surface parallel to the plates (**Figure 30.28**). To calculate the change in electric flux intercepted by this surface, I need to determine the magnitude of the (uniform) electric field between the plates. In Example 26.2 I determined that the magnitude of the electric field between the plates is related to the plate separation distance d and the magnitude of the potential difference between the plates: $V_{cap} = Ed$.

Figure 30.28

3 EXECUTE PLAN Because the electric field between the plates is uniform and perpendicular to the plates, the electric flux Φ_E through the surface I chose is $\Phi_E = EA = E\pi R^2$, where $A = \pi R^2$ is also the area of the capacitor plates. The time rate of change of the electric flux is then given by

$$\frac{d\Phi_E}{dt} = \pi R^2 \frac{dE}{dt}.$$

Substituting this result in Eq. 30.6 and setting the current term equal to zero because no current is intercepted by the surface I've chosen, I get

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \pi R^2 \frac{dE}{dt}.$$

Around my integration path, the magnitude of the magnetic field is constant, and the left side of this expression simplifies to $2\pi RB$. Solving for B, I obtain

$$B = \frac{\mu_0 \epsilon_0 R}{2} \frac{dE}{dt}. \qquad (1)$$

Because $V_{cap} = Ed$, I can write $E = V_{cap}/d$ and so

$$B = \frac{\mu_0 \epsilon_0 R}{2d} \frac{dV_{cap}}{dt} \qquad (2)$$

$$B = (4\pi \times 10^{-7}\ \text{T}\cdot\text{m/A})\,(8.85 \times 10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2) \times \frac{0.10\ \text{m}}{2(0.10 \times 10^{-3}\ \text{m})} \frac{10\ \text{V}}{1.0 \times 10^{-6}\ \text{s}}$$
$$= 5.6 \times 10^{-8}\ \text{T},$$

where I have used the Eq. 25.16 definition of the volt, $1\ \text{V} \equiv 1\ \text{J/C} \equiv 1\ \text{N}\cdot\text{m/C}$, and Eq. 27.3, for the ampere, $1\ \text{C} = 1\ \text{A}\cdot\text{s}$, to simplify the units. ✔

4 EVALUATE RESULT The magnetic field magnitude I obtain is very small, in spite of the substantial rate at which the potential difference between the plates increases. I have no way of knowing whether my numerical result is reasonable or not, but what I can do to evaluate the result is use another method to obtain an expression for B. Because my flat surface intercepts all the electric flux, I know that the magnitude of the magnetic field should be the same at all positions a distance R from the current-carrying wire. I can obtain the current by solving Eq. 26.1, $q/V_{cap} = C$, for the charge q on the capacitor plate and then using the definition of current, $I \equiv dq/dt$:

$$I \equiv \frac{dq}{dt} = C\frac{dV_{cap}}{dt}.$$

Substituting the capacitance of a parallel-plate capacitor $C = \epsilon_0 A/d = \epsilon_0 \pi R^2/d$ (see Example 26.2) into this expression, and then substituting the result into the expression for the magnetic field around a current-carrying wire from Example 28.3, $B = \mu_0 I/(2\pi r)$ (setting $r = R$ for the distance to the wire), I get

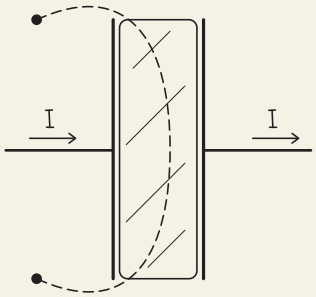
$$B = \frac{\mu_0 I}{2\pi R} = \frac{\mu_0 \epsilon_0 R}{2d} \frac{dV_{cap}}{dt},$$

the same result I obtained in Eq. 2, as I expect.

Note that in Example 30.5 the rate of change of the electric field is very large (about $10^{11}\ \text{V}/(\text{m}\cdot\text{s})$), but the accompanying magnetic field is small. This is not the case for electric fields that accompany changing magnetic fields, as substantial emfs can be induced by the motion of ordinary magnets.

30.11 Consider again the parallel-plate capacitor of Figure 30.23. For circular plates of radius R, calculate the magnitude of the magnetic field a distance $r < R$ from the horizontal axis of the capacitor (*a*) between the plates and (*b*) a short distance to the right of the right plate.

QUANTITATIVE TOOLS



EXAMPLE 30.6 Displacement current in the presence of a dielectric

Suppose a slab of dielectric with dielectric constant κ is inserted between the plates of the capacitor in Figure 30.23 and the capacitor is charged with a current I, as considered in Example 30.1. How does Eq. 30.6 have to be modified to account for the dielectric?

❶ **GETTING STARTED** For a given amount of charge on the capacitor plates, the presence of a dielectric decreases the magnitude of the electric field between them. As I concluded in Example 30.1, however, the magnetic field surrounding the wires that lead to the capacitor wires is determined only by the current I through the wires and therefore cannot be affected by the insertion of the dielectric.

❷ **DEVISE PLAN** Given that the magnetic field surrounding the wires cannot be affected by the presence of the dielectric, the displacement current intercepted by a surface spanning a circular path around the wire and passing between the capacitor plates (**Figure 30.29**) should be equal to I, regardless of the presence of the dielectric. By setting the displacement current through the surface in Figure 30.29 equal to I, I can determine how the right side of Eq. 30.6 needs to be modified to account for the presence of the dielectric.

Figure 30.29

❸ **EXECUTE PLAN** As the capacitor charges, the presence of the dielectric reduces the magnitude of the electric field by a factor $1/\kappa$ (see Eq. 26.15): $E = E_{\text{free}}/\kappa$. As a result, the rate of change of the electric field dE/dt and the rate of change in the electric flux intercepted by the surface $d\Phi_E/dt$ are also reduced by a factor $1/\kappa$. To compensate for this reduction, I need to multiply $d\Phi_E/dt$ by κ in order to make the right side of Eq. 30.4 equal to I again. Therefore Eq. 30.6 becomes

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I + \mu_0 \epsilon_0 \kappa \frac{d\Phi_E}{dt}. \checkmark$$

❹ **EVALUATE RESULT** My modification to Eq. 30.6 is identical to the modification we made to make Gauss's law work in dielectrics (Eq. 26.25): In both cases the term containing the electric field or electric flux includes the factor κ.

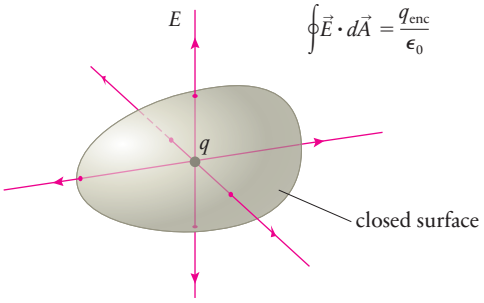
30.5 Maxwell's equations

With Maxwell's addition of the displacement current $\epsilon_0 d\Phi_E/dt$ to Ampère's law, $\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I$, we now have a complete mathematical description of electric and magnetic phenomena and the relationship between the two. Let us summarize this description in the absence of a dielectric.

Electric and magnetic fields are *defined* by Eq. 27.20, which gives the force exerted on a charged particle moving in an electric field and a magnetic field:

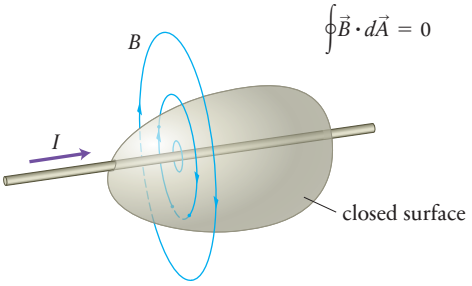
$$\vec{F} = q(\vec{E} + \vec{v} \times \vec{B}). \tag{30.9}$$

Charged particles are the source of electrostatic fields, and electrostatic field lines always begin or end on charged particles. We can calculate electric fields from each individual charged particle if we wish, but when dealing with a distribution of charge that exhibits a certain symmetry (Section 24.4), it is most convenient to use Gauss's law (Eq. 24.8) to work out the electric field. Gauss's law tells us that the electric flux Φ_E through a closed surface (a Gaussian surface) is proportional to the charge enclosed by the surface:



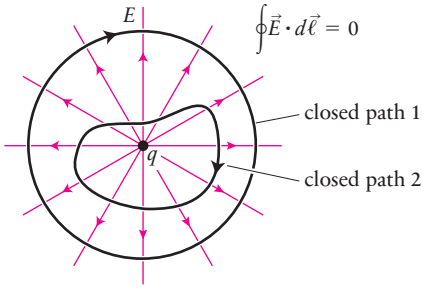
$$\Phi_E \equiv \oint \vec{E} \cdot d\vec{A} = \frac{q_{\text{enc}}}{\epsilon_0}. \tag{30.10}$$

Figure 30.30*a* shows the electric field created by a charged particle, along with a Gaussian surface enclosing that particle.

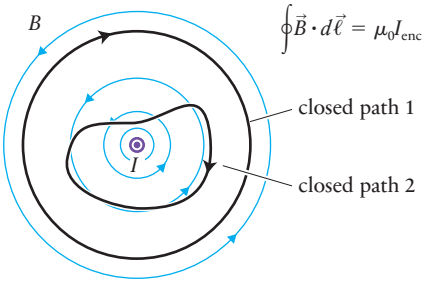


Magnetic fields are generated by moving charged particles, commonly in the form of currents. Unlike electric field lines, magnetic field lines always form loops. There are no isolated magnetic poles, only magnetic

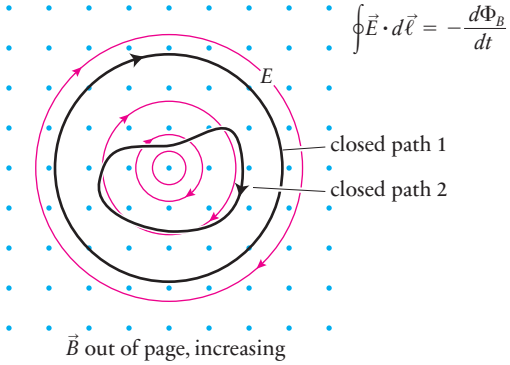
Figure 30.30 Graphical representation of the physics behind Maxwell's equations, together with their mathematical expressions. (*a*) Electric field surrounding a charged particle and a Gaussian surface enclosing that particle. Gaussian surfaces can be used to relate the electric field to the enclosed charge. (*b*) Magnetic field surrounding a current-carrying wire and a closed surface intercepted by the wire; the integral of the magnetic field over a closed surface is always zero. (*c*) Electrostatic field and two closed paths through that field; the path integral of the electric field around either path must be zero. (*d*) Steady magnetic field surrounding a current and two closed paths through that field; the path integral of the magnetic field is proportional to the encircled current. (*e*) Changing magnetic field and two closed paths through it; an electric field accompanies the changing magnetic field; the path integral of this electric field around either path is nonzero. (*f*) Changing electric field and two closed paths through it; a magnetic field accompanies the changing electric field; the path integral of this magnetic field around either path is nonzero. Assume that no current is enclosed by either path.



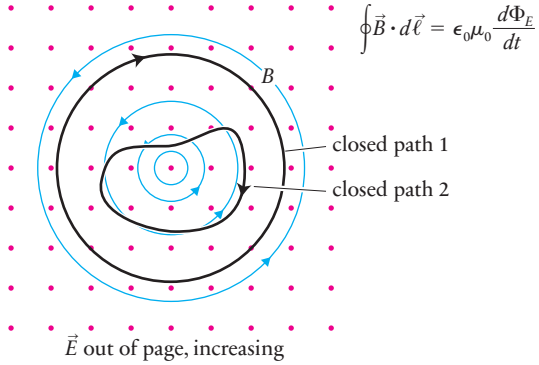
(*a*) Surface integral of electric field (Gauss's law)



(*b*) Surface integral of magnetic field (Gauss's law for magnetism)



(*c*) Line integral of constant electric field



(*d*) Line integral of constant magnetic field (Ampère's law)

(*e*) Line integral of changing electric field (Faraday's law)

(*f*) Line integral of changing magnetic field (Maxwell's displacement current)

QUANTITATIVE TOOLS

dipoles. Consequently, as we showed in Chapter 27, the magnetic flux through any closed surface is always zero (Eq. 27.11):

$$\Phi_B \equiv \oint \vec{B} \cdot d\vec{A} = 0. \tag{30.11}$$

Figure 30.30*b* shows the magnetic field surrounding a current-carrying wire, along with a closed surface intercepted by the wire.

For electrostatic fields, we showed in Chapter 25 that the path integral of the electric field around a closed path is zero, which means that when a charged object is moved around a closed path in an electrostatic field, the work done on it is zero (Eq. 25.32). This situation is represented in Figure 30.30*c*. However, the electric field accompanying a changing magnetic field does work on charged particles even when those particles travel around closed paths:

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt}. \tag{30.12}$$

Figure 30.30*e* shows the electric field lines associated with a changing magnetic field. For such an electric field, no potential can be defined because the path integral of the electric field depends on the path chosen.

Finally, Ampère's law gives the line integral of the magnetic field produced by a current (Figure 30.30*d*). The magnetic field that accompanies a changing electric field forms loops around the direction of the change in electric field, as shown in Figure 30.30*f*. Combining these two contributions to the line integral of the magnetic field gives us Maxwell's generalization of Ampère's law, which is our Eq. 30.6, repeated here:

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I_{\text{int}} + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.13}$$

Equations 30.10–30.13 are referred to as **Maxwell's equations** because Maxwell not only added the displacement current term to Ampère's law but also recognized the coherence and completeness of this set of equations. Together with conservation of charge, these four equations give a complete description of electromagnetic phenomena. In the presence of matter, these equations have to be modified to account for the effects of matter on electric and magnetic fields (see, for example, Example 30.6).

Maxwell's equations were developed from and subsequently verified by a vast body of experimental evidence. Equation 30.10 (Gauss's law) comes from the measured inverse-square dependence of the electric force on separation distance and the finding that, in the steady state, the interior of a hollow charged conductor carries no surplus charge. Equation 30.11 (Gauss's law for magnetism) states that isolated magnetic monopoles do not exist, and none have been detected to date, in spite of very sensitive experiments conducted to search for them. Equation 30.12, a quantitative statement of Faraday's law, comes from extensive experiments by Faraday and others on electromagnetic induction, and Eq. 30.13, Maxwell's generalization of Ampère's law, comes from measurements of the magnetic force between current-carrying wires and the observed properties of electromagnetic waves.

30.12 Suppose that isolated magnetic monopoles carrying a "magnetic charge" m did exist, and that the interaction between these monopoles depended on $1/r^2$, where r is the distance between two monopoles. How would you modify Maxwell's equations to account for these monopoles? Ignore any physical constants that may need to be added.

QUANTITATIVE TOOLS

EXAMPLE 30.7 Maxwell's equations in free space

What is the form of Maxwell's equations in a region of space that does not contain any charged particles?

❶ **GETTING STARTED** If there are no charged particles, there can be no accumulation of charge and no currents, which means $q_{\text{enc}} = 0$ and $I = 0$.

❷ **DEVISE PLAN** All I need to do is set q_{enc} and I equal to zero in Eqs. 30.10–30.13.

❸ **EXECUTE PLAN** Setting $q_{\text{enc}} = 0$ in Eq. 30.10 and $I = 0$ in Eq. 30.13, I obtain the following form of Maxwell's equations:

$$\oint \vec{E} \cdot d\vec{A} = 0 \tag{1}$$

$$\oint \vec{B} \cdot d\vec{A} = 0 \tag{2}$$

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt} \tag{3}$$

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \checkmark \tag{4}$$

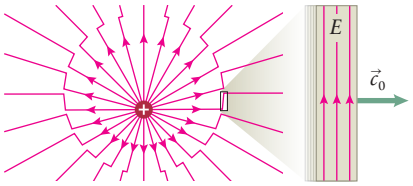
❹ **EVALUATE RESULT** Maxwell's equations simplify greatly in the absence of charged particles (the only asymmetry is the sign difference between Eqs. 3 and 4, which comes from Lenz's law). Equations 1 and 2 state that both the electric and magnetic fluxes through a closed surface are zero in the absence of charged particles. Consequently, both electric and magnetic field lines must form loops. Equations 3 and 4 state that electric field line loops accompany changes in magnetic flux and magnetic field line loops accompany changes in electric flux.

30.13 As you saw in Section 30.3, the magnetic and electric fields in an electromagnetic wave are perpendicular to each other. How do Maxwell's equations in free space (Eqs. 1–4 of Example 30.7) express that perpendicular relationship?

30.6 Electromagnetic waves

From Maxwell's equations, we can derive the fundamental properties of electromagnetic waves. To begin, let's consider an electromagnetic wave pulse that arises from the sudden acceleration of a charged particle, as we discussed in the first part of this chapter (**Figure 30.31**). The magnitude of the electric field in the kinked part of the pulse in Figure 30.31 is essentially uniform and much greater than it is anywhere else. We shall consider the propagation of this wave pulse through a region of space containing no matter and no charged particles, so we can use the form of the Maxwell equations derived in Example 30.7. At great distances from the particle, only the transverse pulse is significant and we can ignore any other contributions to the electric field. This wave pulse is essentially a slab-like region of space that extends infinitely in the x and y directions and has a finite thickness in the z direction. Inside the slab, the electric field is uniform and has magnitude E; outside the slab, $E = 0$. We let the wave pulse move along the z axis (**Figure 30.32**) and denote its speed by c_0 (the subscript 0

Figure 30.31 Electric field pattern of an accelerated charged particle. The kinks in the electric field pattern correspond to a transverse electric field pulse propagating away from the particle at speed c_0.



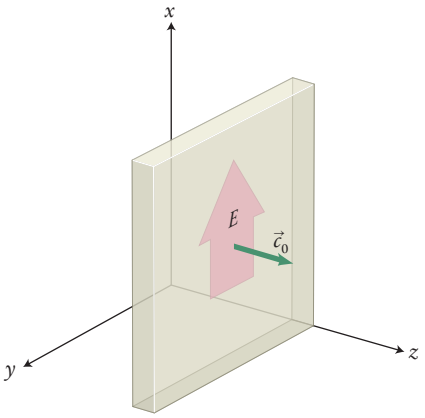


Figure 30.32 Perspective view of a planar electromagnetic wave pulse moving in the $+z$ direction. The electric field points in the $+x$ direction and has the same magnitude throughout an infinite plane parallel to the xy plane.

indicates that this speed is in vacuum). The magnitude of the electric field depends only on z, not on x and y. The wave pulse is an example of a **planar electromagnetic wave** because of the constant magnitude of the electric field in a plane normal to the direction of propagation.

What magnetic field pattern is associated with the electric field in the planar electromagnetic wave pulse in Figure 30.32? Viewing Figure 30.32 from the side (**Figure 30.33**), we see that the electric field is zero in front and in back of the pulse, nonzero and uniform inside the pulse, and changing at the front and back surfaces of the pulse. At the front surface, the electric field increases in the upward direction, corresponding to an upward displacement current I_{disp} (**Figure 30.34**). At the back surface of the pulse, the displacement current points down.

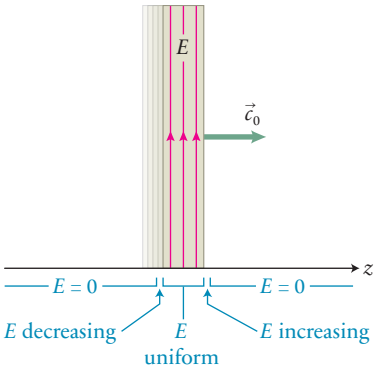
In Checkpoint 28.13*b*, you determined the magnetic field of two infinite planar sheets of oppositely directed current. The electric field in the planar electromagnetic wave pulse gives a similar arrangement of oppositely directed displacement currents. The magnetic field associated with this current distribution is uniform and points in the $+y$ direction (**Figure 30.35**). We now see that the planar electromagnetic wave pulse consists of uniform electric and magnetic fields that are perpendicular to each other and to the direction of propagation of the pulse, as we already concluded in Section 30.3. In fact, for a planar electromagnetic wave pulse, there is a right-hand relationship among the directions of $\vec{E}$, $\vec{B}$, and $\vec{c}_0$. If you curl the fingers of your right hand from the direction of $\vec{E}$ to the direction of $\vec{B}$, in Figure 30.35, your thumb points in the direction of propagation of the pulse. (This means that the vector product $\vec{E} \times \vec{B}$ yields a vector pointing in the direction of propagation of the electromagnetic wave pulse.)

To calculate the magnitude of the magnetic field in the planar electromagnetic wave pulse, we can use the version of Eq. 30.13 valid in a region of space that does not contain any charged particles (see Example 30.7):

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.14}$$

Let's begin by evaluating the left side of this equation. To exploit the fact that the magnetic field points in the $+y$ direction in the pulse, we choose the Ampèrian path in Figure 30.35. This rectangular path lies in the yz plane and has width ℓ in the y direction; side ad is inside the pulse and side fg is far off to the right in the positive z direction. We let the

Figure 30.33 Side view of the planar electromagnetic wave pulse of Figure 30.32. The electric field inside the pulse is uniform except at the front and back surfaces, where it drops rapidly to zero.



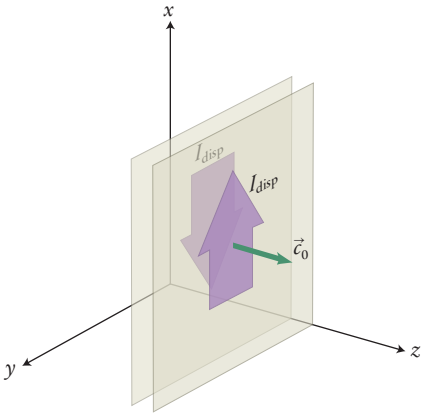


Figure 30.34 Displacement currents corresponding to the upwardly increasing electric field at the front surface and upwardly decreasing electric field at the back surface of the planar electromagnetic wave pulse of Figure 30.32.

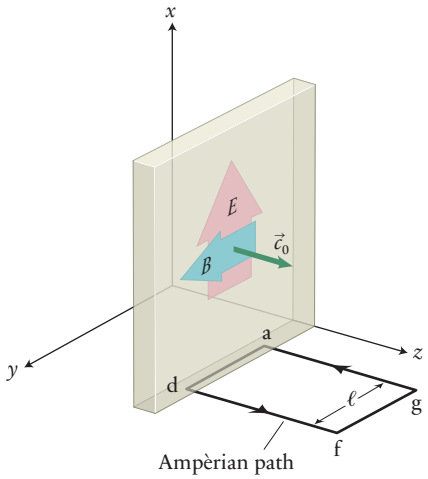

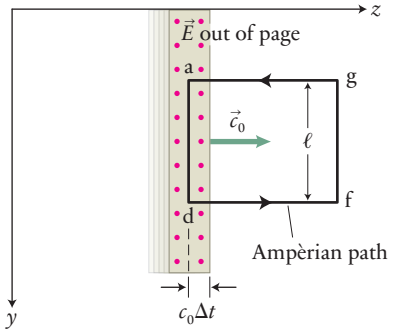

Figure 30.35 Magnetic field associated with the planar electromagnetic wave pulse of Figure 30.32. The Ampèrian path in the yz plane can be used to calculate the magnitude of the magnetic field.

direction of the path be such that it coincides with the direction of the magnetic field, so that $\vec{B} \cdot d\vec{\ell} = B\, d\ell$. Only side ad of the rectangular path contributes to the line integral; the magnetic field is zero around side fg, and the two long sides are perpendicular to the magnetic field. Thus, the left side of Eq. 30.14 becomes

$$\oint \vec{B} \cdot d\vec{\ell} = B\ell. \tag{30.15}$$

Figure 30.36 Top view of moving planar electromagnetic wave pulse of Figures 30.32–30.35, showing motion of the pulse through the Ampèrian path.

The electric flux through the path is given by $\Phi_E = \vec{E} \cdot \vec{A} = EA$, where $\vec{A}$ is a surface area vector pointing in the $+x$ direction, as dictated by the choice of direction of the integration path (Appendix B). To determine the rate of change of the electric flux through the path, note that the planar electromagnetic wave pulse is moving to the right with speed c_0. Before the front surface of the pulse reaches side ad of the Ampèrian path, the electric flux Φ_E through the path is zero. In a time interval Δt after the front surface of the pulse reaches side ad, the pulse travels a distance $c_0\Delta t$ into the rectangular path (**Figure 30.36**), and so at this instant the area over which the electric field is nonzero is $A = \ell c_0 \Delta t$. The electric flux through the path is then $\Phi_E = E\ell c_0 \Delta t$. The change in electric flux through the path during the interval Δt is thus

$$\Delta\Phi_E = E\ell c_0 \Delta t - 0, \tag{30.16}$$

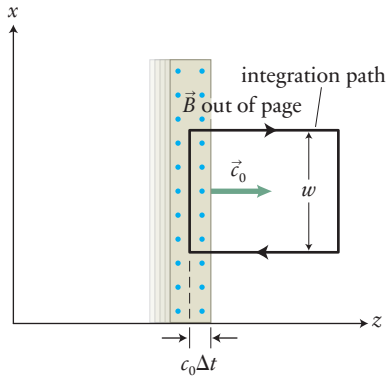
and the rate of change in electric flux is

$$\frac{\Delta\Phi_E}{\Delta t} = E\ell c_0. \tag{30.17}$$

Substituting Eqs. 30.15 and 30.17 into Eq. 30.14 yields

$$B\ell = \mu_0 \epsilon_0\, E\ell c_0 \tag{30.18}$$

or, solving for B,



$$B = \mu_0 \epsilon_0\, E c_0. \tag{30.19}$$

We have thus obtained a relationship between the magnitudes of the magnetic and electric fields in the planar electromagnetic wave pulse.

We can now use Faraday's law (Eq. 30.12) to obtain an additional relationship between these two transverse fields:

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt}. \tag{30.20}$$

Figure 30.37 Top view of the planar electromagnetic wave pulse of Figures 30.32–30.35, showing motion of the pulse through an integration path lying in the xz plane.

Let's begin by evaluating the left side of this equation. To exploit the fact that the electric field points in the $+x$ direction in the pulse, we choose the rectangular integration path in **Figure 30.37**. We let the direction of the path be such that it coincides with the direction of the electric field in the pulse, so that $\vec{E} \cdot d\vec{\ell} = E\, d\ell$. As in our derivation of the magnetic field, the only contribution to the line integral of the electric field around the rectangular path comes from the left side of the path:

$$\oint \vec{E} \cdot d\vec{\ell} = Ew. \tag{30.21}$$

To evaluate the right side of Eq. 30.20, we note that the geometry of this situation is the same as in our treatment of the electric pulse, except that now $\Phi_B = \vec{B} \cdot \vec{A} = -BA$, where $\vec{A}$ is a surface area vector pointing in

QUANTITATIVE TOOLS

the $-y$ direction, as dictated by the choice of direction of the integration path (see Appendix B). In analogy to Eqs. 30.16 and 30.17, the rate at which the magnetic flux through the path changes is then given by

$$\frac{\Delta\Phi_B}{\Delta t} = -Bwc_0. \tag{30.22}$$

Substituting Eqs. 30.21 and 30.22 into Eq. 30.20 gives us

$$Ew = Bwc_0 \tag{30.23}$$

or

$$B = \frac{E}{c_0}. \tag{30.24}$$

We now have two different relationships between the magnitudes of the electric and magnetic fields: Eq. 30.19 comes from Maxwell's generalization of Ampère's law, and Eq. 30.24 comes from Faraday's law. Setting the right sides of these two equations equal, we get

$$\frac{E}{c_0} = \mu_0\epsilon_0 Ec_0. \tag{30.25}$$

This result implies that the speed of the planar electromagnetic wave pulse is

$$c_0 = \frac{1}{\sqrt{\epsilon_0\mu_0}}. \tag{30.26}$$

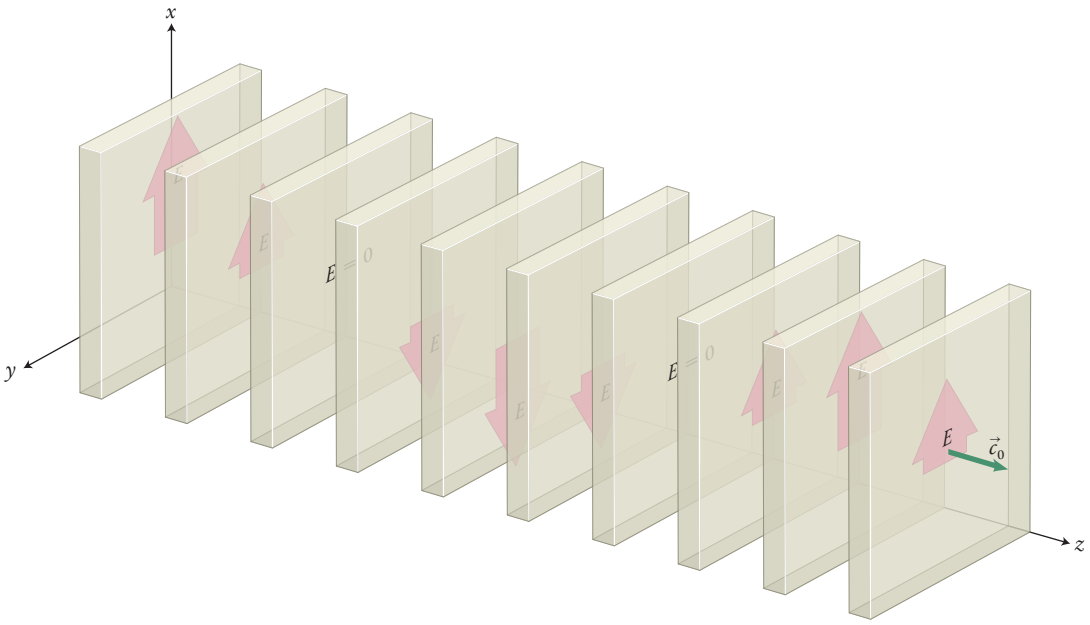
Equation 30.26 tells us something surprising: The speed of the planar electromagnetic wave pulse in vacuum is determined by two fundamental constants, ϵ_0 and μ_0. The first, ϵ_0, is introduced in Coulomb's law (see Eqs. 22.1 and 24.7). The second, μ_0, (see Eq. 28.1), is introduced in Ampère's law. In 1862, when Maxwell first worked out the relationship expressed in Eq. 30.26, no one knew that light and electromagnetic waves were related. To evaluate c_0 in Eq. 30.26, Maxwell used the results of experiments made with electric circuits and obtained a value of $c_0 = 3 \times 10^8$ m/s, in excellent agreement with values obtained for the speed of light in vacuum. This agreement led Maxwell to the remarkable conclusion that light is an electromagnetic wave.

Nowadays, the speed of light is set to be exactly 299,792,458 m/s (see Section 1.3) to define the meter. The value of μ_0 is set to be exactly $4\pi \times 10^{-7}$ T·m/A (see Section. 28.5). The value of $\epsilon_0 = 1/(c_0^2\mu_0)$ as given in Eq. 24.7 is therefore also fixed.

Most electromagnetic waves have a more complex shape than the planar electromagnetic wave pulse we have used to arrive at Eq. 30.26. Through the superposition principle (see Section 16.3), however, we can superpose any number of planar electromagnetic wave pulses to obtain whatever planar electromagnetic wave shape interests us. The central property of these electromagnetic waves does not depend on shape: The electromagnetic wave pulse consists of electric and magnetic fields that are perpendicular to each other and to the direction of propagation of the pulse. The ratio of the magnitudes of the electric and magnetic fields is always given by Eq. 30.24. The field vectors $\vec{E}$ and $\vec{B}$ are always perpendicular, and they always travel at speed c_0 in a direction given by the vector product $\vec{E} \times \vec{B}$.

Mathematically, it is more convenient to build arbitrary wave shapes out of harmonic (sinusoidal) waves than out of rectangular wave pulses.

Figure 30.38 Perspective view of the electric field of a sinusoidal planar electromagnetic wave propagating in the z direction. The electric field vectors are embedded in rectangular slabs to emphasize that the electric field has the same magnitude everywhere in the plane of the slab. The magnitude of the electric field does vary from plane to plane along the z axis. The magnetic field (not shown) is uniform on planes parallel to the xy plane.



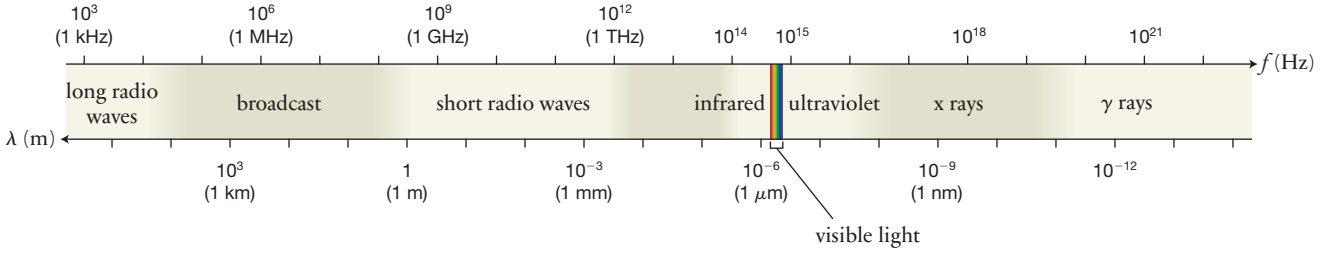


Figure 30.38 shows a planar electromagnetic wave for which the electric field varies sinusoidally in space. The field vectors for the electric field are shown embedded in rectangular slabs to emphasize that the electric field has the same magnitude everywhere throughout the plane of a slab, not just on the z axis. The magnitude of this electric field depends only on z, not on x and y.

As we saw in Chapter 16, harmonic waves are characterized by a propagation speed c, a frequency f, and a wavelength λ, and these quantities are related by $c = f\lambda$. The remarkable thing about electromagnetic waves is that waves of all frequencies travel at the same constant speed c_0 in vacuum. Consequently, in vacuum, frequency and wavelength are inversely proportional to one another over a vast range of values.

Figure 30.39 shows the classification of electromagnetic waves as a function of wavelength and frequency. Extending over a span of nearly 20 orders of magnitude, the figure shows electromagnetic waves ranging from radio waves to gamma rays. Only a very small part of this range corresponds to what we are familiar with as "light." Our eyes are most sensitive to wavelengths between 430 nm and 690 nm, though we can see light somewhat outside this wavelength range if the light is sufficiently intense. However, waves outside the visible range are governed by exactly the same physics as visible light.

QUANTITATIVE TOOLS

Figure 30.39 Classification of electromagnetic radiation as a function of frequency (top scale) and wavelength (bottom scale).

As we shall explore in more detail in Chapter 33, the frequency of an electromagnetic wave determines how the wave interacts with materials.

EXAMPLE 30.8 Speed of light in a dielectric

At what speed does an electromagnetic wave pulse propagate through a dielectric for which the dielectric constant is κ?

❶ **GETTING STARTED** In the presence of a dielectric, both Gauss's law and the displacement current are modified (Eq. 26.25 and Example 30.6, respectively). These changes affect the derivation I used to obtain the speed of electromagnetic waves in vacuum, Eq. 30.26.

❷ **DEVISE PLAN** The modification of the displacement current by the dielectric changes Eq. 30.14. To obtain an expression for the speed at which the electromagnetic wave pulse propagates, I carry the modified expression through the same logic I used to go from Eq. 30.14 to Eq. 30.26.

❸ **EXECUTE PLAN** Because there can be no conventional currents through a dielectric, I in Eq. 30.13 is still zero. Substituting the modified displacement current from Example 30.6, I get

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \kappa \frac{d\Phi_E}{dt}.$$

Carrying this expression through the logic leading from Eq. 30.14 to Eq. 30.19, I obtain the magnitude of the magnetic field in terms of the electric field:

$$B = \mu_0 \epsilon_0 \kappa \, Ec, \tag{1}$$

where the κ comes from the modification of the displacement current and where I have written c for the speed in the dielectric rather than c_0, our symbol for the speed in vacuum.

Because Faraday's law is unaffected by the presence of the dielectric, the only modification required in Eq. 30.24 is replacing c_0 with c. Solving Eq. 30.24 for E and substituting that expression for E into Eq. 1, I get

$$B = \mu_0 \epsilon_0 \kappa \, Bc^2,$$

so the speed of an electromagnetic wave pulse moving through a dielectric is

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0 \kappa}} = \frac{c_0}{\sqrt{\kappa}}, \checkmark$$

where I have used Eq. 30.26, $c_0 = 1/\sqrt{\epsilon_0 \mu_0}$, to simplify.

❹ **EVALUATE RESULT** Because $\kappa > 1$ for most dielectrics, my result indicates that the speed of electromagnetic waves (including light) in a dielectric is smaller than their speed in vacuum. The dielectric constant is a measure of the reduction of the electric field (Eq. 26.15, $\kappa = E_{\text{free}}/E$). For a material that completely attenuates the electric field so that $E = 0$—in other words, for a conductor—κ is infinite and so my result yields $c = 0$. This means that an electromagnetic wave cannot propagate in such a material, a conclusion that agrees with the familiar observation that a conductor, such as a slab of metal, does not transmit visible light.

30.14 An electromagnetic wave with a wavelength of 600 nm in vacuum enters a dielectric for which $\kappa = 1.30$. What are the frequency and wavelength of the wave inside the dielectric?

30.7 Electromagnetic energy

Because electric and magnetic fields contain energy, energy is transported as an electromagnetic wave travels away from its source. Let us work out how much energy is transported by a planar electromagnetic wave. In Section 26.6, we calculated the energy density contained in an electric field in vacuum (Eq. 26.6):

$$u_E = \tfrac{1}{2} \epsilon_0 E^2. \tag{30.27}$$

Similarly, the energy density in a magnetic field in vacuum is given by Eq. 29.29:

$$u_B = \frac{1}{2} \frac{B^2}{\mu_0}. \tag{30.28}$$

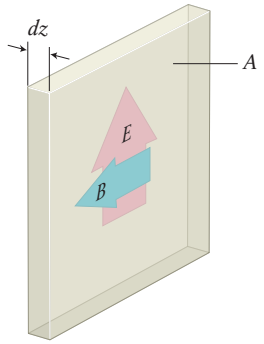
The energy density in a combined electric and magnetic field is therefore

$$u = \tfrac{1}{2} \epsilon_0 E^2 + \frac{1}{2} \frac{B^2}{\mu_0}. \tag{30.29}$$

Because the magnitudes of the electric and magnetic fields in an electromagnetic wave are related by Eq. 30.24, we can rewrite Eq. 30.29 in terms of just the magnitude of the electric field. Using Eqs. 30.24 and 30.26, we get

$$u = \tfrac{1}{2}\epsilon_0 E^2 + \tfrac{1}{2}\frac{E^2}{c_0^2\mu_0} = \tfrac{1}{2}\epsilon_0 E^2 + \tfrac{1}{2}\epsilon_0 E^2 = \epsilon_0 E^2. \tag{30.30}$$

Comparing Eqs. 30.29 and 30.30, we see that in vacuum the electric and magnetic fields each contribute half of the energy density—the electric and magnetic energy densities are equal.



Alternatively, the energy density can be written in terms of only the magnitude of the magnetic field,

$$u = \frac{B^2}{\mu_0}, \tag{30.31}$$

or in terms of the magnitudes of both the electric and the magnetic fields,

$$u = \sqrt{\frac{\epsilon_0}{\mu_0}}EB. \tag{30.32}$$

Figure 30.40 Perspective view of a slice of thickness dz of an electromagnetic wave, taken normal to the direction of propagation.

Let us now calculate the rate at which energy flows through a certain area in an electromagnetic wave. Consider taking a slice of an electromagnetic wave normal to the direction of propagation (**Figure 30.40**). The slice has thickness dz and area A. The energy dU in this slice is the product of the energy density and the volume of the slice:

$$dU = uA\,dz. \tag{30.33}$$

From Section 17.5, you know that the intensity S of a wave is defined as the energy flow per unit time (the power) across a unit area perpendicular to the direction of wave propagation.* Using Eq. 30.33, we can express this relationship in the form

$$S = \frac{1}{A}\frac{dU}{dt}. \tag{30.34}$$

To determine the intensity of an electromagnetic wave, we substitute the expression for dU from Eq. 30.33 and recall that the wave travels at speed $dz/dt = c_0$. We can then rewrite Eq. 30.34 as

$$S = \frac{1}{A}uA\frac{dz}{dt} = uc_0 \tag{30.35}$$

or, after substituting Eqs. 30.32 and 30.26,

$$S = \frac{1}{\mu_0}EB. \tag{30.36}$$

*In Chapter 17, we used I for intensity. That is fine in a discussion of mechanical waves, but now that we must deal with current I so frequently, we switch to the symbol S for intensity.

As the electromagnetic wave travels, energy travels with it in the direction of wave propagation. As we saw in Section 30.6, the propagation direction is the same as that of the vector product $\vec{E} \times \vec{B}$. So with Eq. 30.36 we can define a vector that fully describes energy flow in the electromagnetic wave:

$$\vec{S} \equiv \frac{1}{\mu_0} \vec{E} \times \vec{B}. \tag{30.37}$$

This vector $\vec{S}$ is called the **Poynting vector,** after J. H. Poynting (1852–1914), the physicist who first defined this vector. The SI units of the Poynting vector are W/m^2 (Checkpoint 30.16). The Poynting vector represents the flow of energy in any combined electric and magnetic field, not just electromagnetic waves (Checkpoint 30.15), and the direction of $\vec{S}$ is the direction of energy flow.

When we describe electromagnetic waves, the magnitude S of the Poynting vector is called the *intensity of the electromagnetic wave* and, as noted in Eq. 30.34, is the instantaneous electromagnetic power (energy per unit time) crossing a unit area. For electromagnetic waves, this area is perpendicular to the direction of the vector product $\vec{E} \times \vec{B}$. To obtain the power P crossing a surface, we integrate the Poynting vector over the surface:

$$P = \int_{\text{surface}} \vec{S} \cdot d\vec{A}. \tag{30.38}$$

The results of this section give expressions for the *instantaneous* values of electromagnetic energy density (Eqs. 30.30–32), intensity (Eq. 30.36), and power (Eq. 30.38). Often, however, it is useful to consider average values over some time interval. Because the average of the square of a sine function is 1/2 (see Appendix B), the average value of $\sin^2 \omega t$ is 1/2. So, although sinusoidally oscillating electric and magnetic fields average to zero, their squares average to 1/2 of the square of their amplitudes: $(E^2)_{\text{av}} = \frac{1}{2} E_{\text{max}}^2$. The square roots of these average values are often referred to as the *root-mean-square values*, or rms values (see Eq. 19.21), and are represented by E_{rms} and B_{rms}:

$$E_{\text{rms}} \equiv \sqrt{(E^2)_{\text{av}}} \quad \text{and} \quad B_{\text{rms}} \equiv \sqrt{(B^2)_{\text{av}}}. \tag{30.39}$$

For sinusoidal electromagnetic waves, energy density, intensity, and power are proportional to the squares of a sine function, and so the average values of these quantities are related to the rms values of the fields in the same manner that the instantaneous values of energy density, intensity, and power are related to the instantaneous values of the fields. For example, Eq. 30.36 yields

$$S_{\text{av}} = \frac{1}{\mu_0} E_{\text{rms}} B_{\text{rms}} \quad \text{(sinusoidal electromagnetic wave)}. \tag{30.40}$$

EXAMPLE 30.9 Tanning fields

The average intensity S of the Sun's radiation at Earth's surface is approximately $1.0\ kW/m^2$. Assuming sinusoidal electromagnetic waves, what are the root-mean-square values of the electric and magnetic fields?

❶ **GETTING STARTED** The electric and magnetic fields in an electromagnetic wave each contribute half of the energy density of the wave (Eq. 30.29). That energy density is related to the wave's Poynting vector $\vec{S}$, whose magnitude S is the intensity of an electromagnetic wave.

❷ **DEVISE PLAN** I can rewrite Eq. 30.35 to obtain the average energy density u_{av} in terms of the average intensity S_{av}. I can then use Eqs. 30.30 and 30.31 to relate the average energy density to the rms values of the electric and magnetic fields.

❸ **EXECUTE PLAN** From Eq. 30.35, I have

$$u_{\text{av}} = \frac{S_{\text{av}}}{c_0} = \frac{1.0 \times 10^3\ \text{W/m}^2}{3.0 \times 10^8\ \text{m/s}} = 3.3 \times 10^{-6}\ \text{J/m}^3.$$

(Continued)

QUANTITATIVE TOOLS

To obtain the value of E_{rms}, I express the relationship between u_{av} and E_{rms} by analogy to Eq. 30.30:

$$u_{av} = \epsilon_0 E_{rms}^2$$

$$E_{rms} = \sqrt{\frac{u_{av}}{\epsilon_0}} = \sqrt{\frac{3.3 \times 10^{-6}\ \text{J/m}^3}{8.85 \times 10^{-12}\ \text{C}^2/\text{N} \cdot \text{m}^2}}$$

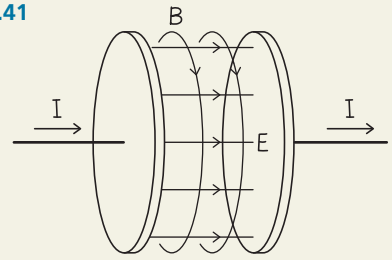
$$= 6.1 \times 10^2\ \text{V/m}, \checkmark$$

where I have used the fact that 1 N/C = 1 V/m.

For sinusoidal electromagnetic waves, the relationship between instantaneous values of the electric and magnetic field magnitudes holds for the rms values of the field magnitudes, so I can use Eq. 30.24 to determine the value of B_{rms}:

$$B_{rms} = \frac{E_{rms}}{c_0} = \frac{6.1 \times 10^2\ \text{N/C}}{3.0 \times 10^8\ \text{m/s}} = 2.0 \times 10^{-6}\ \text{T}. \checkmark$$

4 EVALUATE RESULT As I expect based on the large value of c_0, the value of B_{rms} in teslas is much smaller than that of E_{rms} in volts per meter. This electric field magnitude is also not large, particularly compared with the electric fields often obtained in capacitors. (Applying a potential difference of just 1 V to the capacitor in the next example would produce an electric field magnitude of 10,000 V/m!) However, this electric field is greater than the typical atmospheric electric field magnitude of roughly 100 V/m (which is due to charged particles in the atmosphere rather than to the Sun's radiation).



30.15 Consider supplying a constant current to a parallel-plate capacitor in which the plates are circular. While the capacitor is charging, what is the direction of the Poynting vector at points that lie on the cylindrical surface surrounding the space between the capacitor plates? What does this Poynting vector represent?

EXAMPLE 30.10 Capacitor power

A parallel-plate capacitor with circular plates of radius $R = 0.10$ m and separation distance $d = 0.10$ mm is charged by a constant current of 1.0 A. (*a*) What is the magnitude of the Poynting vector associated with the electric and magnetic fields at the edge of the space between the plates? (*b*) What is the rate at which electromagnetic energy is delivered to the cylindrical space between the plates?

1 GETTING STARTED While the capacitor is charging, the charge on the plates and consequently the electric field between them and the energy stored in the capacitor are changing with time. The changing electric field is accompanied by a magnetic field. The electric field between the plates is uniform, and the magnetic field lines form circular loops centered on the horizontal axis of the capacitor, in a direction given by the right-hand current rule. At each point in the space between the plates, the electric and magnetic fields are perpendicular to each other, as shown in my sketch in **Figure 30.41**.

Figure 30.41

2 DEVISE PLAN Because the electric and magnetic fields are perpendicular to each other, I can use Eq. 30.36 to calculate the magnitude of the Poynting vector. For this equation, I must know E and B. I calculated the magnitude of the electric field between two capacitor plates in Example 26.2, and from Checkpoint 30.11*a* I have an expression for the magnitude of the magnetic field between the plates.

To obtain the rate at which electromagnetic energy is delivered to the capacitor, I must integrate the Poynting vector over the cylindrical surface surrounding the space between the plates, as given in Eq. 30.38. From Checkpoint 30.15, I know that the Poynting vector points radially inward toward the capacitor axis, and I also know that at any given instant, the magnitudes of the electric and magnetic fields do not vary on the cylindrical surface surrounding the space between the plates. To integrate the Poynting vector over that surface, I therefore need to multiply the expression for the magnitude of the Poynting vector at any point on the surface by the area of the surface.

3 EXECUTE PLAN (*a*) From Example 26.2 I know that the electric field between the capacitor plates is $E = q/(\epsilon_0 A)$, where $A = \pi R^2$ is the area of each plate. Because a constant current is supplied to the capacitor while the capacitor is charging, $q = I\Delta t$ (Eq. 27.1, where Δt is the time interval that has elapsed since the capacitor began

charging), I can therefore rewrite my expression for E in the form

$$E = \frac{I\Delta t}{\epsilon_0 A} = \frac{I\Delta t}{\pi\epsilon_0 R^2}.$$

From the solution to Checkpoint 30.11*a* I have $B = \mu_0 Ir/2\pi R^2$, where r is the radial distance from the axis of the capacitor to the position where the magnetic field is measured and R is the radius of each plate. For this case, $r = R$, so

$$B = \frac{\mu_0 I}{2\pi R}.$$

To obtain the magnitude of the Poynting vector, I substitute the above values for E and B into Eq. 30.36:

$$S = \frac{EB}{\mu_0} = \frac{I^2\Delta t}{2\pi^2\epsilon_0 R^3}$$

$$= \frac{(1.0\text{ A})^2\Delta t}{2\pi^2[8.85\times10^{-12}\text{ C}^2/(\text{N}\cdot\text{m}^2)](0.10\text{ m})^3}$$

$$= [5.7\times10^{12}\text{ W}/(\text{m}^2\cdot\text{s})]\Delta t. \checkmark$$

(*b*) To calculate the rate at which electromagnetic energy is delivered to the cylindrical space between the capacitor plates, I multiply the expression for S by the area of the surface, which is the product of the circumference of the cylinder ($2\pi R$) and the height of the cylinder, which is the plate separation distance d:

$$P = 2\pi Rd\frac{I^2\Delta t}{2\pi^2\epsilon_0 R^3} = \frac{I^2 d\Delta t}{\pi\epsilon_0 R^2}$$

$$= \frac{(1.0\text{ A})^2(1.0\times10^{-4}\text{ m})\Delta t}{\pi[8.85\times10^{-12}\text{ C}^2/(\text{N}\cdot\text{m}^2)](0.10\text{ m})^2}$$

$$= (3.6\times10^8\text{ W/s})\Delta t. \checkmark$$

❹ **EVALUATE RESULT** I have no way of gauging the reasonableness of my numerical results, but I can check the reasonableness of my expression for the power (which incorporates my result for part *a*) by using an alternative method to obtain that expression. The rate at which energy is delivered to the capacitor is the power delivered to it by the current. I know from Eq. 26.2 that the electric potential energy of the capacitor changes by an amount $dU^E = V_{\text{cap}}\,dq$ during charging. To get the rate at which the amount of energy stored in the capacitor changes with time, I take the derivative

$$P \equiv \frac{dU_E}{dt} = V_{\text{cap}}\frac{dq}{dt} = V_{\text{cap}}I = \frac{qI}{C} = \frac{I^2\Delta t}{C}. \qquad (1)$$

For a parallel-plate capacitor, $C = \epsilon_0 A/d$, so with $A = \pi R^2$,

$$P = \frac{I^2 d\Delta t}{\epsilon_0\pi R^2},$$

which is the same result I obtained for part *b*.

30.16 Use Eq. 30.36 to show that the SI units of the Poynting vector are W/m^2.

Chapter Summary

Changing electric fields (Sections 30.1, 30.4)

Concepts A changing electric field is accompanied by a magnetic field, and a changing magnetic field is accompanied by an electric field.

Table 30.1 Properties of electric and magnetic fields

	Electric field	Magnetic field
associated with	charged particle	moving charged particle
	changing magnetic field	changing electric field
exerts force on	any charged particle	moving charged particle

Quantitative Tools The **displacement current** due to a changing electric flux through a surface is

$$I_{\text{disp}} \equiv \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.7}$$

The *Maxwell-Ampère law* is

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 (I_{\text{int}} + I_{\text{disp}}), \tag{30.8}$$

where I_{int} is the current intercepted by a surface spanning an Ampèrian path.

Maxwell's equations (Section 30.5)

Concepts **Maxwell's equations** provide a complete mathematical description of electric and magnetic phenomena and the relationship between the two.

Quantitative Tools **Maxwell's equations** are

$$\Phi_E \equiv \oint \vec{E} \cdot d\vec{A} = \frac{q_{\text{enc}}}{\epsilon_0} \tag{30.10}$$

$$\Phi_B \equiv \oint \vec{B} \cdot d\vec{A} = 0 \tag{30.11}$$

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt} \tag{30.12}$$

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I_{\text{int}} + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \tag{30.13}$$

Electromagnetic waves (Sections 30.2, 30.3, 30.6, 30.7)

Concepts An **electromagnetic wave** is a propagating disturbance in a combined electric and magnetic field. The electric and magnetic fields in these waves are perpendicular to each other, and the direction of wave propagation is the direction of $\vec{E} \times \vec{B}$.

A **planar electromagnetic wave** is one in which the wavefronts are planes perpendicular to the direction of propagation. At each point on a planar wavefront, the instantaneous magnitude of the electric field has the same value, as does the instantaneous magnitude of the magnetic field.

Oscillating dipoles and antennas to which an alternating potential is applied emit electromagnetic waves.

The **polarization** of an electromagnetic wave is the orientation of the electric field as seen by an observer looking in the direction of propagation.

Quantitative Tools The speed of an electromagnetic wave in vacuum is

$$c_0 = \frac{1}{\sqrt{\epsilon_0 \mu_0}}. \tag{30.26}$$

The speed of an electromagnetic wave in a dielectric of dielectric constant κ is

$$c = \frac{c_0}{\sqrt{\kappa}}.$$

The **Poynting vector** $\vec{S}$ gives the energy transported by an electromagnetic wave per unit time across a unit area perpendicular to the direction of propagation of the wave:

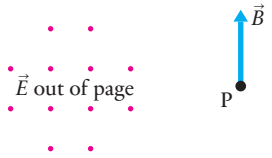
$$\vec{S} \equiv \frac{1}{\mu_0} \vec{E} \times \vec{B}. \tag{30.37}$$

The power transported by an electromagnetic wave crossing a surface is

$$P = \int_{\text{surface}} \vec{S} \cdot d\vec{A}. \tag{30.38}$$

Questions and Problems

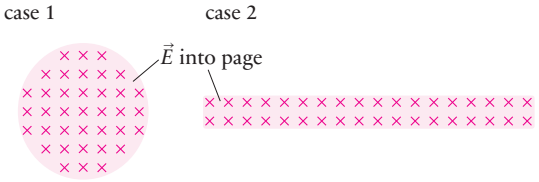
For instructor-assigned homework, go to Mastering Physics



Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

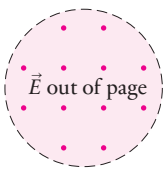
Unless directed otherwise, use $c_0 = 3.0 \times 10^8$ m/s for the speed of electromagnetic waves traveling in vacuum.

30.1 Magnetic fields accompany changing electric fields



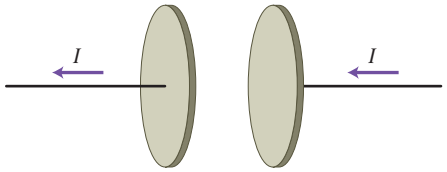
1. The magnitude of the electric field of Figure P30.1 is changing with time. As a result of this change, there is an upward-pointing magnetic field at position P. Is the electric field magnitude increasing or decreasing? •

Figure P30.1



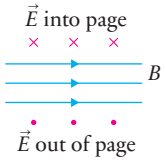
2. Figure P30.2 shows two electric fields, one in a region of circular cross-section and one in a long flat region. In both cases, the electric field decreases over time. What is the direction of the accompanying magnetic field in each case? •

Figure P30.2



3. A parallel-plate capacitor is charged until it carries charge $+q$ on one plate and charge $-q$ on the other plate. The capacitor is then disconnected from the power supply and isolated. What is the direction of the magnetic field that surrounds the charged capacitor? •
4. The uniform electric field shown in Figure P30.4 points out of the page and is contained in a cylindrical volume of space. If the electric field is rapidly turned off, a magnetic field is produced. (*a*) What is the direction of this magnetic field? (*b*) Does this magnetic field exist only in the volume where the electric field exists, only outside that volume, or both inside and outside that volume? ••

Figure P30.4



5. The capacitor of Figure P30.5 is being charged by a steady current I. What are the directions of (*a*) the electric field between the plates, (*b*) the change in the electric field, and (*c*) the magnetic field between the plates? ••

Figure P30.5

6. Figure P30.6 shows an increasing magnetic field and the electric field that accompanies it according to Faraday's law. If the magnetic field is increasing at an increasing rate, (*a*) is the electric field magnitude constant, increasing, or decreasing? (*b*) Does the behavior of the electric field produce an additional magnetic field? If so, what is the direction of the additional magnetic field? Does it reinforce or counteract the original magnetic field? ••

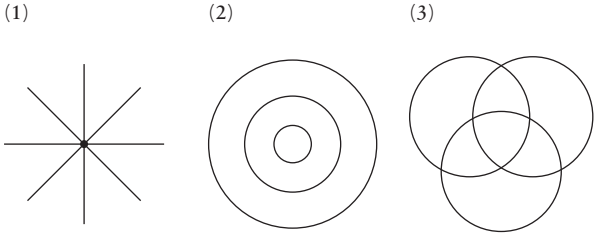


Figure P30.6

30.2 Fields of moving charged particles

7. Are the radiating electric field lines around a charged particle straight lines when the particle (*a*) is stationary, (*b*) moves at constant velocity, (*c*) accelerates? •
8. Which field line patterns in Figure P30.8 could represent (*a*) electric field lines and (*b*) magnetic field lines? •

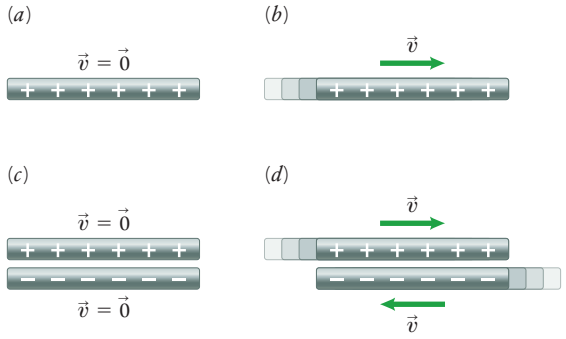

Figure P30.8

9. Would a charged particle moving at a high speed in a circle create kinks in its electric field? •
10. A positively charged particle moving to the right is stopped rapidly. Sketch the resultant radiated pulse. ••

11. Is any type of electric field produced when (*a*) a wire having zero surplus charge carries a constant current, (*b*) a wire having zero surplus charge carries a time-varying current, (*c*) a bar magnet moves translationally at constant velocity, (*d*) a bar magnet rotates about an axis that passes symmetrically through its poles? ●●
12. Is any magnetic field produced when (*a*) a uniformly charged sphere rotates at constant rotational speed about an axis that passes through its fixed center, (*b*) a charged particle moves translationally at constant velocity, (*c*) a charged particle that is moving translationally accelerates? ●●
13. Sketch the electric and magnetic field line patterns produced by the four situations shown in Figure P30.13: (*a*) a stationary charged rod carrying a linear charge density of $+\lambda$, (*b*) a charged rod carrying a linear charge density of $+\lambda$ that moves at constant velocity along the length of the rod, (*c*) a stationary charged rod carrying a linear charge density of $+\lambda$ that is infinitesimally close to a parallel stationary charged rod carrying a linear charge density of $-\lambda$, (*d*) a charged rod carrying a linear charge density of $+\lambda$ that moves at constant velocity along the length of the rod and is infinitesimally close to a parallel charged rod carrying a linear charge density of $-\lambda$ and moving in the opposite direction. ●●

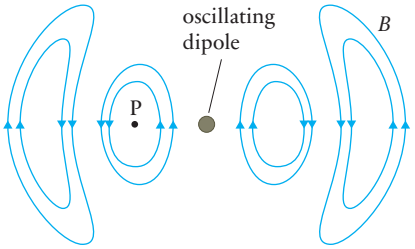

Figure P30.13

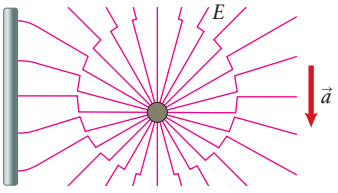
30.3 Oscillating dipoles and antennas



14. What antenna length should be used to create a dipole antenna that emits 100-MHz electromagnetic waves, a frequency typical of FM radio broadcasts? ●
15. An electromagnetic wave is traveling eastward. If at a given instant the magnetic field for one section of the wave points south, in which direction does the electric field for that section point at that instant? ●
16. An electric dipole with its center located at the origin of a Cartesian coordinate system oscillates along the x axis, creating an electromagnetic wave. At a position on the z axis far from the origin, (*a*) what is the polarization of the wave and (*b*) which axis are the magnetic field lines parallel to? ●●
17. Figure P30.17 shows a magnetic field line pattern radiating from an oscillating electric dipole. (*a*) What is the direction of the change, over the next infinitesimal time interval, in the magnetic field at P? (*b*) Use your answer to part *a* to determine the direction of the electric field loop around P. (*c*) Is the dipole oscillating right-left, up-down, or in-out of the page? ●●

Figure P30.17

18. A router used for wireless Internet access follows the 802.11g standard, which operates at 2.4 GHz. (*a*) What is the wavelength of the electromagnetic waves emitted by the router? (*b*) How tall would a dipole antenna need to be? Is this length comparable to the length of any router antennas you've seen? ●●
19. Why are radio transmission towers oriented vertically rather than laid horizontally on the ground? ●●
20. To detect an incoming planar electromagnetic wave, we observe a single charged particle that begins at rest and is free to move only in the xy plane. If we observe the particle oscillating along the y axis, with no motion along the x axis, what can we say about the direction of the electric and magnetic fields and the direction of wave propagation? ●●
21. In Figure P30.21, a charged particle has been suddenly accelerated downward, producing the electric field line pattern shown. When the kinks in the field lines reach the metal rod at the left, they produce a downward current in the rod. Is the particle that has been accelerated positively or negatively charged? ●●

Figure P30.21

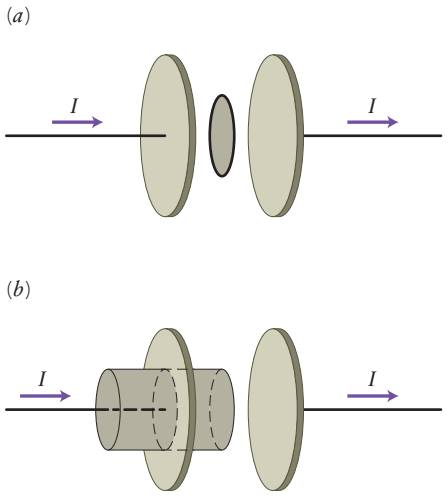
22. As we saw in Checkpoint 30.9, a receiving dipole antenna has to be aligned with the oscillating electric field in order to produce a measurable potential difference in the antenna. What if we wanted to detect the potential difference caused by the changing magnetic field? (*a*) What antenna shape would we need? (*b*) How would this antenna need to be oriented relative to the wave in order to maximize its ability to detect the wave? (*c*) Use Faraday's law to explain whether this antenna is a better detector for low-frequency waves or for high-frequency waves. ●●●

30.4 Displacement current

23. A parallel-plate capacitor with circular plates has a steady charging current of 3.0 A. The wires into and out of the plates attach to the plate centers. If the radius of each plate is 5 cm and there is no dielectric between the plates, what is the magnetic field magnitude inside the plates at a distance of (*a*) 2 cm and (*b*) 10 cm from the symmetry axis of the capacitor? •

24. A parallel-plate capacitor of capacitance 10 μF is being charged by a voltage source $V = V_0 \cos(\omega t)$. Suppose that $V_0 = 240$ V and $\omega = 50\ \text{s}^{-1}$. (*a*) What is the maximum displacement current through a cross-sectional area inside the capacitor that is half the area of each plate? (*b*) How would this area have to be oriented relative to the electric field to get this maximum displacement current? •

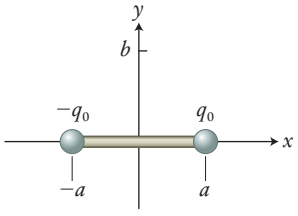
25. Instead of a capacitor in a circuit, we can get the same effect by slicing a thick wire in two, making our cut perpendicular to the wire's long axis. If the wire diameter is 5 mm and we place the two parallel circular surfaces of the cut wire 0.02 mm apart, what is the magnetic field magnitude at a position that lies between the two surfaces and is 1.0 mm from the long central axis of the wire at the instant the current in the wire is 1.5 A? Assume the charge carriers that create the current are uniformly distributed over the cross-sectional area of the wire. ••



26. A parallel-plate capacitor has a steady charging current of 4.0 A. What is (*a*) the time rate of change of the electric flux between the plates and (*b*) the displacement current between the plates? (*c*) How do your answers to parts (*a*) and (*b*) change if there is a dielectric for which $\kappa = 2.2$ between the plates? Assume the area of the plates is much greater than the separation distance between them. ••

27. A parallel-plate capacitor with circular plates of radius r is charging with constant current I. At some instant, $B = 1.6 \times 10^{-8}$ T at a position 7.0 mm from the center of a long wire leading to the capacitor. (*a*) Calculate the current magnitude at that instant. (*b*) Draw the current in one plate to show why you get the same value of B no matter where you place the surface bounded by your Ampèrian path. Draw the lengths of your current arrows to scale to show how the current magnitude does or does not change at various positions in the plate. ••

28. For a capacitor of capacitance C, show that the displacement current between the capacitor's plates is given by $C(dV/dt)$, where V is the potential difference across the capacitor. ••

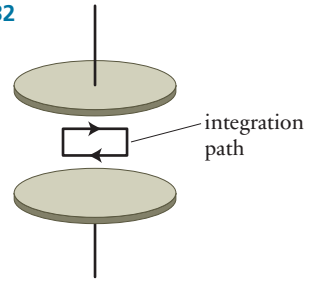


29. The circular plates of a parallel-plate capacitor have a radius of 30 mm. A steady 2.0-A current is charging the initially uncharged capacitor, and the surface charge on the plates is distributed uniformly. (*a*) Derive an expression for the magnitude of the electric field between the plates as a function of time. (*b*) In Figure P30.29*a*, the flat circular surface between the capacitor plates has a radius of 10 mm. What is the displacement current through this flat circular surface? (*c*) Consider the open surface shown in Figure P30.29*b*, a cylindrical shell open at the right end that passes through the left capacitor plate. If the radius of the flat circular end is 10 mm, what is the displacement current through the open shell? (*d*) Why is your answer to part *c* different from your answer to part *b*? Why are both these answers different from $I = 2.0$ A, the current through the capacitor? ••

Figure P30.29

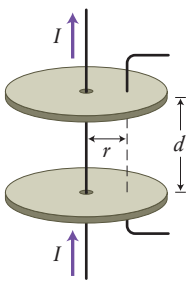
30. A short wire runs along an x axis from $x = a$ to $x = -a$ (Figure P30.30). At $t = 0$, there is a small sphere carrying charge $+q_0$ at $x = a$ and a small sphere carrying charge $-q_0$ at $x = -a$. As the spheres discharge and a current is established in the wire, show that, for $t > 0$, the generalized form of Ampère's law (Eq. 30.13) and the Biot-Savart law (Eq. 28.12) give the same result for the magnitude of the magnetic field a distance b up the y axis. (Hint: Obtain the electric flux through a circular disk in the yz plane, centered at the origin. Because the electric field is not constant over the surface of the disk, you must divide the disk into a nested set of rings of various radii and integrate. A representative ring should have radius r and radial extent dr.) •••

Figure P30.30



31. A parallel-plate capacitor has circular plates of radius $R = 15$ cm and plate separation distance $d = 1$ mm. While it is charging, the potential difference across the plates is given by $V(t) = V_0(1 - e^{-t/\tau})$ where $V_0 = 12$ V and $\tau = 4.0$ ms. What is the magnitude of the magnetic field between the plates at a distance $r = 5$ cm from the axis of the capacitor at $t = 2$ ms? •••

30.5 Maxwell's equations



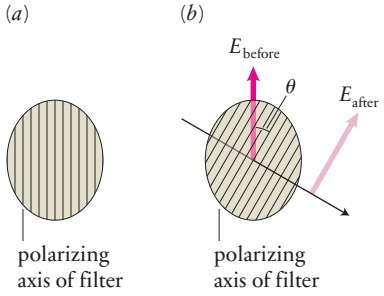
32. When you use Maxwell's equations to determine electric and magnetic fields, a lot depends on making the "right" choice for the integration path. What happens if you choose the "wrong" path? Do the equations still hold? Consider a parallel-plate capacitor with circular plates, but use a rectangular integration path that has two sides parallel to the plates and two sides perpendicular to them, as in Figure P30.32. What do you get? •

Figure P30.32

33. Using Eq. 30.11, show that the normal component of the magnetic field is continuous across any surface. ••
34. In free space, Maxwell's equations simplify greatly. The two equations involving surface integrals of the fields (Eqs. 30.10 and 30.11) are zero, and the two equations involving line integrals of the fields (Eqs. 30.12 and 30.13) have values proportional to the rate of flux change of the other field. Because the fluxes are surface integrals of the fields, why don't all four equations reduce to zero? ••
35. For a perfect conductor, $E = 0$ everywhere inside, and all the charge resides on the surface even when charge carriers are flowing. (*a*) Use Maxwell's equations to show that the magnetic field inside a conductor is constant. (*b*) Use Maxwell's equations to show that the magnetic flux through a perfect conducting loop is constant. (*c*) A superconductor is more than just a perfect conductor. It also has the property that $B = 0$ inside the superconductor. Use Maxwell's equations to show why the current in a superconductor is confined to the surface. •••
36. A physics teacher tries to build a device that illustrates Maxwell's generalization of Ampère's law. She drills a hole in the center of each plate of a parallel-plate capacitor and then runs a wire through the holes (Figure P30.36). There is no connection between the wire and the plates, and the potential difference across the plates can be controlled. Can the teacher adjust this potential difference so that there is no magnetic field at a distance r from the wire? In particular, what must be the rate of change of the potential difference if she wants no magnetic field at a distance $r = 20$ mm from the wire when it carries a steady current of 0.0200 A and the distance between the plates is $d = 3.0$ mm? •••

Figure P30.36

30.6 Electromagnetic waves



37. The frequency of AM radio channels is typically on the order of 10^5 Hz or 10^6 Hz. What is the wavelength of these waves? FM waves have wavelengths between 1.0 m and 10 m. What is the frequency of these waves? •
38. The speed of light drops to 2.26×10^8 m/s in water. What is the dielectric constant of water? •
39. The optical fibers used for telecommunications links have dielectric constant $\kappa = 1.6$. How long does a signal originating in California take to reach New York in a fiber-optic cable? •
40. A phone call you make from the United States to Germany is routed via a satellite that is in a geostationary orbit at an altitude of 36,000 km. How long is the time interval between the instant you say "Hello" to the instant your greeting arrives in Germany? Ignore the distance between the United States and Germany. •
41. The antenna of a WiFi access point has a length of about 80 mm. What does this say about the likely frequency of the wireless network? •
42. (*a*) At a distance from an emitting antenna where the electric field has a maximum magnitude of 15 V/m when the air is dry, what is the maximum magnetic field magnitude? (*b*) How does the value of E_{max} change when the air is very damp, increasing the dielectric constant of the air? (*c*) How does the value of B_{max} change in the damp air? Assume that the antenna's potential difference is unaffected by the damp air. ••
43. Using electromagnetic waves, you generally cannot resolve any structures that are smaller than the wavelength you are using. CD, DVD, and Blu-ray players use small "pits" that encode the 0s and 1s of the digital information stored on them—the smaller the pits, the more information you can store. A DVD can store 4.7 GB, and a Blu-ray can store 25 GB. If a DVD player typically uses lasers that emit red light in the wavelength range from 640 nm to 660 nm, what do you expect the wavelength and color of a Blu-ray laser to be? ••
44. The light produced by a sodium vapor lamp has a wavelength of 589.3 nm in vacuum. What is its wavelength after it enters a sheet of glass with dielectric constant $\kappa = 4.8$? ••
45. *3K cosmic background radiation* is energy left over from events that occurred when the universe was in a very early stage of development. Given that the amount of energy associated with any radiation is linearly proportional to the radiation frequency and that the energy associated with a 10^6-Hz radio wave is 6.6×10^{-28} J, what is the frequency of the cosmic background radiation? Assume that the energy of this radiation can be approximated as $k_B T$, where $T = 3.0$ K (thus the name given to this radiation). ••
46. If the electric field in an electromagnetic wave 5 cm from a radio-emitting antenna has a maximum magnitude of 3.0×10^5 V/m, what is the maximum magnetic field magnitude 1 km from the antenna? ••

30.7 Electromagnetic energy

47. An electromagnetic wave has an average Poynting vector magnitude of 4×10^{-7} W/m^2. What is the maximum value of the magnitude of the electric field? •

48. An electromagnetic wave has root-mean-square magnetic field magnitude $B_{rms} = 5\ \mu T$. What is the root-mean-square electric field magnitude and the average intensity of the wave? •
49. The power of a laser is much smaller than the power of an incandescent light bulb, but the laser light does not spread out very much. Explain why this tendency not to spread has such an effect over long distances. •
50. A 2.0-mW laser has a beam radius of 0.5 mm. What is the intensity of this beam? •
51. The intensity of the HERCULES laser, one of the world's most powerful, is $2.0 \times 10^{20}\ W/mm^2$. Granted, the beam pulse lasts for only 30 fs, but if we assume the beam is an electromagnetic pulse, what is its average energy density, and what energy can one pulse deliver to a 1.0-μm^2 target? ••
52. Radio signals typically have a very small intensity. Imagine that a vehicle receives an average signal of 20 $\mu W/m^2$. (*a*) What are the maximum magnitudes of the electric and magnetic fields? (*b*) If the tower emitting the radio waves is located 10 km away from the vehicle, how powerful is the emitting antenna? ••
53. For a constant current of 2 A, what time interval is required to deliver 0.5 MW of power to the space between the plates of a capacitor if the plates are circular and parallel, their diameter is 10 cm, and their separation distance is 1 mm? ••
54. Assume a 40-W incandescent light bulb radiates uniformly in all directions. At a distance of 1 m from the bulb, determine (*a*) the intensity of the electromagnetic waves, (*b*) the maximum electric field magnitude, and (*c*) the maximum magnetic field magnitude. ••
55. The emitting antenna of a 50-kW radio station radiates equally in all directions. What are the magnitudes E_{max} and B_{max} (*a*) 200 m from the antenna and (*b*) 20 km from the antenna? (*c*) For these two distances from the antenna, calculate the maximum potential difference caused between the ends of a receiving antenna that is 0.5 m long, assuming the antenna is aligned perfectly with the electric field of the radio wave. ••
56. A laser beam has a radius of 1 mm. How powerful does the laser have to be for the maximum magnitude of the magnetic field in the beam to be 4 μT? ••
57. Sunlight on Earth has an intensity of about $S = 1.0\ kW/m^2$. How much power can be harvested from a solar energy panel that is 2.0 m long and 1.6 m wide if the sunlight comes in at an angle of $\theta = 20°$ with respect to the surface normal vector of the panel and the panel is 20% efficient? ••
58. You want to use your microwave oven to heat 0.20 L of water from room temperature to boiling. The water is in a cup that has a radius of 30 mm, and you want the water to reach its boiling point in 3.00 min. What are the required (*a*) average power, (*b*) average intensity, and (*c*) root-mean-square electric field of the microwaves? Assume all the microwaves come in from the top and are completely absorbed by the water. ••
59. The human eye can detect light intensities as small as $S_{min} = 10^{-12}\ W/m^2$. If an incandescent 100-W light bulb is about 10% efficient, how far away could you see it under the simplest assumptions? Does your result make sense? ••
60. Similar to perceived loudness in hearing, the brightness the human eye and brain perceive for light is logarithmic rather than linear. For example, you do not perceive light that has an intensity of S as being twice as bright as light of intensity $S/2$. What happens to the perceived brightness of a light bulb if you double the distance from it? ••
61. A radio wave, with a wavelength of 300 m in vacuum, has an average intensity of 200 W/m^2. (*a*) What is the frequency of this electromagnetic wave (you may need to review material in Chapter 16)? (*b*) Fix a reference frame with the z axis along the direction of propagation of the wave. What is the Poynting vector of the wave as a function of position and time? (*c*) What is the time-averaged energy per unit time radiated through a 2.0-m^2 surface aligned with its normal parallel to the direction of propagation? (*d*) What are the electric and magnetic field vectors, as functions of position and time? •••
62. A cylindrical solenoid of radius R and height h consists of N windings. There is a current through the windings, and this current increases with time as $I = \alpha t$, where α is a constant. (*a*) Describe the directions of the electric field, the magnetic field, and the Poynting vector. (*b*) Determine the magnitude of the Poynting vector at a radial distance $r = R$ from the center of the long center axis of the solenoid. (*c*) Use the result of part *b* to derive an expression for the power input to the solenoid as a function of time. (*d*) Using the formula for the inductance of an ideal solenoid, calculate the power from the rate of change of the stored magnetic energy. Does this answer agree with your answer in part *c*? •••
63. A polarizing filter is a plastic sheet that allows only certain components of the electric field in an electromagnetic wave to pass through, and a wave that has passed through such a filter is said to be *polarized*. After an initially unpolarized wave has passed through the filter shown in Figure P30.63*a*, for instance, the wave's electric field contains only the vertical components of all the electric field vectors present before the wave passed through. Because the horizontal components have been blocked, the wave has lost half of its initial intensity. If this polarized wave then passes through the filter of Figure P30.63*b*, where the filter-polarizing direction is at an angle θ to the direction of the vertically polarized wave, the wave loses more of its intensity. If the polarized wave has an intensity $S_{before} = 200\ W/m^2$ before passing through the filter of Figure P30.63*b* and $\theta = 20.0°$, what is the intensity after the wave passes through? •••

Figure P30.63

Additional Problems

64. Liquid argon has a dielectric constant of 1.5. What is the speed of an electromagnetic wave pulse through this medium? •
65. What would be the length of a half-wave antenna for a radio station that emits its signal at 90.5 MHz? •
66. Full-body scanners at airports are sometimes referred to as *millimeter-wave scanners* and sometimes as *terahertz scanners*. Does this make sense? •
67. A home microwave oven typically uses 2.45-GHz microwaves, and a microwave oven in a restaurant kitchen is more likely to run at 915 MHz. Calculate the wavelength for each frequency and the length of the emitting antenna needed in each case. •
68. A sinusoidal electromagnetic wave has a maximum electric field magnitude of $E_{max} = 500$ N/C. What is the root-mean-square value of the electric field? •
69. By focusing an ultraviolet laser pulse, you can produce an apparently hovering plasma point in midair. If it takes an electric field magnitude of 1.0×10^6 N/C to ionize air, what must the intensity of the pulse be? ••
70. For a particular electromagnetic wave, B_{rms} is 0.30×10^{-6} T. For this wave, calculate (*a*) E_{rms} , (*b*) the average energy density, and (*c*) the intensity. ••
71. A 500-W industrial carbon dioxide cutting laser is capable of cutting 3.0-mm thick steel at a rate of 20 mm/s. Carbon dioxide lasers operate at a wavelength of 10.6 μm. If the spot size of the cutting laser is 0.17 mm in diameter and the intensity is uniform in this spot, what are the magnitudes of the Poynting vector, the rms magnetic field, and the rms electric field for this laser? ••
72. A radio station sends out its signal via a 20-kW emitting antenna. Assuming the signal is emitted equally in all directions and no signal strength is lost, how much power per unit area remains in the signal at a location 10 km from the emitting antenna? ••
73. It takes sunlight about 8 min to travel from the Sun to Earth, where it has an average intensity of 1400 W/m^2. If it takes 44 min for light to travel from the Sun to Jupiter, what is the sunlight intensity there? ••
74. The intensity of sunlight striking Earth's upper atmosphere is approximately 1.35×10^3 W/m^2. (*a*) Calculate E_{max} and B_{max} at this location. (*b*) Given that Earth is 1.5×10^{11} m from the Sun, what is the power output of the Sun? (*c*) If all the sunlight that strikes the upper atmosphere reached Earth's surface, how many watts of power would reach Earth's surface? (Hint: The Earth–Sun distance is so great that you can assume all the sunlight is perpendicular to the cross section of Earth.) ••
75. At a distance of 50 mm (about the distance from your ear to the center of your brain), the 824.6-MHz microwave radiation from a cell phone has an intensity of 35 W/m^2. The maximum permissible radiation leaking from a microwave oven at the same distance is 10 W/m^2. It occurs to you that you could estimate the average magnetic fields generated by the two devices. You also know that people concerned about the possible effects of cell phone radiation on the brain often use a Bluetooth headset, which has an intensity of 0.080 W/m^2 at a distance of 50 mm. But in this case the cell phone itself is probably near your waist—on a belt or in a pocket or purse. There must be an improvement in intensities and field magnitudes at the center of the brain or people would not do this. While contemplating these things, you realize that there may also be a concern that the wavelength of cell phone radiation is comparable to the size of the skull. ••• CR
76. Some people are concerned about "electromagnetic smog" and install meshes on their windows to absorb electromagnetic waves. A particular product advertises "50-dB attenuation in the range from 10 MHz to 3 GHz," with attenuation defined as

$$\text{attenuation (dB)} = 10 \log\left(\frac{\text{input intensity}}{\text{output intensity}}\right).$$

The meshes (sometimes called *Faraday cages* or *Faraday meshes*) generally work if the diameter of the holes is smaller than the wavelength of the radiation. You naturally wonder what this means in terms of reductions in the wave intensity and field strengths. However, it is also curious that the manufacturer advertises a frequency range, so you begin to think about the maximum mesh diameter allowed and whether a minimum is required. ••• CR

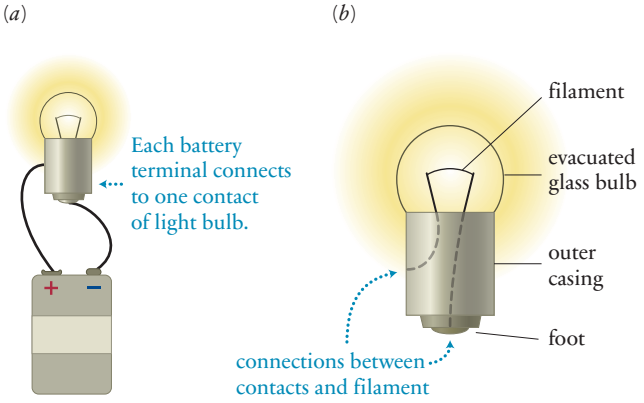
CONCEPTS

QUANTITATIVE TOOLS

Electric circuits surround us. We light our work and living spaces, start our cars, communicate with each other, and cook our food with electric circuits. Almost everything that consumes energy in our offices and homes is powered by electricity, whether by batteries or by the electric circuitry of the building.



Electrical devices are ubiquitous because electric circuits offer an extremely versatile means of producing and distributing electrical energy for a variety of tasks. Circuits are designed to control the flow of charge carriers—the current—in a device. The current then provides energy to the device, allowing it to perform its function.

In this chapter we explore the basic principles of electric circuits powered by sources of electric potential energy that maintain a constant potential difference, such as batteries. Such circuits are known as *direct-current circuits* or *DC circuits*. In the next chapter, we'll learn about *alternating-current* (*AC*) circuits, which run on time-varying potential differences, such as the electricity delivered to buildings by means of electrical power lines.

31.1 The basic circuit

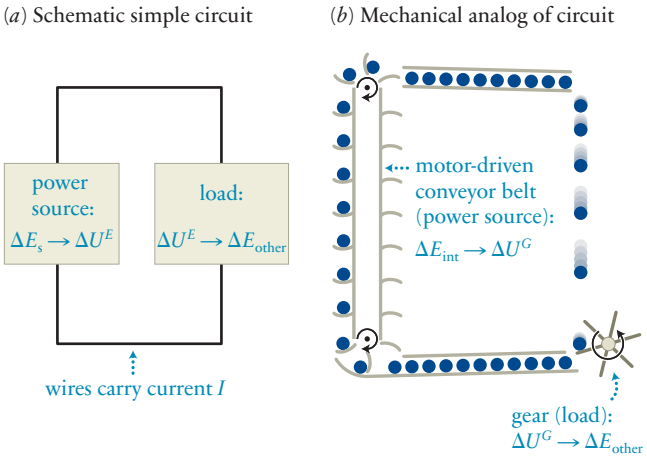
One familiar way to make electricity do something useful is to connect a battery to a light bulb. To do so, we connect each terminal of the battery to one of the two contacts on the light bulb (**Figure 31.1*a***). On incandescent light bulbs (discussed throughout this chapter), the two contacts are the threaded metal casing and a metallic "foot" that is separated from the casing by an insulator (Figure 31.1*b*). Inside the bulb, each contact is connected by a metal wire to one end of a tungsten *filament*, a very thin wire of tungsten wound in a tight coil. When connected as shown in Figure 31.1, the wires, contacts, and filament form a continuous conducting path from one terminal to the other, and charge carriers flow through the filament. The current in the filament causes the filament to become white hot and glow. (Tungsten is used for light bulb filaments because its very high melting temperature allows it to glow and not melt.)

Figure 31.1 A light bulb connected to a battery.

Experiments with light bulbs show that:

1. A bulb doesn't glow—not even briefly—if only one contact is connected to a battery terminal.
2. In order for a bulb to glow, both contacts must be connected through a continuous conducting path to the terminals of a battery. If the path is broken, the bulb goes out. It doesn't matter where in the path the break occurs.
3. A glowing light bulb generates light and thermal energy.
4. The wires connecting a light bulb to a battery usually do not get hot.
5. A light bulb left connected to a battery over a long time interval eventually goes out because the battery runs down. Once this happens, not enough chemical energy remains in the battery to maintain a large enough potential difference to light the bulb.

In the rest of this chapter we explore the reasons for these observations. The first two observations can be summarized as follows: In order for the light bulb to glow, one of the bulb's contacts must be connected to the positive terminal of the battery and the bulb's other contact must be connected to the negative terminal of the battery. Because the battery maintains a potential difference between its terminals, charge carriers move from one terminal toward the other when a conducting path is provided between the terminals.



The arrangement shown in Figure 31.1 is an example of an **electric circuit**—an interconnection of electrical components (called *circuit elements*). Any closed conducting path through the circuit is called a **loop.** We shall first study electric circuits that have a single loop.

CONCEPTS

31.1 (*a*) Consider the system comprising the single-loop circuit shown in Figure 31.1*a*, including the light and thermal energy generated by the bulb. (*a*) Is this system closed? (*b*) Is the energy of the system constant? (*c*) Where do the light energy and the thermal energy come from?

Checkpoint 31.1 demonstrates an important feature of circuits: Energy is converted from electric potential energy to some other form. With this in mind, we can draw a general single-loop circuit (**Figure 31.2*a***) consisting of a power source, a load, and wires that connect the load to the source. The **power source** provides electric potential energy to the rest of the circuit, usually by converting some form of energy to electric potential energy. The potential difference across the terminals of the power source drives a current in the circuit. The **load** in an electric circuit is all the circuit elements connected to the power source. In the load, the electric potential energy of the moving charge carriers is converted to other forms of energy, such as thermal or mechanical

Figure 31.2 The energy conversions in a single-loop circuit and in a mechanical analog of the circuit.

energy. The wires connecting the elements in a circuit are considered to be ideal; that is, the wires serve to transport electric potential energy to the load, and we ignore the small amount of energy dissipated in the wires.

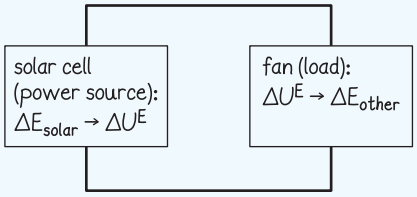
Figure 31.2*b* shows a mechanical analog of a single-loop electric circuit. The motor-driven conveyor belt is analogous to the power source in the electric circuit. The conveyor belt lifts the balls, converting source energy to gravitational potential energy. The balls then roll through a horizontal tube, losing only a tiny amount of gravitational potential energy in the process, in the same manner that charge carriers flow with very little loss of energy through wires. Next, the balls drop from the tube onto the gear, which corresponds to the load of an electric circuit. As the balls fall and make the gear turn, their gravitational potential energy is converted to mechanical energy. Finally, the balls roll down a second tube to the bottom of the conveyor belt, completing the cycle.

Notice two things about the mechanical circuit of Figure 31.2*b*. First, because the system is filled with balls, the balls have to move through the circuit one after the other. If the right end of the upper tube were blocked rather than open (the equivalent of the connecting wire in Figure 31.2*a* being disconnected from the load), no more balls could be pushed into it from the conveyor belt. There has to be a closed path through the system in order for the balls to move, just as charge carriers can flow through a circuit only when there is an unbroken conducting path.

The second thing to notice in Figure 31.2*b* is that there is no net transport of balls from the power source to the load. There are as many balls traveling from the power source to the load as the other way around. The balls travel around a closed path through the system, and if we watched one particular ball long enough, we would see it circle repeatedly around the circuit. The balls are simply vehicles transporting energy through the system.

We can therefore propose an operational description of a single-loop DC circuit in terms of energy conversion:

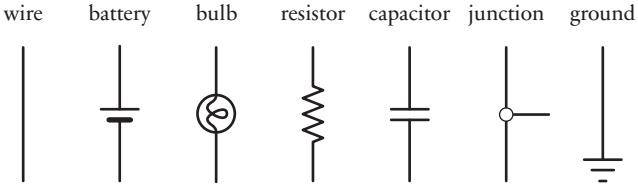
> **In a single-loop DC circuit, electric potential energy acquired by the carriers in the power source is converted to another form of energy in the load.**



The power source in such an electric circuit doesn't have to be a battery—it can be anything that produces a constant potential difference, thereby driving a current around the circuit, such as a solar cell or an electric generator. Likewise, the load doesn't have to be a light bulb. A toaster acting as a circuit load converts electric potential energy to thermal energy, a loudspeaker acting as a load converts electric potential energy to mechanical energy in sound waves, and a motor load converts electric potential energy to mechanical energy.

EXERCISE 31.1 Solar fan

A solar cell, which converts solar energy (a form of source energy, see Section 7.4) to electric potential energy, is connected to a small fan. Represent this circuit by a diagram analogous to Figure 31.2*a* and describe the energy conversions taking place in this circuit.



SOLUTION The solar cell is the power source, and the fan is the load. **Figure 31.3** shows my diagram for this circuit. The solar cell converts solar energy to electric potential energy, and the fan converts electric potential energy to another form of energy by setting the air in motion. I add these conversions to my diagram. ✔

Figure 31.3

The various parts of electric circuits are commonly represented by graphical symbols rather than by such words as *power source* and *load*. **Figure 31.4** shows the symbols for some common circuit elements. In

Figure 31.4 Standard representations of common elements of electric circuits.

CONCEPTS

Figure 31.5 Circuit diagram of bulb-and-battery circuit of Figure 31.1.

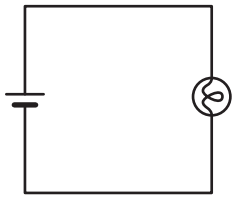


Figure 31.5 these symbols are used to represent the bulb-and-battery circuit of Figure 31.1. Note that in the battery symbol the short, heavy line represents the negative terminal and the longer, thin line represents the positive terminal. A schematic representation of a circuit using the standard symbols shown in Figure 31.4 is called a **circuit diagram.**

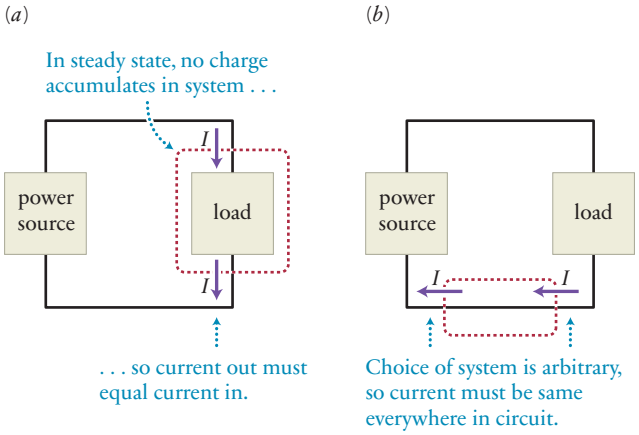
31.2 Two wires connect the plates of a charged capacitor to the contacts of a light bulb. (*a*) Does this assembly constitute a circuit? If so, identify the power source and the load. (*b*) Does the bulb glow? (*c*) What energy conversions take place after the bulb and capacitor are connected?

31.2 Current and resistance

Why does the filament of a light bulb get hot and glow, but the wires connecting the bulb to the battery do not? And why does the battery run out of energy and the bulb eventually stop glowing? To answer these questions, we need to look at the motion of charge carriers through an electric circuit.



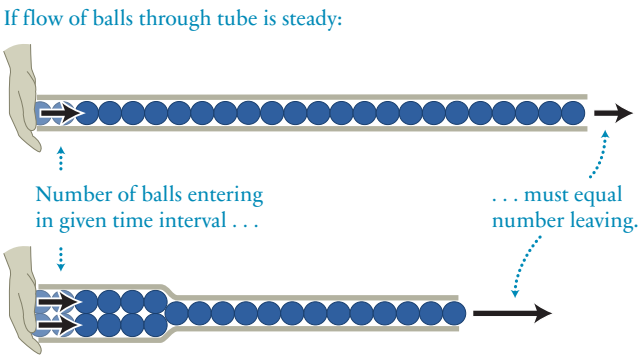
31.3 Suppose you connect a light bulb to a battery. How do you expect the current in the bulb to vary over the course of (*a*) a minute, (*b*) a few days?

CONCEPTS

Experiments show that as long as the power source in a circuit like the one in Figure 31.1 maintains a constant potential difference across its terminals, the current remains constant. Given that a battery connected to a bulb can maintain a constant potential difference for hours, the current in a circuit like the one in Figure 31.1 is constant over that same time interval. This current is established almost instantaneously after the circuit is completed (that is, after all the circuit elements are connected together), and it vanishes almost instantaneously when the circuit is broken. Other than the instants after the circuit is completed or broken, therefore, we have a **steady state** with constant current.

As we found in Section 25.3, positively charged particles tend to move toward regions of lower potential and negatively charged particles tends to move toward regions of higher potential. Indeed, this is why charge carriers flow through a closed circuit. For metal conductors, the mobile charge carriers are electrons; when a metallic conducting path is provided, electrons flow from the negative terminal of the power source to the positive terminal. In materials in which the mobile charge carriers are positively charged, the carriers travel in the opposite direction—from the positive terminal of the power source to the negative terminal. The rate at which the charges on the carriers cross a section in the conductor is the current, and the sign of the carriers and the direction of their motion determine the direction of the current (see Sections 27.3 and 27.5). Remember, however, that for a given potential difference between two points, the current direction is from points of higher potential to points of lower potential regardless of the sign of the mobile charge carriers (see Section 27.3).

Figure 31.6 Because charge is conserved, in steady state it doesn't accumulate in the load or in any other part of the circuit. Hence, in steady state the current into any part of the circuit must be the same as the current out of that part.



In steady state we can draw an important conclusion regarding currents in circuits. Consider, for example, the system comprising just the load in the circuit shown in **Figure 31.6*a***. Because charge is conserved (see Section 22.3), the amount of charge inside this system can only change due to a flow of charge into or out of the system. In steady state the charge of the system is constant, and so the flow of charge carriers into the system must be equal to the flow of charge carriers out of it. Put differently, the current into the system must equal the current out of the system.

Because we can choose any system we like—as in Figure 31.6*b*, for example—we conclude:

> **In a steady state, the current is the same at all locations along a single-loop electric circuit.**

We shall refer to this requirement as the **current continuity principle.** **Figure 31.7** illustrates the principle for balls flowing through a tube. Because the tube is filled, if the flow of balls through the tube is steady, there is nowhere for the balls to pile up without changing the rate of flow. As a result, when one ball is pushed into the left end of the tube, one ball must come out at the right end. Likewise, if two balls are pushed into the left end at the same instant, two must come out at the right end.

Figure 31.7 The continuity principle.

The current continuity principle tells us something else about the operation of circuits: As electrons flow through a light bulb, they are not accumulating, or "used up," in the bulb. For every electron that goes into one end of the filament, one electron comes out the other end. What then is consumed (used up) by the bulb as it glows? In our discussion of the mechanical circuit of Figure 31.2*b*, we found that the balls moving through the circuit are not consumed anywhere. Instead, they act to transfer energy from the power source to the load. Before we examine the energy of the electrons in the electric circuit of Figure 31.2*a*, answer the next checkpoint.

31.4 Does an electron lose or gain electric potential energy (*a*) while moving inside a battery from the positive terminal to the negative terminal and (*b*) while moving through the rest of the circuit from the negative battery terminal to the positive terminal? (*c*) While flowing through the wire and load portions of the circuit, where do the electrons lose most of their energy?

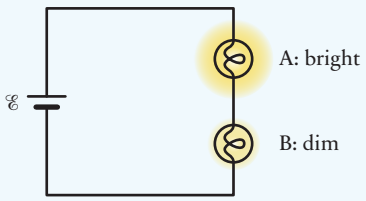
As we saw in Section 26.4, *inside* a battery, chemical energy is converted to electric potential energy, and electrons at the negative terminal have greater potential energy than those at the positive terminal. In the rest of a circuit, electrons lose that same amount of electric potential energy as they move from the negative terminal through the load to the positive terminal, and that energy is converted to other forms of energy.

For a charged particle moving between two locations through the load, the difference in potential energy from one location to the other is equal to the potential difference between those two locations multiplied by the charge of the particle. Therefore, for each electron that moves through the load of a circuit, an amount of electric potential energy eV_{load} is converted to some other form of energy (light, say, or thermal energy, or mechanical energy), where V_{load} is the magnitude of the potential difference across the load.*

*When the subscript of potential refers to a device or circuit element (say, V_{device}), the symbol is taken to denote the *magnitude* of the potential difference across the device or circuit element.

Thus, changes in the potential difference in an electric circuit show us where energy conversion is taking place. Experiments indicate that V_{load} is essentially equal to V_{batt}, while V_{wire} is negligible. In other words, essentially all of the energy conversion in the circuit takes place in the load and the source, and almost none takes place in the wires.

Because we can ignore the energy dissipation that takes place in the wires:



Every point on any given wire is essentially at the same potential.

Therefore we can consider the load in a circuit to be connected directly to the battery if the two are connected to each other through wires.

EXAMPLE 31.2 Current and potential difference

In **Figure 31.8**, two light bulbs are connected to each other by a wire and the combination is connected to a battery. In steady state, bulb A glows brightly and bulb B glows dimly. If the magnitude of the potential difference across the battery terminals is 9 V, what can you say about the magnitude of the potential difference across A?

Figure 31.8 Example 31.2.

1 GETTING STARTED The battery and light bulbs constitute a circuit in steady state. The electrons in this circuit gain electric potential energy inside the battery, and this electric potential energy is converted to light (a form of energy) and thermal energy in the bulbs. I assume that the ratio of light to thermal energy is the same in the two bulbs. Because bulb A glows more brightly than bulb B, bulb A must convert more electric potential energy than bulb B.

2 DEVISE PLAN Because this circuit is in steady state, I know that the current is the same throughout the circuit, and therefore during any given time interval, the same number of electrons pass through both bulbs. For each electron that moves through the load of the circuit, an amount of electric potential energy eV_{load} is converted to light and thermal energy. Therefore the magnitude of the potential difference across each bulb is proportional to the amount of electric potential energy converted to light and thermal energy.

3 EXECUTE PLAN The fact that A glows more brightly than B tells me that A is producing more light and thermal energy. Bulb A must therefore be converting more electric potential energy to these other forms, and the electrons must be losing more energy in A than in B. Because the electrons lose more energy in A than in B, the magnitude of

(Continued)

CONCEPTS

the potential difference across A, V_A, must be greater than the magnitude of the potential difference across B, V_B. Because $V_A > V_B$ and because $V_A + V_B$ must equal V_{batt}, it must be true that V_A is more than half of V_{batt}, which means $9.0\ V > V_A > 4.5\ V$. ✔

4 EVALUATE RESULT It makes sense that the bulb that has the greater potential difference across it glows more brightly.

Example 31.2 illustrates an important point: The magnitudes of the potential difference across various circuit elements in an electric circuit need not be the same, even if the current in them is the same.

The two light bulbs in Figure 31.8 are said to be connected *in series:* There is only a single current path through them, and the charge carriers flow first through one and then through the other. As we have seen in Example 31.2:

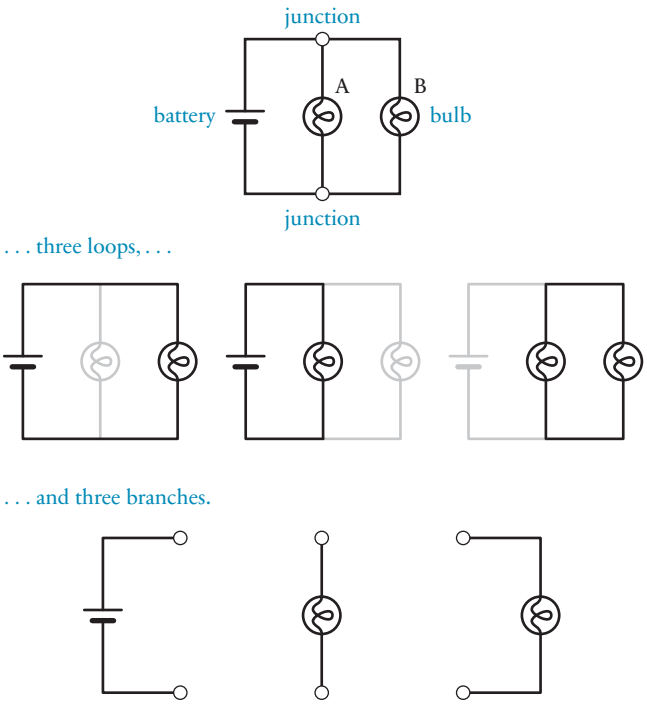
The potential difference across circuit elements connected in series is equal to the sum of the individual potential differences across each circuit element.

Experiments show that to obtain a particular current in a circuit element, different elements require widely different potential differences. As noted in passing in Section 29.5, for a given circuit element, the constant of proportionality between the potential difference across the element and the current in it is called the **resistance** of the circuit element:

The resistance of any element in an electric circuit is a measure of the potential difference across that element for a given current in it.

The greater the potential difference required to obtain a certain current in a circuit element, the greater the element's resistance.

The resistance of a particular circuit element depends on the material of which it is made, its dimensions, and its temperature. The resistance of a combination of circuit elements connected in series is equal to the sum of the individual resistances of each element. Therefore, the more light bulbs we connect in series to a battery, the greater the resistance of the combination of light bulbs and the smaller the resulting current in the circuit.



CONCEPTS

31.5 (*a*) Which light bulb in Example 31.2 has the greater resistance? (*b*) Suppose you connect each bulb separately to the battery. Do you expect the current in bulb A to be greater than, equal to, or smaller than that in bulb B?

31.3 Junctions and multiple loops

Circuit elements can also be connected so that more than one conducting path is formed, as illustrated in Figure 31.9. Such circuits contain more than one loop and are called *multiloop circuits*. These circuits contain

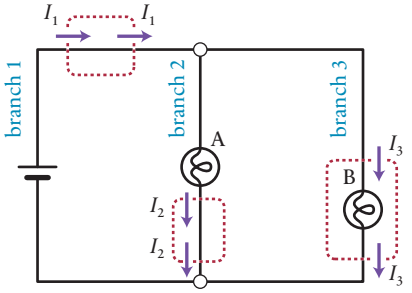
Figure 31.9 Circuit diagram of two light bulbs connected to a battery.

junctions—locations where more than two wires are connected together—and **branches**—conducting paths between two junctions that are not intercepted by another junction. The circuit in Figure 31.9, for example, contains two junctions (represented by open circles), three branches, and three loops.

The continuity principle permits us to draw some important conclusions about the currents in multiloop circuits. Let us begin by applying the current continuity principle to the circuit shown in Figure 31.10. Because we can select any system boundary along a branch, the current continuity principle requires the current to be the same throughout that branch. We can apply the same reasoning to the other two branches, so:

The current in each branch of a multiloop circuit is the same throughout that branch.

Figure 31.10 The branch rule: In each branch, the current must be the same throughout that branch.



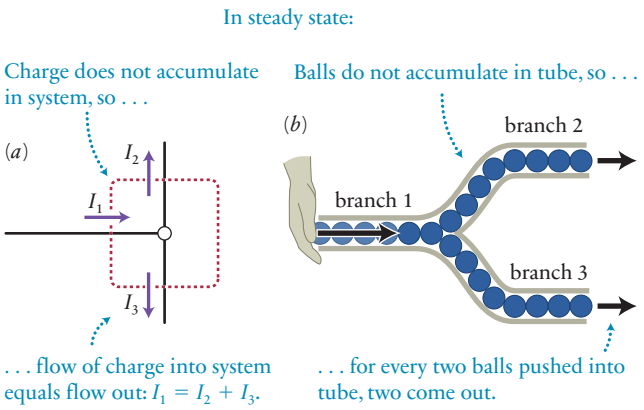


Figure 31.11 The continuity principle at a junction is illustrated by the flow of balls through a branched tube.

This statement is known as the **branch rule.** We shall label the current in each branch according to the branch. In Figure 31.10, for example, the currents in the three branches are I_1, I_2, and I_3.

To examine how charge carriers flow at a junction, we draw a system boundary around a junction, as in **Figure 31.11a**. Because the charge inside the system is not changing and because charge is conserved, it follows that the flow of charge carriers into the system must be equal to the flow of charge carriers out of the system. Specifically, if a current I_1 goes into the junction and the other two wires carry currents I_2 and I_3 out of the junction, then $I_2 + I_3$ must equal I_1. The general statement of this principle is known as the **junction rule:**

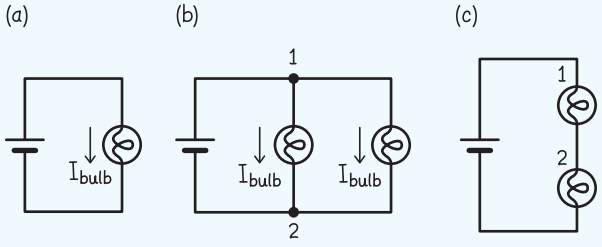
> **The sum of the currents directed into a junction equals the sum of the currents directed out of the same junction.**

Figure 31.11*b* illustrates this principle for balls flowing through a junction of tubes. If we push four balls in at one end of branch 1, four balls have to come out from branches 2 and 3 combined. In the junction shown in the figure, branch 2 and branch 3 are equivalent and two balls are likely to come out from each. In general, however, the branches do not need to be equivalent, and in that case the number of balls going into branch 1 must be equal to the sum of the balls coming out of branches 2 and 3. Because the pushing in and the coming out occur during the same time interval, the "current" of balls through branch 1 equals the sum of the currents in branches 2 and 3, which is what we concluded for the currents in Figure 31.11*a*.

Let us return now to the circuit in Figure 31.9. Because the two bulbs are each connected to the same two junctions, they are said to be connected *in parallel* across the battery. Because each junction is at a given potential, we can conclude that for parallel circuit elements:

> **The potential differences across circuit elements connected in parallel are always equal.**

More specifically, for the circuit shown in Figure 31.9, the potential difference across the two light bulbs is equal to the emf of the battery.



In the next example we study the resistance of parallel combinations of circuit elements.

EXAMPLE 31.3 Series versus parallel

Two identical light bulbs can be connected in parallel or in series to a battery to form a closed circuit. How do the magnitudes of the potential differences across each bulb and the current in the battery compare with those in a single-bulb circuit when the bulbs in the two-bulb circuit are connected in parallel? When they are connected in series?

❶ **GETTING STARTED** I begin by drawing circuit diagrams for the single-bulb circuit and for the parallel and series two-bulb circuits (**Figure 31.12**). To connect the bulbs in parallel to the battery, one contact of each bulb is connected directly to the positive terminal of the battery, and the other contact of each bulb is connected directly to the negative terminal of the battery. For the series circuit, one contact of bulb 1 is connected directly to the positive terminal of the battery, the other contact of bulb 1 is connected to one contact of bulb 2, and the other contact of bulb 2 is connected directly to the negative terminal of the battery.

Figure 31.12

❷ **DEVISE PLAN** To determine the magnitude of the potential difference across each bulb, I need to analyze how the bulbs are connected to the battery. To determine the current in the battery, I must first determine the current through each bulb. To determine the current in each bulb, I use the fact that the resistance and potential difference determine the amount of current in each bulb. I can use the junction rule to determine the currents in the parallel circuit, and so I label the junctions 1 and 2 in Figure 31.12*b*. Because there is only one branch in the series circuit, I know that the current in the battery is the same as the current in the bulbs. Because the bulbs are identical, their resistances are identical too. I assume the wires have no resistance.

❸ **EXECUTE PLAN** Because in the parallel circuit one contact of each bulb is connected to the battery's positive terminal and the other contact of each bulb is connected to the negative terminal, the potential difference across each bulb is equal to the potential difference across the battery. By the same argument, the potential difference across the bulb in the single-bulb circuit is also equal to the potential difference across the battery. Therefore the potential

(Continued)

CONCEPTS

difference across each bulb in the parallel circuit is the same as that across the bulb in the single-bulb circuit. ✔

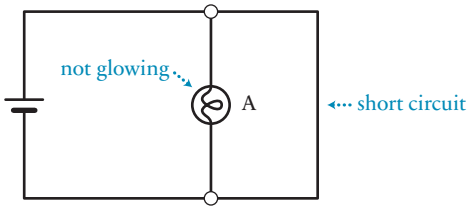
Because the potential difference is the same across these three bulbs, the current must also be the same in all three bulbs. I'll denote this current by I_{bulb}. In the parallel circuit, the fact that the current in each bulb is I_{bulb} means that the current in the battery must be $2I_{bulb}$. (The current pathway at junction 1 of Figure 31.12*b* is just like the pathway shown in Figure 31.11, with $I_2 = I_3 = I_{bulb}$.) In the single-bulb circuit, the current must be the same at all locations in the circuit, so the current in the battery must be I_{bulb}. ✔

In the series circuit, the potential difference across the two-bulb combination is equal to the potential difference across the battery, which means the magnitude of the potential difference across each bulb must be half the magnitude of the potential difference across the battery. The potential difference across each bulb is thus equal to half the potential difference across the bulb in the single-bulb circuit. ✔

Because the potential difference across each bulb in series is half the potential difference across the battery, the current in each bulb must be half the current in the single-bulb circuit, $I_{bulb}/2$. Because the series circuit in Figure 31.12*c* is a single-loop circuit, the current is the same at all locations. Therefore the current in the battery must also be $I_{bulb}/2$. The current in the battery in the single-bulb circuit is therefore twice that in the series two-bulb circuit. ✔

In tabular form my results are

	Parallel	Series	Single
V_{bulb}	V_{batt}	$V_{batt}/2$	V_{batt}
I_{batt}	$2I_{bulb}$	$I_{bulb}/2$	I_{bulb}



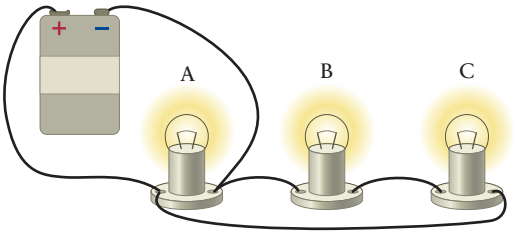
4 EVALUATE RESULT The current in the battery in the parallel circuit is therefore four times that in the series circuit. That makes sense because in the parallel circuit each bulb glows identically to the bulb in the single-bulb circuit, while in the series circuit, the battery has to "push" the charge carriers through twice as much resistance. Therefore it makes sense that in the series circuit, both the potential difference across each bulb and the current in the battery are much smaller than they are in the parallel circuit.

CONCEPTS

31.6 In Figure 31.9, treat the parallel combination of two light bulbs as a single circuit element. Is the resistance of this element greater than, equal to, or smaller than the resistance of either bulb?

Checkpoint 31.6 highlights an important point about electric circuits: Adding circuit elements in parallel *lowers* the combined resistance and *increases* the current. How can adding elements with a certain resistance lower the combined resistance? The resolution to this apparent contradiction is that adding elements in parallel really amounts to adding paths through which charge carriers can flow, rather than adding resistance to existing paths in the circuit. If you are emptying the water out of a swimming pool, it empties faster if you have multiple hoses draining the water than if you drain the entire pool through a single hose.

Figure 31.13 A wire that is connected to a battery *in parallel* to a light bulb constitutes a short circuit.



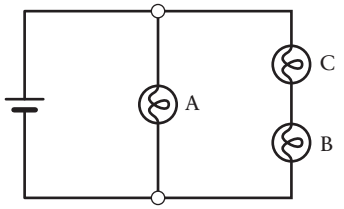
Instead of connecting two light bulbs in parallel as in Figure 31.9, what if we connected a wire in parallel with a bulb as in **Figure 31.13**? Experimentally, we find that replacing bulb B of Figure 31.9 with a wire causes bulb A to stop glowing. Why does this happen? The potential difference across a branch is determined by the potential difference between the two junctions on either end of the branch, and therefore the potential difference across all branches between two junctions must be the same. Because the wire is made from a conducting material, the potential difference between its two ends is zero, and therefore the two junctions in Figure 31.13 are at the same potential. Consequently there is no current in the light bulb.

That doesn't mean there is no current in the circuit. As we'll discuss in more detail in Section 31.4, because of the wire's very small resistance, there is a very large current in the wire. Therefore, if the wire is left connected to the battery as in Figure 31.13, the battery quickly discharges through the wire and the wire heats up. A circuit branch with negligible resistance in parallel with an element is commonly called either a **short** or a **short circuit.**

The circuits in Figures 31.8, 31.10, and 31.12 are all drawn neatly with the circuit elements on a rectangular grid. Real circuits are rarely so neatly laid out, of course, and typically look more like the one shown in **Figure 31.14**. It takes time and concentration to look at the tangle of wires in Figure 31.14 and figure out whether or not the bulbs light up (they do) and identify the path taken by the charge carriers through the circuit.

To analyze such a circuit, therefore, it is helpful to draw a circuit diagram, with elements and wires arranged

Figure 31.14 Real circuits don't always look like circuit diagrams.



horizontally and vertically. The circuit diagram must accurately show the connections between elements that are present in the actual circuit, but wires that are not connected to each other should, as far as possible, be drawn so that they do not cross.

To draw a circuit diagram for the circuit in Figure 31.14, we begin by identifying the junctions and the branches connecting the junctions. Note that the two terminals of bulb A are connected to two wires each. Because the terminals of the bulb are also connected to each other via the filament inside the bulb, each of these terminals is a junction. There are three branches. One branch consists of the battery and the wires that connect the left and right contacts of light bulb A. The second branch connects the left contact of light bulb A through the filament to the right contact of light bulb A. The third branch connects the right contact of light bulb A through light bulbs B and C to the left contact of light bulb A. **Figure 31.15** shows a circuit diagram for the circuit in Figure 31.14. Junctions are marked by open circles. The battery and light bulbs have been replaced by the symbols introduced in Figure 31.4. The connecting wires between the circuit elements have been straightened out and replaced by lines.

It is not important that the branch of the circuit containing bulb A appears to the left of the branch containing bulbs B and C. The two-bulb branch could be shown to the left of the branch containing bulb A, and the diagram would still be correct. It is also not important that the branch that contains the battery is shown at the left. There is always more than one way to draw a circuit diagram for any given circuit; any diagram that correctly represents the connections between elements in the circuit is valid.

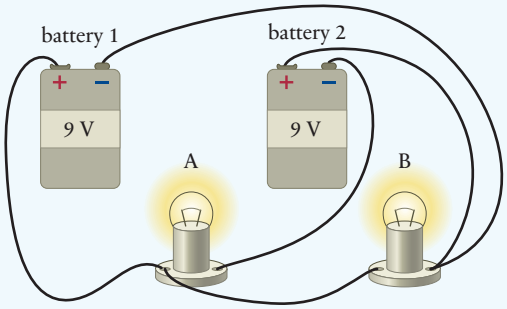


Figure 31.15 Circuit diagram for the circuit of Figure 31.14.

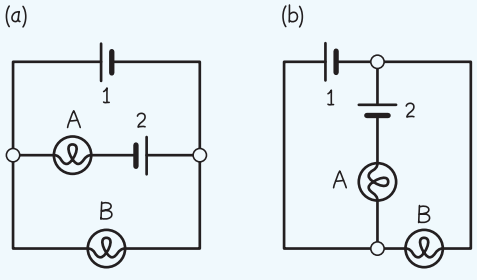
EXERCISE 31.4 Bulbs and batteries

Draw a circuit diagram for the arrangement shown in **Figure 31.16**.

Figure 31.16 Exercise 31.4.



SOLUTION I begin by identifying the junctions and branches. I identify two junctions: one is the left terminal of bulb A and the other is the right terminal of bulb B. I can trace out three branches going from the left terminal of bulb A to the right terminal of bulb B. One branch includes battery 1. The second branch includes bulb A and battery 2, and the third branch includes just bulb B.

I begin by drawing the two junctions. Then I connect these two junctions by each of the three branches, making sure to get the directions of the batteries correct—positive terminal of battery 1 connected to the left terminals of bulbs A and B, and negative terminal of battery 1 connected to the positive terminal of battery 2 and bulb B. This yields the diagram shown in **Figure 31.17*a***.

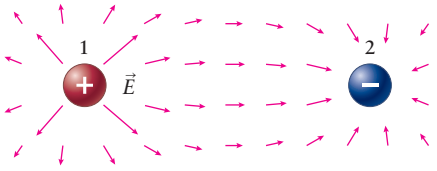
Note that the diagram I drew is not unique. Had I chosen to draw one junction above the other, I might have obtained the diagram shown in Figure 31.17*b*. By comparing the two diagrams, I see that by sliding battery 1 in Figure 31.17*b* to the leftmost vertical branch, sliding bulb B to the rightmost branch, and then rotating the diagram 90° clockwise, I obtain the diagram shown in Figure 31.17*a*.

Figure 31.17

31.7 If each battery in Figure 31.16 has an emf of 9 V, what is the magnitude of the potential difference across (*a*) bulb A and (*b*) bulb B? (*c*) If the two bulbs are identical, which one glows more brightly?

CONCEPTS

31.4 Electric fields in conductors



In Section 24.5 we found that the electric field is zero inside a conducting object in electrostatic equilibrium. A conductor through which charge carriers flow is *not* in electrostatic equilibrium, however. (Remember, *electrostatic* means that the arrangement of charged particles is fixed.) To keep charge carriers flowing through a conductor, we need an electric field inside it.

Let us examine more closely the electric field in current-carrying conductors. Consider connecting the two charged spheres of **Figure 31.18*a*** with a metal rod that is much thinner than the radius of the spheres. Charge carriers can now flow from one sphere to the other along this rod (Figure 31.18*b*). For simplicity, we assume that a power source (not shown in the figure) keeps the charge on each sphere and the potential difference between the two constant.

Initially, the electric field along the axis of the rod points from the positive sphere to the negative sphere. However, the electric field is stronger near the spheres, at A and C in Figure 31.18*b*, than in the middle, at B. Consequently, the charge carriers at A and C get pushed along horizontally more strongly than in the middle, causing positive charge carriers to accumulate between A and B and negative carriers to accumulate between B and C. This accumulation changes the electric field in the rod. For example, as charge carriers accumulate between A and B, the flow of carriers at A is reduced and that at B is enhanced. The carriers stop accumulating when the electric field is the same throughout the rod (Figure 31.18*c*). Thus, any unevenness in the electric field causes charge to accumulate, and the accumulation, in turn, affects the electric field. This feedback continues until the electric field is uniform and points along the conductor everywhere. In practice, this evening out takes place in an extremely short time interval (10^{-9} s).

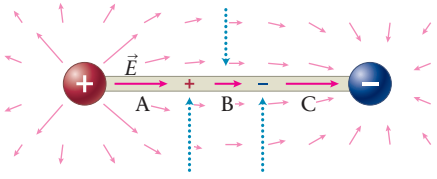


Figure 31.18 The source of the electric field in a current-carrying conductor. (For simplicity, we assume that the charge on each sphere is kept constant by an unseen power source.)

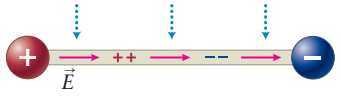
(*a*) Electric field around a pair of charged spheres

(*b*) Just after spheres are joined by conducting rod

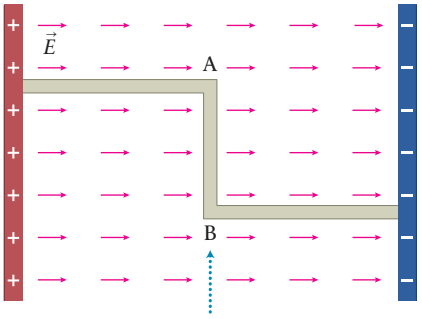


Electric field in rod is smallest in middle (at B).

Unequal electric field in rod causes charge to accumulate.

(*c*) Steady state

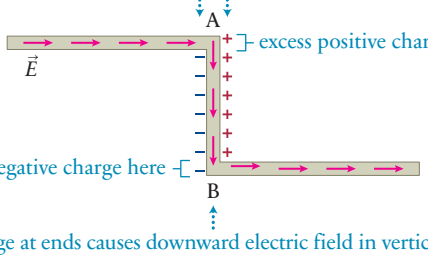
Accumulation continues until field is equal throughout rod.



31.8 Suppose the distance between the spheres in Figure 31.18 is ℓ and the potential difference between them is V_{12}. What is the magnitude of the electric field inside the connecting rod?

What is the electric field in a bent conductor, as opposed to the straight conductor of Figure 31.18? Consider the conductor connecting the charged plates in **Figure 31.19*a***. When the plates are first connected to each other via a long thin conductor, the only electric field present is that of the plates, and this field pushes electrons everywhere to the left. Because of this, electrons pile up on the left surface of vertical segment AB of the conductors, leaving behind positive ions on the right side (Figure 31.19*b*). The surface of the conductor

Figure 31.19 Electric field in a bent conductor that connects two charged plates.



(*a*) Just after charged plates are joined by bent conductor

Electric field of capacitor pushes electrons in vertical segment to left.

(*b*) Steady state

Electric field causes charge to accumulate on surfaces of vertical segment.

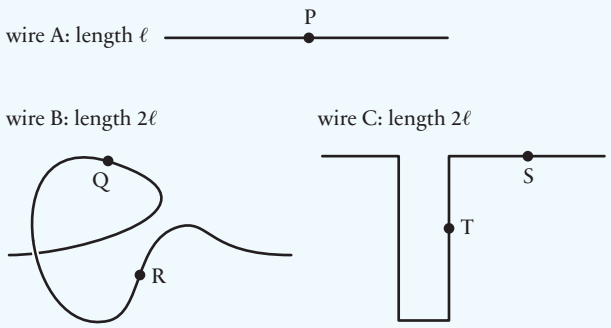
Excess charge at ends causes downward electric field in vertical segment.

CONCEPTS

accumulates charge in this manner until the horizontal component of the electric field is zero within segment AB. The electric field within AB then no longer pushes electrons to the left surface.

While charged particles accumulate on the two sides of segment AB, the corners at A and B also acquire a charge (positive at A and negative at B, Figure 31.19*b*). The accumulated charge reduces the electric field in the horizontal portions of the conductor and establishes a downward-pointing electric field in segment AB. Charge accumulates in this manner until the electric field due to the charged plates and the accumulated charge no longer pushes charged particles to the corners, but instead guides them along the conductor.

In general, when the ends of a wire are held at a fixed potential difference, charge accumulates on the surface of the conductor. The accumulation stops when the electric field due to the combined effects of the surface charge distribution and the applied potential difference has the same magnitude everywhere inside the conductor and points along a path through the conductor that is everywhere parallel to the sides of the conductor. Once this electric field is established, it no longer pushes charge carriers to the surface of the conductor but instead drives a steady flow of charge carriers through the conductor:



> **In a conductor of uniform cross section carrying a steady current, the electric field has the same magnitude everywhere in the conductor and is parallel to the walls of the conductor.**

Keep in mind that because potential differences across conductors are generally small, the electric fields inside conductors are also generally small, even in the presence of substantial currents.

EXAMPLE 31.5 Bending fields

Consider the three pieces of wire in **Figure 31.20**. All three are made of the same material and have identical circular cross sections. Conductor A has length ℓ; conductors B and C have length 2ℓ. With the wires kept in the configurations shown, a positively charged conducting plate is connected to the left end of each wire and a negatively charged conducting plate is connected to the right end of each wire.

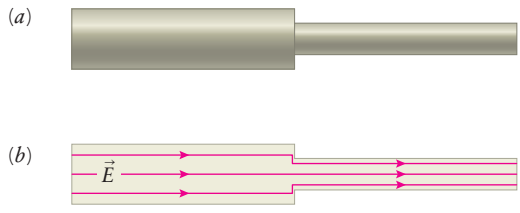
Figure 31.20 Example 31.5.

Rank the magnitudes of the steady-state electric field at P, Q, R, S, and T.

❶ **GETTING STARTED** Once a steady flow of charge carriers has been established in each wire, the electric field in each wire has the same magnitude everywhere in that wire and is always parallel to the walls of the wire.

❷ **DEVISE PLAN** Because the electric field is uniform along each wire, I can use the result I obtained in Example 25.5*a* (Eq. 1): The magnitude of a uniform electric field between two points is equal to the magnitude of the potential difference between those points divided by the distance between those points.

❸ **EXECUTE PLAN** In each case the magnitude of the potential difference between the ends of the conductor is equal to the potential difference between the plates, which I'll denote by V_{plates}. The electric field magnitude in A is then V_{plates}/ℓ, and that in B and C is $V_{\text{plates}}/2\ell$. Therefore, if I use E_P for the electric field magnitude at P, I can say $E_P > E_Q = E_R = E_S = E_T$. ✔



❹ **EVALUATE RESULT** My result is not surprising because I can think of a wire as a load with very small resistance. A wire of length 2ℓ is equivalent to two wires of length ℓ connected in series. Based on the result I obtained in Example 31.3, I expect the current in the wire of length ℓ (analogous to the single-bulb case of Example 31.3) to be twice the current in the wire of length 2ℓ (analogous to the two-bulb series case). To obtain this greater current, I need a greater electric field, as my result shows.

31.9 Sketch the electric field lines inside the conductors in Figures 31.18 and 31.19.

As Example 31.5 shows, the current in wire A is twice the current in wires B and C, which are twice as long. To get the same current in wires B and C as in A, the magnitude of the potential difference across wires B and C must be doubled. This means that the resistance of wires B and C is twice the resistance of wire A. Therefore, the resistance of a conductor is proportional to the length of the conductor.

So far, the only conductors we have considered have all had a uniform cross section. Suppose now that we have a conductor that has a circular cross section that decreases in radius by a factor of 2 at its midpoint (**Figure 31.21a**). How do the current and the electric

Figure 31.21 (*a*) Conductor of circular cross section that decreases in radius by a factor of 2 at the midpoint. (*b*) Electric field lines in the conductor when it is connected between two charged objects (not shown).

CONCEPTS

field in this conductor compare in the wide and the narrow parts?

If we think of this conductor as two circuit elements (the wide part and the narrow part) connected in series, we see that the current must be the same through the entire conductor. At steady state, electric field lines inside a conductor in a circuit must satisfy the continuity principle, just as the current must. Therefore the electric field lines in the wide part of our conductor must all continue into the narrow part (Figure 31.21*b*). The density of the electric field lines, and consequently the magnitude of the electric field, must therefore increase by the same factor by which the area decreases. Because the cross-sectional area decreases by a factor of 4, the magnitude of the electric field must increase by a factor of 4.

Now consider the magnitude of the potential difference across each part of the conductor. In each part, the magnitude of the electric field is equal to the magnitude of the potential difference across the part divided by the length of the part (see Example 31.5). Because the electric field is four times greater in the narrow part and because the two parts have the same length, the potential difference across the narrow part must also be four times greater than the potential difference across the wide part.

To get the same current in both parts, four times as much potential difference must be applied to the narrow part! This means that the resistance of the narrow part is four times greater than the resistance of the wide part, even though both are made of the same material. Therefore, the resistance of a conductor not only depends on the material from which it is made and is proportional to the length of the conductor, but also is inversely proportional to the cross-sectional area of the conductor.

CONCEPTS

EXAMPLE 31.6 Electric fields in conductors

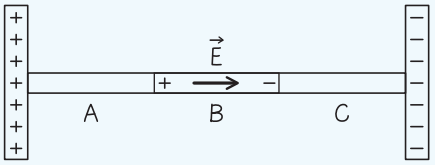


Figure 31.22 shows a rod made of three pieces of conducting material connected end to end. The pieces are of equal size but are made of different materials; pieces A and C have negligible resistance, but piece B has significant resistance. Consider connecting two oppositely charged plates to the ends of this rod. After the plates have been connected, how does the electric field in B compare with the electric field that existed between the plates before they were connected to the rod? Assume the charge on the plates is maintained.

Figure 31.22 Example 31.6.

❶ **GETTING STARTED** I begin by making a sketch of the rod connected to the two charged plates (**Figure 31.23**).

Figure 31.23

❷ **DEVISE PLAN** As I noted in Example 31.5 in using my result from Example 25.5*a*, the magnitude of the electric field in B is equal to the magnitude of the potential difference across B divided by the length of B. Likewise, the electric field magnitude between the plates is equal to the magnitude of the potential difference between the plates divided by the distance between them. To compare these two field magnitudes, I need to compare the magnitude of the potential difference across B with that across the plates.

❸ **EXECUTE PLAN** Because the resistance of A and C is negligible, the potential difference across A and C is negligibly small; the potential difference across B is therefore essentially the same as that between the plates. Because B is one-third as long as the distance between the plates, the electric field magnitude in B is roughly three times the electric field magnitude that existed between the plates before connection. ✔

❹ **EVALUATE RESULT** Because A and C have negligible resistance, I expect the charge to distribute itself along the rod as shown in Figure 31.23, with positive charge residing at the end of B nearer the positively charged plate and negative charge residing at the other end. This distribution of charge reduces the electric field in A and C and increases the electric field in B, as I concluded.

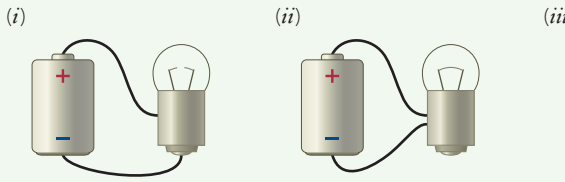
The rod in Figure 31.22 is a common circuit element called a **resistor,** a piece of conducting material that has non-negligible resistance (piece B) attached at both ends to pieces of wire called electrical *leads* (represented in Figure 31.22 by pieces A and C).

31.10 If a potential difference of 9 V is applied across the conductor in Figure 31.21, what is the magnitude of the potential difference (*a*) across the wide part and (*b*) across the narrow part?

Self-quiz

1. Why are none of the bulbs in **Figure 31.24** lit?

Figure 31.24



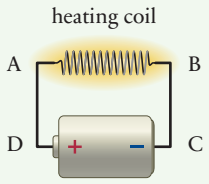


Figure 31.25

2. In **Figure 31.25**, identify the energy conversions that occur between points A and B, B and C, C and D, and D and A.
3. In **Figure 31.26**, bulb B is brighter than bulb C, which in turn is brighter than bulb A. Rank, largest first, (*a*) the magnitudes of the potential differences across the bulbs, (*b*) the currents in them, and (*c*) their resistances.

Figure 31.26

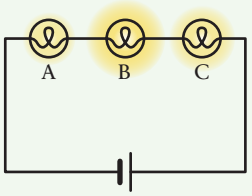

Figure 31.27

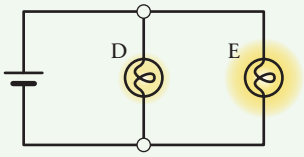

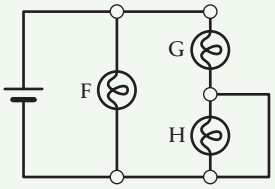

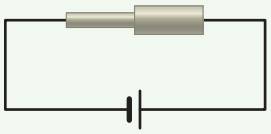

Figure 31.28

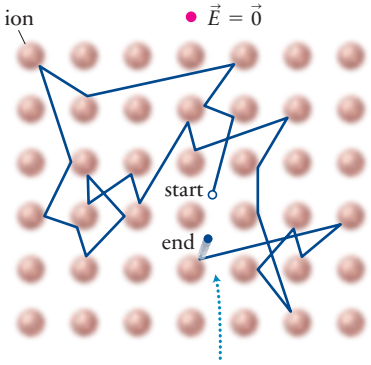
4. In **Figure 31.27**, bulb E is brighter than bulb D. Which bulb has (*a*) the greater potential difference across it, (*b*) more current in it, and (*c*) more resistance?
5. In **Figure 31.28**, which of the three bulbs F, G, and H light up?
6. A thick resistor and a thin resistor of the same length and material are connected in series, as shown in **Figure 31.29**. Which resistor has (*a*) the greater potential difference across it and (*b*) the greater resistance?

Figure 31.29



Answers

1. (*i*) Filament broken. (*ii*) Battery connected to only one contact on bulb. (*iii*) Bulb connected to only one battery terminal.
2. AB: electric potential energy converted to thermal energy; CD: chemical energy converted to electric potential energy; BC and DA: negligible conversion of energy.
3. (*a*) $V_B > V_C > V_A$ because the brightest bulb converts the most energy. (*b*) $I_B = I_C = I_A$ because the bulbs are in series and the current is the same throughout the circuit. (*c*) $R_B > R_C > R_A$ because, for a given current in a circuit element, R is proportional to V.
4. (*a*) $V_D = V_E$ because the bulbs are in parallel. (*b*) $I_E > I_D$ because E is brighter. (*c*) $R_D > R_E$ because less current passes through D.
5. F and G light up, but H does not because the wire in parallel with H carries all of the current through the right branch. (The wire "shorts out" H.)
6. (*a*) $V_{thin} > V_{thick}$ because the density of electric field lines through the thin resistor has to be greater, and if the lengths of the resistors are the same and E is greater, then V is greater. (*b*) $R_{thin} > R_{thick}$ because resistance is inversely proportional to cross-sectional area.

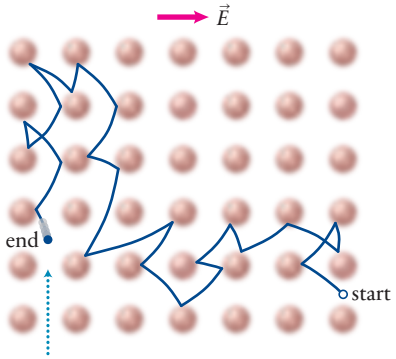


Figure 31.30 The effect of an applied electric field on the motion of a free electron through a lattice of ions.

(*a*) Motion in absence of an electric field

Electron's displacement is very small over long time interval.

(*b*) Motion with applied electric field

Electron undergoes displacement in direction opposite to electric field.

31.5 Resistance and Ohm's law

Recall from Section 22.3 that a metal consists of a lattice of positively charged ions through which electrons can move relatively freely. Although the lattice positions are fixed (meaning there is no motion of ions through the metal), the ions vibrate around their lattice positions, as if they were connected to those positions by springs. (The amplitude of the vibrations depends on temperature.) The ions consist of atomic nuclei surrounded by most of their electrons; the outermost one or more electrons of each atom are free to move through the entire lattice. Because of their thermal energy, these free electrons move through the lattice at very high speeds (10^5 m/s at room temperature, or about 0.1% of the speed of light), and they move in straight lines without any change in energy or momentum except in the instants when they collide with the ions.

In the absence of an electric field and over a time interval long enough for many collisions to take place, the displacement of an electron is very small in spite of its high speed (**Figure 31.30***a*). This is true because each collision changes the direction of the electron's motion, randomizing the direction of the electron's velocity. Consequently, the average velocity of all the electrons is zero. However, when an electric field is applied, as in Figure 31.30*b*, the electric field causes the electrons to accelerate in the direction opposite to the electric field.

A quantitative description of the motion of charge carriers in a conductor was given by P. K. Drude in 1900, shortly after the discovery of the electron. His model (called the *Drude model*) applies remarkably well to metals. Let's describe the motion of the electrons in this model. In the presence of a uniform electric field $\vec{E}$, in the absence of nonelectric interactions, the electrons are subject to a force $-e\vec{E}$ and therefore have an acceleration $\vec{a} = -e\vec{E}/m_e$. For any one electron moving along a straight path between two consecutive collisions, the electron's final velocity $\vec{v}_f$ just before the second collision is

$$\vec{v}_f = \vec{v}_i + \vec{a}\Delta t = \vec{v}_i - \frac{e\vec{E}}{m_e}\Delta t, \tag{31.1}$$

where $\vec{v}_i$ is the electron's initial velocity on that path (its velocity just after the first collision), Δt is the time interval the electron spends on that path (in other words, the time interval between collisions), e is the elementary charge (Eq. 22.3), $\vec{E}$ is the applied electric field, and m_e is the mass of the electron. The magnitude of $\vec{v}_i$ is roughly 10^5 m/s, as noted above, and the direction is determined by the first of the two collisions. Because of the high electron speed, the time interval Δt between collisions is extremely short—on the order of 10^{-14} s.

To calculate the average velocity of all the electrons, we take the average of Eq. 31.1 for all of the electrons:

$$(\vec{v}_f)_{av} = (\vec{v}_i)_{av} - \frac{e\vec{E}}{m_e}(\Delta t)_{av}. \tag{31.2}$$

(I have assumed here that the electric field is either constant over time or takes a time interval much longer than Δt to change significantly.)

Even though the magnitude of $\vec{v}_i$ is quite large, its average value for all electrons is zero because the collisions produce a random distribution of the directions of the initial velocities. The resulting average velocity, called the **drift velocity** $\vec{v}_d$ of the electrons, is thus

$$\vec{v}_d = -\frac{e\vec{E}}{m_e}\tau, \tag{31.3}$$

QUANTITATIVE TOOLS

where $\tau \equiv (\Delta t)_{\text{av}}$ is the average time interval between collisions. (The value of τ depends on the number density, size, and charge of the lattice ions, and on temperature.) The magnitude of the drift velocity is called the *drift speed*. Equation 31.3 shows that the drift velocity of the electrons is in a direction opposite that of the electric field, and the drift speed is proportional to the electric field magnitude.

31.11 (*a*) Does the electric field do work on the electrons of Figure 31.30*b* as they accelerate between collisions? (*b*) On average, does the kinetic energy of the electrons increase as they drift through the lattice? (*c*) What do your answers to parts *a* and *b* imply about the energy in the lattice?

In Chapter 27 we found that the current in a conductor can be expressed in terms of the speed v of the charge carriers (Eq. 27.16). Because the speed of the charge carriers is what we are now calling the drift speed, we can write Eq. 27.16 in the form

$$I = nAqv_{\text{d}}, \tag{31.4}$$

where A is the cross-sectional area of the conductor, q is the charge on each charge carrier in the conductor, and n is the number of carriers per unit volume in the conductor. Because of the current's dependence on cross-sectional area, it is convenient to introduce the current per unit area, called the **current density,** whose magnitude is given by the magnitude of the current per unit area:

$$J \equiv \frac{|I|}{A} = n|q|v_{\text{d}}. \tag{31.5}$$

Because the drift velocity is a vector, the current density is a vector, too:

$$\vec{J} = nq\vec{v}_{\text{d}}. \tag{31.6}$$

The direction of the current density is the same as that of the drift velocity for positive charge carriers and opposite the direction of the drift velocity for negative charge carriers. Therefore the current density is always in the same direction as the current. The SI unit of current density is A/m^2.

Substituting the absolute value of the right side of Eq. 31.3 for v_{d} and e for $|q|$ in Eq. 31.5 yields

$$J = n(e)\left(\frac{eE}{m_{\text{e}}}\tau\right) = \frac{ne^2\tau}{m_{\text{e}}}E. \tag{31.7}$$

Equation 31.7 shows that the current density is proportional to the applied electric field. The proportionality constant σ is called the **conductivity** of the material of which the conductor is made:*

$$\sigma \equiv \frac{J}{E}. \tag{31.8}$$

The SI unit of conductivity is equal to $(\text{A/m}^2)/(\text{V/m}) = \text{A/(V}\cdot\text{m)}$. The conductivity is a measure of a material's ability to conduct a current for a

*Note that conductivity is *not* the same as surface charge density, which is represented by the same symbol.

Table 31.1 Conductivities of various materials at room temperature [A/(V · m)]

Conductors	Silver	6.3×10^7
	Copper	5.9×10^7
	Aluminum	3.6×10^7
	Tungsten	1.8×10^7
	Nichrome	6.7×10^5
	Carbon	7.3×10^4
Semiconductors	Silicon	4×10^{-4}
	Germanium	2
Poor conductors	Seawater	4
Insulators	Pure water	4.0×10^{-6}
	Glass	10^{-12}

given applied electric field. The conductivity is a property of the material and is therefore the same for any piece of that material you might choose.

Table 31.1 gives the conductivities of some common materials at room temperature. Note that the first four materials, all metals, have very similar conductivities. Nichrome is an alloy of nickel and chromium used in heating elements because of its relatively low conductivity. Silicon is a *semiconductor;* its conductivity is intermediate between that of an electrical conductor and that of an electrical insulator. The conductivities of insulators (such as pure water and glass) are many orders of magnitude smaller than those of metals. Seawater has a greater conductivity than pure water because the ions dissolved in seawater serve as charge carriers for a current, just as the ions in the electrolyte of a battery do.

Comparing Eqs. 31.7 and 31.8 gives us an expression for the conductivity of a metal in terms of the average time interval between collisions, the mass and charge of the electrons, and the number density of electrons present in the material:

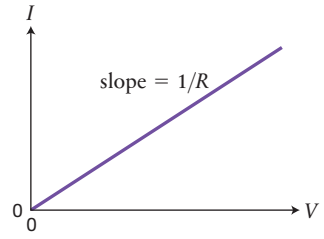
$$\sigma = \frac{ne^2\tau}{m_e}. \tag{31.9}$$

Because of the temperature dependence of τ, the conductivity σ depends on temperature and, for some materials, on the magnitude of the current in the material, but it is independent of the shape of the piece of material in which the current density is measured.

We obtained Eq. 31.9 for a metal, in which the charge carriers are electrons, but it applies to any system in which the charge carriers in a conducting material move freely between collisions. To generalize Eq. 31.9 for charge carriers other than electrons, simply substitute q^2 for e^2, and m_q for m_e, where q is the charge on the carriers and m_q is the mass of one carrier.

The conductivity describes how large a current density and hence current are created by an external electric field. Such an electric field is produced by applying a potential difference across a material. In Section 31.2, we looked at resistance as a way of relating the applied potential difference V across a circuit element to the resulting current in the element. In general, the resistance of any element is defined to be

$$R \equiv \frac{V}{I}. \tag{31.10}$$



QUANTITATIVE TOOLS

The derived SI unit of resistance is the **ohm** ($1\ \Omega \equiv 1\ \text{V/A}$). Resistance is always positive, so in Eq. 31.10 the direction in which V and I are measured must be such that they both have the same algebraic sign. The resistance of most circuit elements is typically in the range of 10 Ω to 100,000 Ω.

The concept of resistance is useful in describing conductors and other objects that provide a continuous conducting path for charge carriers, such as filaments, bulbs, and resistors. (It is not especially useful for other types of circuit elements, such as capacitors.) For some conducting materials, the resistance R of a piece of this material is fixed at a given temperature. For these materials, Eq. 31.10 indicates that the current in the conductor is proportional to the potential difference across it and inversely proportional to the resistance:

$$I = \frac{V}{R}. \tag{31.11}$$

Figure 31.31 Current versus applied potential difference for an ohmic conductor. The current is proportional to the potential difference.

Such materials are said to be *ohmic*. If we plot the magnitude of the current in a piece of this material as a function of the potential difference across it, the result is a straight line whose slope is equal to the inverse of the resistance R of the piece (**Figure 31.31**).

Equation 31.11 is often referred to as **Ohm's law.** It is important to keep two things in mind about Eq. 31.11. First, many materials and many circuit elements are not ohmic. For such materials and elements, a plot of current as a function of applied potential difference is not a straight line, but has a more complicated shape, indicating that R depends on the potential difference. Second, Eq. 31.11 is really a definition, not a law. It simply amounts to the observation that in certain materials, the current is proportional to the applied potential difference. In this chapter, we concern ourselves only with ohmic materials and circuit elements.

Let's now relate the resistance of a conductor to the conductivity of the material of which it is made. From Checkpoint 31.8 we know that the magnitude of the potential difference across a wire of length ℓ is given by (Eq. 25.25 and Example 25.5):

$$|V| = E\ell. \tag{31.12}$$

Combining Eqs. 31.5 and 31.8, we see that $J \equiv |I|/A = \sigma E$, so $E = |I|/(\sigma A)$. Substituting this expression into Eq. 31.12 and dropping the absolute-value symbol, we obtain a relationship between V and I:

$$V = \frac{I}{\sigma A}\ell = I\frac{\ell}{\sigma A}. \tag{31.13}$$

Substituting this expression into the definition of resistance, Eq. 31.10, we obtain for ohmic conductors,

$$R = \frac{\ell}{\sigma A}. \tag{31.14}$$

Equation 31.14 shows that the resistance of a conductor not only depends on the material from which it is made (through the conductivity σ) but also is proportional to the length ℓ of the conductor and inversely proportional to the cross-sectional area, as we had concluded in Section 31.4.

EXAMPLE 31.7 Drifting electrons

Consider a piece of copper wire that is 10 m long and has a diameter of 1.0 mm. The number density of free electrons in copper is 8.4×10^{28} electrons/m^3. If the wire carries a current of 2.0 A, what are (*a*) the magnitude of the potential difference across the wire, (*b*) the drift speed of the electrons in the wire, and (*c*) the average time interval between collisions for the electrons?

❶ **GETTING STARTED** Ohm's law relates the potential difference across the wire to the current in it and its resistance. Even though the wire is made of copper, it has a finite resistance, which depends on the conductivity of copper and on the length and cross-sectional area of the wire. This resistance is caused by collisions between the electrons and copper ions in the wire, and these collisions limit the drift speed of the electrons through the wire. The drift speed is related to the average time interval between collisions, which is one of the parameters I need to calculate and which appears in the expression for conductivity in the Drude model, Eq. 31.3, $v_d = eE\tau/m_e$.

❷ **DEVISE PLAN** The potential difference across the wire is related to the current by Eq. 31.11, but in order to use this equation, I must determine the wire's resistance, which is given by Eq. 31.14. I can look up the conductivity of copper in Table 31.1 ($\sigma = 5.9 \times 10^7$ A/V·m). To obtain the drift speed of the electrons, I can use Eq. 31.4, which contains the charge on the electron ($q = e = 1.6 \times 10^{-19}$ C), the current (given), the number density of the electrons (given), and the cross-sectional area of the wire, which I can calculate from the given diameter. To obtain the average time interval between collisions, I can use Eq. 31.9, which contains the mass of the electron ($m_e = 9.11 \times 10^{-31}$ kg).

❸ **EXECUTE PLAN** (*a*) I obtain the resistance of the wire from Eq. 31.14 and the cross-sectional area of the wire, $A = \pi r^2 = \pi(5.0 \times 10^{-4}\ \text{m})^2 = 7.9 \times 10^{-7}\ \text{m}^2$:

$$R_{\text{wire}} = \frac{\ell}{\sigma A} = \frac{10\ \text{m}}{(5.9 \times 10^7\ \text{A/V·m})(7.9 \times 10^{-7}\ \text{m}^2)}$$

$$= 0.21\ \Omega.$$

Now that I have R_{wire}, I can obtain V_{wire} from Eq. 31.11:

$$V_{\text{wire}} = IR_{\text{wire}} = (2.0\ \text{A})(0.21\ \Omega) = 0.42\ \text{V}. \checkmark$$

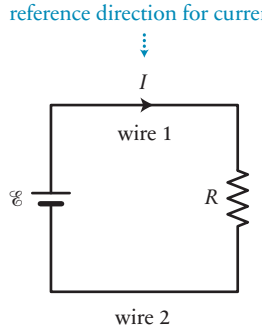
(*b*) I first obtain the drift speed of the electrons from Eq. 31.4:

$$v_d = \frac{I}{neA} = \frac{2.0\ \text{C/s}}{(8.4 \times 10^{28}\ \text{m}^{-3})(1.6 \times 10^{-19}\ \text{C})(7.9 \times 10^{-7}\ \text{m}^2)}$$

$$= 1.9 \times 10^{-4}\ \text{m/s}. \checkmark$$

(*c*) Solving Eq. 31.9 for τ, I get

$$\tau = \frac{m_e\sigma}{ne^2} = \frac{(9.11 \times 10^{-31}\ \text{kg})(5.9 \times 10^7\ \text{A/V·m})}{(8.4 \times 10^{28}\ \text{m}^{-3})(1.6 \times 10^{-19}\ \text{C})^2}$$



$$= 2.5 \times 10^{-14}\ \text{s}. \checkmark$$

❹ **EVALUATE RESULT** Because the conductivity of copper is high, it makes sense that I obtain a small resistance and consequently a small potential difference across the wire even though it is 10 m long. My answer to part *b* shows that the drift speed of the electrons in the wire is very small. The drift speed indicates that it takes the electrons about 5 s to move just 1 mm, even though I know from experience that when I turn on a light switch, the light turns on instantly even if the bulb is meters away from the switch. The reason the light bulb comes on almost instantaneously, however, is that the current is the same throughout the circuit—all of the electrons throughout the circuit are set in motion almost simultaneously when I flip the switch.

How can my very small calculated value for drift speed be reasonable when the current is a significant 2.0 A = 2.0 C/s at any given location in the wire? The reason is that the number density of electrons in the wire is very high. Although it takes 5 s for an electron to move 1 mm, there are nearly 10^{20} electrons per cubic millimeter of the wire. This means that on the order of 10^{20} electrons, or 10 coulombs of charge, pass a given location in 5 s—hence the current is 2 C/s, or 2 A.

The very high number density of the electrons is also responsible for the extremely short time interval between collisions. If I imagine the 10^{20} electrons per cubic millimeter arranged on a cubic lattice where each cube of the lattice has a side length of 1.0 mm, there are about 10^7 electrons along each side of the cube, and so the average distance between them is about 10^{-10} m. As the electrons move at about 10^5 m/s (see Section 31.5), they cover this average distance in about 10^{-15} s, which is within an order of magnitude of what I obtained.

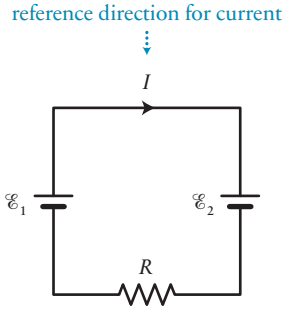
Figure 31.32 Circuit diagram for a battery connected in series with a single resistor.

31.12 If the temperature of a metal is raised, the amplitude of the vibrations of the metal-lattice ions increases. (*a*) What effect, if any, do you expect these greater vibrations to have on the resistance of a piece of that metal? (*b*) What effect does running a current in a metal have on the temperature of the metal? (*c*) Make a graph of current versus potential difference, taking into account the effect you described in part *b*.

31.6 Single-loop circuits

In this section, we quantitatively analyze single-loop circuits. We begin with the simplest possible circuit: a single battery connected to a single resistor, obeying Ohm's law (Figure 31.32). The emf of the battery is $\mathscr{E}$, and the resistance of the resistor is R.

QUANTITATIVE TOOLS



The emf of the battery establishes an electrostatic field that drives a current in the circuit. In steady state, this current is the same at all locations in the circuit, as we discussed in the first part of this chapter. For a single-loop circuit we can express this condition quantitatively as

$$I_{\text{battery}} = I_{\text{wire}} = I_{\text{resistor}} = I. \tag{31.15}$$

In Section 27.3 we called the direction of decreasing potential in a conducting object the *direction of current*, and we indicated this direction by an arrow labeled I next to the object carrying the current (Figure 27.18). When working with circuits, however, we generally won't know the direction of current in advance. To analyze the circuit we therefore need to choose a *reference direction for the current* in each circuit branch. We indicate this direction by an arrowhead on a wire in the circuit (Figure 31.32) and label that arrowhead with a symbol for the current in that branch. In a single-loop circuit, there are no junctions and therefore only one current. As the next checkpoint shows, the reference direction for the current and the direction of current need not be the same. As we shall see later, we obtain a positive value for I when the direction of current and the reference direction for the current are the same. When these two directions are opposite, we find that $I < 0$.

31.13 If $\mathscr{E}_1 < \mathscr{E}_2$ in **Figure 31.33**, is the direction of current the same as the reference direction for the current indicated in the diagram?

Figure 31.33 Checkpoint 31.13.

Let's next consider the energy transformations that occur in the circuit shown in **Figure 31.34**. Nonelectrostatic work done on the negative charge carriers as they travel from point a to point b through the source raises the electric potential energy of the charge carriers. In the load, this electric potential energy is converted to other forms of energy, such as thermal energy, mechanical energy, or radiation energy:

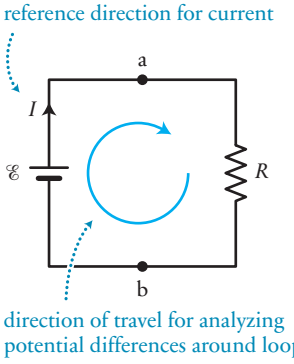
$$\Delta E_{\text{other}} = W_{\text{nonelectrostatic}}(\text{a} \to \text{b}). \tag{31.16}$$

Considering just the load by itself, we also know that the amount of energy converted to other forms of energy must be equal to the work done by the electrostatic field on the charge carriers as they travel from point b to point a through the load:

$$\Delta E_{\text{other}} = W_{\text{electrostatic}}(\text{b} \to \text{a}), \tag{31.17}$$

so

$$W_{\text{nonelectrostatic}}(\text{a} \to \text{b}) = W_{\text{electrostatic}}(\text{b} \to \text{a}). \tag{31.18}$$



Using Eqs. 26.7 and 25.15 this becomes

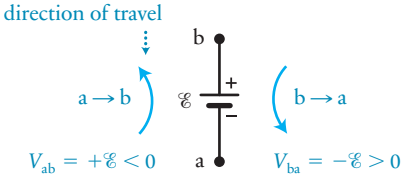
$$q\mathscr{E} = -qV_{\text{ba}} \tag{31.19}$$

or

$$\mathscr{E} + V_{\text{ba}} = 0. \tag{31.20}$$

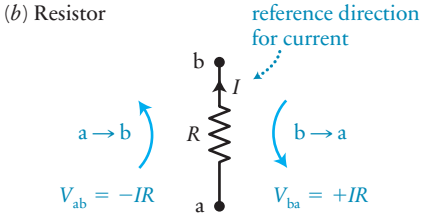
Figure 31.34 Choosing a direction of travel for analyzing a single-loop circuit.

For circuits that contain many elements, Eq. 31.20 can be generalized by replacing each term by a sum. In that case the algebraic sum of the emfs and the potential differences around the loop is zero:



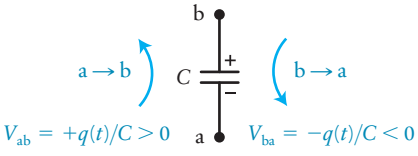
$$\Sigma\mathscr{E} + \Sigma V = 0 \quad (\text{steady state, around loop}). \tag{31.21}$$

Equation 31.21 is called the **loop rule.**



When evaluating the sum on the left in Eq. 31.21, we need to pay close attention to the signs of the emfs and potential differences. We begin by

Figure 31.35 Potential differences across batteries, resistors, and capacitors.



(*a*) Battery

(*b*) Resistor

(*c*) Capacitor

choosing a *direction of travel* around the loop. We denote this direction of travel by a curved arrow at the center of the loop (Figure 31.34). As we shall see shortly, this choice does not affect the end result—we must just be sure to use the same direction for all elements in the loop. In single-loop circuits it makes sense to let the travel direction be the same as the reference direction for the current. In multiloop circuits, however, it is generally not possible to let both directions coincide.

Because the potential is the same everywhere along any of the wires, we only need to consider the potential differences across circuit elements: Each circuit element contributes one term to the sum. For a battery, the potential difference is positive when traveling from the negative terminal to the positive terminal because the potential of the positive terminal is higher than that of the negative terminal (**Figure 31.35*a***). Conversely, the potential difference is negative when traveling in the opposite direction. If the battery is ideal, the magnitude of the potential difference is equal to the emf $\mathscr{E}$ of the battery (Eq. 26.8).

The sign of the potential difference across a resistor depends on both the choice of current reference direction and the choice of travel direction (Figure 31.35*b*). When traveling in the same direction as the reference direction for the current, the potential difference is $-IR$. To see why this is so, let us assume that in Figure 31.35*b* the current is positive (that is, the current is in the reference direction for the current). Because the direction of current is from higher potential to lower potential, we see that the potential at b must be lower than at a, $V_b < V_a$, and therefore $V_{ab} = V_b - V_a < 0$. Indeed when $I > 0$ the potential difference $V_{ab} = -IR$ is negative. When traveling in the opposite direction, the potential difference is $+IR$.

Next we examine the potential difference across a capacitor (Figure 31.35*c*). The potential difference is positive when traveling from the negatively charged plate to the positively charged one because the potential of the positive terminal is higher than that of the negative terminal; the potential difference is negative when traveling in the opposite direction. The magnitude of the potential difference can be obtained from Eq. 26.1: $C \equiv q/V_{cap}$, where C is the capacitance and q is the magnitude of the charge on the plates. It is important to keep in mind that the charge on the plate and the potential difference typically vary as a function of time as the capacitor charges or discharges. At any given instant, the magnitude of the potential difference across the capacitor is

$$V_{cap}(t) = \frac{q(t)}{C}, \tag{31.22}$$

where $q(t)$ is the magnitude of the charge on the plates at that instant. Because of this time-dependence, the current also depends on time. When solving Eq. 31.21 for circuits that contain capacitors, remember that the time-dependent current $I(t)$ and $q(t)$ are related by Eq. 27.2: $I(t) \equiv dq/dt$.

The Procedure box "Applying the loop rule in single-loop circuits" and **Table 31.2** summarize how to apply the loop rule to a single-loop circuit. Let us return to the circuit in Figure 31.34 and apply this procedure to obtain a relationship between the current and the emf. The figure already indicates a reference direction for the current (the arrowhead labeled I) and a direction of travel (the clockwise circular arrow). We shall begin our analysis at the bottom left corner. If we go clockwise, the first circuit element is the battery; because we are traveling from the negative to the positive terminal, the potential difference is $+\mathscr{E}$ (Figure 31.35*a* and Table 31.2). Next is the resistor; because we are traveling in the same direction as the

QUANTITATIVE TOOLS

reference direction for the current, the potential difference is $-IR$. Substituting these values in Eq. 31.21, we get

$$+\mathscr{E} - IR = 0 \tag{31.23}$$

or

$$I = \frac{\mathscr{E}}{R}. \tag{31.24}$$

PROCEDURE: Applying the loop rule in single-loop circuits

When applying the loop rule to a single-loop circuit consisting of resistors, batteries, and capacitors, we need to make several choices in order to calculate the current or the potential difference across each circuit element.

1. Choose a reference direction for the current in the loop. (This direction is arbitrary and may or may not be the direction of current, but don't worry, things sort themselves out in step 4.) Indicate your chosen reference direction by an arrowhead, and label the arrowhead with the symbol for the current (I).
2. Choose a direction of travel around the loop. This choice is arbitrary and separate from the choice of the reference direction for the current in step 1. (You may want to indicate the travel direction with a circular clockwise or counterclockwise arrow in the loop.)
3. Start traversing the loop in the direction chosen in step 2 from some arbitrary point on the loop. As you encounter circuit elements, each circuit element contributes a term to Eq. 31.21. Use Table 31.2 to determine the sign and value of each term. Add all terms to obtain the sum in Eq. 31.21. Make sure you traverse the loop completely.
4. Solve your expression for the desired quantity. If your solution indicates that $I < 0$, then the direction of current is opposite the reference direction you chose in step 1.

Table 31.2 Signs and values of potential differences across batteries and resistors (Figure 31.35)

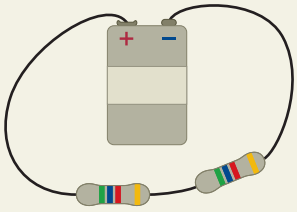
Circuit element	Plus sign when traversing	Value
ideal battery	from − to +	$\mathscr{E}$
capacitor	from − to +	$q(t)/C$
resistor	opposite reference direction of current	IR

31.14 In the analysis of the circuit in Figure 31.34, we chose a clockwise reference direction for the current and a clockwise direction of travel. Redo the analysis using (*a*) a clockwise reference direction for the current and a counterclockwise direction of travel and (*b*) a counterclockwise reference direction for the current and a clockwise direction of travel.

EXERCISE 31.8 Series resistors

Consider the circuit shown in **Figure 31.36**, containing two resistors with resistances R_1 and R_2 and a battery with an emf $\mathscr{E}$. Determine the current in the circuit in terms of R_1, R_2, and $\mathscr{E}$.

Figure 31.36 Exercise 31.8.



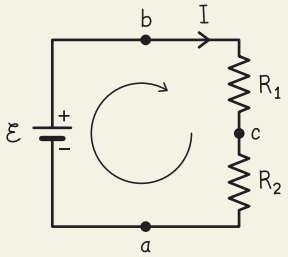


Figure 31.37

SOLUTION I begin by making a diagram, **Figure 31.37**, labeling the points a, b, and c, and choosing a clockwise reference direction for the current and a clockwise direction of travel. If I begin at point a, as I travel from the negative to the positive terminal, the potential difference is $+\mathscr{E}$. As I travel across resistor 1, I am traveling in the same direction as the reference direction for the current, so the potential difference is $-IR_1$. Next I travel across resistor 2 in the same direction as the reference direction for the current, so the potential difference is $-IR_2$. I now add all these terms and set the sum to zero (Eq. 31.21):

$$+\mathscr{E} - IR_1 - IR_2 = 0.$$

Solving this equation for the current yields

$$I = \frac{\mathscr{E}}{R_1 + R_2}. \checkmark$$

QUANTITATIVE TOOLS

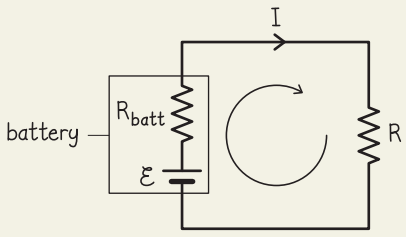
Comparing the result of Exercise 31.8 with Eq. 31.11, we see that the effect on the current of placing two (or more) resistors in series is equivalent to adding the resistances, as we had concluded in Section 31.2. In other words, the same current would exist in the circuit if we replaced the two resistors in series with a single resistor having resistance

$$R_{eq} = R_1 + R_2. \tag{31.25}$$

By following the same line of reasoning, I can show that for more than two resistors in series, this result generalizes to

$$R_{eq} = R_1 + R_2 + R_3 + \cdots \text{ (resistors in series)}. \tag{31.26}$$

The resistance that could be used to replace a combination of circuit elements without altering the current from the battery is often referred to as the **equivalent resistance** of that part of the circuit.



31.15 (*a*) In Figure 31.37, determine the potential difference between c and b by going counterclockwise from c to b. (*b*) For $\mathscr{E} = 9$ V, $R_1 = 10\ \Omega$, and $R_2 = 5\ \Omega$, calculate V_{cb} going counterclockwise from c to b.

EXAMPLE 31.9 Internal resistance

Even the best batteries dissipate some energy, which means that not all the chemical energy is converted to electric potential energy. We can take this dissipation into account by modeling a nonideal battery as consisting of an ideal battery of emf $\mathscr{E}$ in series with a small resistor R_{batt}, often called the *internal resistance* of the battery. The effect of this internal resistance is that the potential difference across the battery terminals is smaller than $\mathscr{E}$ when there is a current. When a nonideal battery is used in a circuit where the load is a resistor of resistance R, is the potential difference across the battery terminals greatest when the resistance of the load is high or when it is low?

❶ **GETTING STARTED** I begin by drawing a circuit diagram for such a nonideal battery connected to a load of resistance R (**Figure 31.38**). I need to determine an expression that shows me how the relative values of R and the internal resistance R_{batt} affect the potential difference across the battery terminals. I arbitrarily choose clockwise both for the reference direction for the current and for my travel around the circuit.

Figure 31.38

❷ **DEVISE PLAN** The potential difference across the nonideal battery terminals is the sum of the potential difference across the ideal battery, $\mathscr{E}$, and the potential difference across the internal resistance, $-IR_{batt}$. This latter term means I need to obtain a value for the current. I note that my circuit is equivalent to the two resistors in series in the circuit shown in Figure 31.37, and the final expression I obtained in Exercise 31.8 lets me express the current in terms of these two resistances. Thus I should be able to use this result to write an expression relating R and R_{batt} to V_{batt}.

❸ **EXECUTE PLAN** I use the solution I obtained in Exercise 31.8 to calculate the current in the circuit:

$$I = \frac{\mathscr{E}}{R_{batt} + R}.$$

I can now substitute this expression for I in the $-IR_{batt}$ term in my expression for V_{batt}:

$$V_{batt} = \mathscr{E} - IR_{batt} = \mathscr{E}\left(1 - \frac{R_{batt}}{R_{batt} + R}\right) = \mathscr{E}\left(\frac{R}{R_{batt} + R}\right).$$

When $R \gg R_{batt}$, the effect of R_{batt} is small and the potential difference across the battery terminals is essentially what it is in an ideal battery. When R is small, and especially when it is comparable to R_{batt}, then R_{batt} reduces the potential difference across the terminals. Thus the potential difference across the terminals of a nonideal battery is greatest when the resistance of the load is high. ✔

❹ **EVALUATE RESULT** If $R \gg R_{batt}$, the resistance in the circuit is great and hence the current is small. Because the current is small, the potential difference due to the internal resistance is small ($-IR_{batt}$) and hence the potential difference across the terminals does not differ significantly from its ideal value. This conclusion agrees with what my expression for V_{batt} shows.

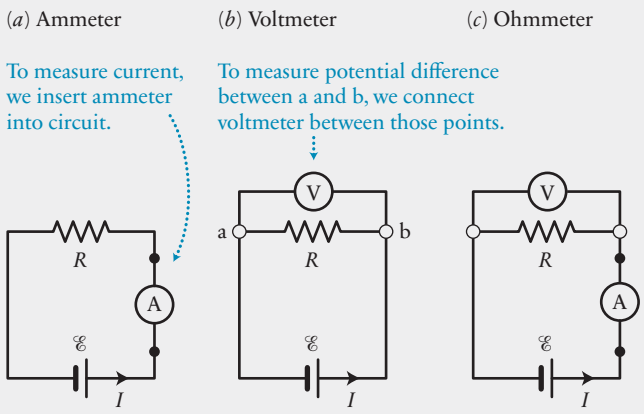
QUANTITATIVE TOOLS

Electrical measuring instruments

Current, potential difference, and resistance can be measured with the following three electrical measuring devices. Often the three functions are combined into one instrument, called a *multimeter*.

Ammeter: To measure the current in a single-loop circuit (or in a branch of a multiloop circuit), an ammeter must be inserted into the loop or branch, as shown in **Figure 31.39*a*** or *c*. The ammeter then indicates the current passing through it.

Voltmeter: To measure the potential difference between two points, a voltmeter is connected to those two points (Figure 31.39*b*). Unlike current measurement, a potential difference measurement does not require breaking the circuit.



Ohmmeter: A voltmeter and an ammeter can be combined to measure a resistance, as shown in Figure 31.39*c*. In practice resistance is measured using a device called an *ohmmeter*. Such a device puts a known potential difference across the resistor to be measured, measures the resulting current though the resistor, and then uses Ohm's law to determine the resistance. To measure the resistance of a circuit element, that element must be disconnected from the circuit.

Voltmeters and ammeters typically affect the circuit under observation. For example, if the resistance R_A of the ammeter in Figure 31.39*a* is nonzero, the current in the circuit is affected by the insertion of the ammeter. The resistance of ammeters must therefore be very small compared to the other resistances in the circuit; an *ideal ammeter* has zero resistance.

Similarly, the resistance R_V of the voltmeter in Figure 31.39*b* must be very great compared to other resistances in the circuit to prevent charge carriers from flowing through the voltmeter and changing the current in the circuit; an *ideal voltmeter* has infinite resistance.

In either case, if we know the resistance of the device, it is possible to correct for its effect on the circuit.

Figure 31.39 Electrical measuring instruments.

According to the model of Example 31.9, an ideal battery is a battery with $R_{batt} = 0$. For a high-quality nonideal battery, R_{batt} can be extremely small—at most a few ohms. Thus, for ordinary loads, with resistances typically hundreds of ohms or more, the battery's internal resistance is not important.

A number of measuring instruments exist to measure electrical quantities in electric circuits and circuit elements. The instrument to measure currents is called an *ammeter*; the instrument to measure potential differences is called a *voltmeter*. By measuring both the current in a resistor and the potential difference across it, one can determine the resistance using Ohm's law. An *ohmmeter* is used to accomplish this task: Connecting a resistor between the terminals of an ohmmeter yields a reading for the resistance. See the box above on Electrical measuring instruments for more information on these devices.

31.7 Multiloop circuits

The analysis of multiloop circuits follows the same principles we laid out in the preceding section, but we need to consider what happens in multiple branches, junctions, and loops. The first thing to note is that the branch rule requires that in steady state, the current in any branch is the same everywhere along that branch. Therefore, in a circuit containing M branches, there are M distinct currents. When analyzing multiloop circuits, you should therefore always begin by identifying all the branches and labeling the current in each of those branches.

As we saw in Section 31.3, the **junction rule** states that in steady state the sum of the currents going into a junction must be equal to the sum of the currents going out of that junction:

$$I_{in} = I_{out} \quad \text{(steady state)}. \tag{31.27}$$

QUANTITATIVE TOOLS

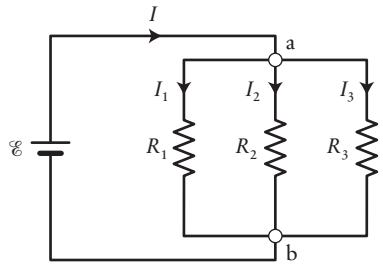


Figure 31.40 Circuit diagram for three resistors connected in parallel across an ideal battery.

As an example of a simple multiloop circuit, let us begin by considering three resistors connected in parallel across an ideal battery, as shown in Figure 31.40. Our goal will be to determine the equivalent resistance of the parallel combination of resistors. The circuit in Figure 31.40 has four branches, two junctions, and six loops (Can you identify them all?). Because there are four branches, we begin by labeling the currents in the four branches: the current in the battery, I, and the currents I_1, I_2, and I_3 through the three resistors. At junction a in Figure 31.40 we have $I_{\text{in}} = I$ and $I_{\text{out}} = I_1 + I_2 + I_3$, so the junction rule yields

$$I = I_1 + I_2 + I_3. \tag{31.28}$$

We can follow the same reasoning at junction b, but as you can easily verify, we would obtain exactly the same equation.

The potential difference V_{ba} is the same across each of the three resistors, so we can write for the currents in the resistors

$$I_1 = \frac{V_{\text{ba}}}{R_1}, \quad I_2 = \frac{V_{\text{ba}}}{R_2}, \quad I_3 = \frac{V_{\text{ba}}}{R_3}. \tag{31.29}$$

Substituting Eq. 31.29 into Eq. 31.28 gives

$$I = \frac{V_{\text{ba}}}{R_1} + \frac{V_{\text{ba}}}{R_2} + \frac{V_{\text{ba}}}{R_3} = V_{\text{ba}}\left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}\right). \tag{31.30}$$

If we replace the combination of the three parallel resistors by a single resistor having an equivalent resistance R_{eq}, we have

$$I = V_{\text{ba}}\left(\frac{1}{R_{\text{eq}}}\right). \tag{31.31}$$

The value of R_{eq} needed to obtain the same current I in the battery as with the three resistors connected in parallel is obtained by comparing Eqs. 31.30 and 31.31:

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}, \tag{31.32}$$

which tells us that the reciprocal of the equivalent resistance of resistors connected in parallel equals the sum of the reciprocals of the individual resistances. Because the line of argument I used in deriving Eqs. 31.28–31.32 can be followed for any number of resistors, this statement is true for any number of resistors in parallel:

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots \quad \text{(resistors in parallel)}. \tag{31.33}$$

For two resistors in parallel, the equivalent resistance can also be written as

$$R_{\text{eq}} = \frac{R_1 R_2}{R_1 + R_2} \quad \text{(two resistors in parallel)}. \tag{31.34}$$

Note that the equivalent resistance is smaller than either of the two individual resistances ($R_{\text{eq}} < R_1$ and $R_{\text{eq}} < R_2$). This is always true for resistors in parallel. As we discussed in Section 31.3, although it may seem paradoxical that combining multiple resistors reduces the equivalent resistance, combining resistors in parallel amounts to providing multiple paths for the current to follow. Viewed from this perspective, it is not surprising

QUANTITATIVE TOOLS

that increasing the number of branches in the circuit reduces the equivalent resistance of the circuit.

31.16 Let $\mathscr{E} = 9$ V, $R_1 = 3\ \Omega$, $R_2 = 10\ \Omega$, and $R_3 = 5\ \Omega$ in Figure 31.40. (*a*) What is the equivalent resistance of the three resistors? (*b*) What is the current in the battery?

The circuit in Figure 31.40 has more than one loop, but it is still a relatively simple circuit. To analyze more complex multiloop circuits, we need to derive a set of mathematical relationships among the unknown quantities (typically the currents in the various branches). Specifically, we need to have as many independent mathematical relationships as there are unknown quantities in the circuit.

One way to obtain a suitable set of equations is to apply the junction rule and the loop rule as many times as necessary to obtain a suitable number of equations. The junction rule and the loop rule are sometimes referred to as either *Kirchhoff's circuit rules* or *Kirchhoff's laws*, after the German physicist Gustav Kirchhoff (1824–1887). These rules do not contain any new physical principles, but instead are simply the application of principles we have already encountered—continuity (the junction rule) and Eq. 25.32 representing conservation of energy (the loop rule)—to an electric circuit in steady state.

Suppose we are interested in determining the currents in the circuit shown in **Figure 31.41**. Specifically, we want to determine the currents I_1, I_2, and I_3 in the three resistors. (The chosen reference directions in Figure 31.41 are arbitrary.) We wish to determine values for these currents in terms of the resistances R_1, R_2, and R_3 and the emfs of the batteries.

The circuit in Figure 31.41 has two junctions, three branches, and three loops. At junction b we have $I_{\text{in}} = I_1$ and $I_{\text{out}} = I_2 + I_3$, so, according to the junction rule,

$$I_1 = I_2 + I_3. \tag{31.35}$$

Applying the junction rule at f yields no new information because we would obtain the same equation. In general, it can be shown that in a circuit that contains N junctions, the junction rule yields $N - 1$ independent equations. This means that in a circuit with N junctions, we should apply the junction rule $N - 1$ times.

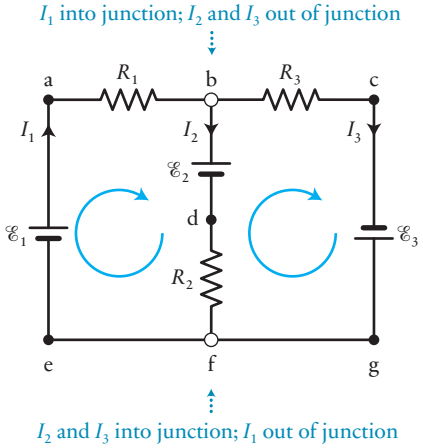
Next we need to use the loop rule. There are three unknown quantities in this problem (the three currents), so we need two equations in addition to Eq. 31.35 to determine the three currents. In other words, we need to apply the loop rule to two loops in the circuit.

First let us apply the loop rule to loop abdfea, choosing a clockwise travel direction around the loop:

$$V_{\text{ab}} + V_{\text{bd}} + V_{\text{df}} + V_{\text{fe}} + V_{\text{ea}} = 0. \tag{31.36}$$

Expressing the potential differences in this equation in terms of the emfs, resistances, and currents (see Table 31.2), we get

$$-I_1R_1 - \mathscr{E}_2 - I_2R_2 + 0 + \mathscr{E}_1 = 0. \tag{31.37}$$



Next we apply the loop rule to loop bcgfdb, going clockwise around the loop:

$$V_{\text{bc}} + V_{\text{cg}} + V_{\text{gf}} + V_{\text{fd}} + V_{\text{db}} = 0, \tag{31.38}$$

or

$$-I_3R_3 + \mathscr{E}_3 + 0 + I_2R_2 + \mathscr{E}_2 = 0. \tag{31.39}$$

Figure 31.41 Using the junction and loop rules to determine the currents in the resistors in this multiloop circuit.

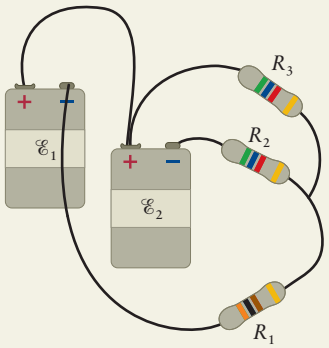
QUANTITATIVE TOOLS

PROCEDURE: Analyzing multiloop circuits

Here is a series of steps for calculating currents or potential differences in multiloop circuits.

1. Identify and label the junctions in the circuit.
2. Label the current in each branch of the circuit, arbitrarily assigning a direction to each current.
3. Apply the junction rule to all but one of the junctions. (The choice of which junctions to analyze is arbitrary; choose junctions that involve the quantities you are interested in calculating.)
4. Identify the loops in the circuit and apply the loop rule (see the Procedure box on page 1099) enough times to obtain a suitable number of simultaneous equations relating the unknowns in the problem. The choice of loops is arbitrary, but every branch must be in at least one of the loops. Traverse each loop in whichever direction you prefer, but be sure you traverse each loop completely and stick with the direction of travel and with the chosen directions of the currents.

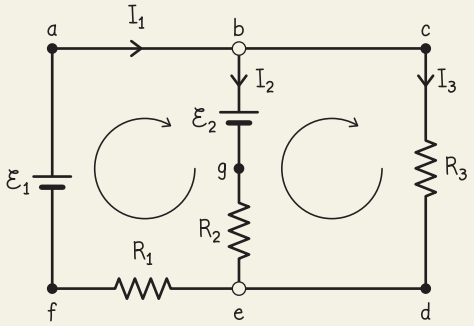
There are several simplifications you can make during your analysis.



1. Multiloop circuits can sometimes be simplified by replacing parallel or series combinations of resistors by their equivalent resistances. If you can reduce the circuit to a single loop, you can solve for the current in the source. You may then need to "unsimplify" and undo the resistor simplification to calculate the current or potential difference across a particular resistor.
2. In general when solving problems, you should solve equations analytically before substituting known numerical values. When solving the simultaneous equations you obtain for multiloop circuits, however, you can often simplify the algebra if you substitute the known numerical values earlier on.

We now have three equations (Eqs. 31.35, 31.37, and 31.39) involving three unknowns (I_1, I_2, and I_3). (As stated earlier, the resistances and emfs are not unknowns. We consider R_1, R_2, R_3, $\mathscr{E}_1$, $\mathscr{E}_2$, and $\mathscr{E}_3$ to have certain values, although we are not given numerical values for them. Other problems might treat one or more of the resistances or emfs as unknowns, in which case some additional information, such as the values of some of the currents, would be needed.) Equations 31.35, 31.37, and 31.39 can be solved using standard algebraic techniques. Because every circuit is different, we shall not solve this particular problem. Complete solutions to such problems are provided in the examples below. All the physics of the circuit is expressed in Eqs. 31.35–31.39; the remainder of the solution simply involves algebra. The steps for analyzing multiloop circuits are summarized in the Procedure box above.

EXAMPLE 31.10 Multiloop circuit



Consider the circuit shown in **Figure 31.42**. Determine the magnitude of the potential difference across R_1 if $\mathscr{E}_1 = \mathscr{E}_2 = 9.0$ V and $R_1 = R_2 = R_3 = 300\ \Omega$.

Figure 31.42 Example 31.10.

❶ **GETTING STARTED** I begin by drawing a circuit diagram for the circuit (**Figure 31.43**).

Figure 31.43

❷ **DEVISE PLAN** To solve this problem I follow the steps in the Procedure box on page 1104. There are two junctions in the circuit (b, e), three loops (abgefa, bcdegb, abcdefa), and three branches (efab, egb, edcb). I label the currents in the three branches I_1, I_2, and I_3. If I apply the junction rule to one of the junctions and the loop rule to two of the loops, I will obtain three equations that I can solve for the three unknowns I_1, I_2, and I_3. I choose loops abgefa and bcdegb and a clockwise travel direction in each of these loops. Once I know the current I_1, I can use Ohm's law (Eq. 31.11) to compute the potential difference across the resistor of resistance R_1. Because the values of the emfs and resistances are all the same, I set $\mathscr{E}_1 = \mathscr{E}_2 = \mathscr{E}$ and $R_1 = R_2 = R_3 = R$ to simplify the calculation.

❸ **EXECUTE PLAN** For junction b I have $I_{in} = I_1$ and $I_{out} = I_2 + I_3$, so applying the junction rule gives

$$I_1 = I_2 + I_3. \tag{1}$$

Applying the loop rule going clockwise around loop abgefa gives

$$0 - \mathscr{E} - I_2R - I_1R + \mathscr{E} = 0,$$

or

$$I_2 = -I_1. \tag{2}$$

Next I apply the loop rule going clockwise around loop bcdegb:

$$0 - I_3R + 0 + I_2R + \mathscr{E} = 0. \tag{3}$$

I now have three equations from which I can determine the three unknown currents.

Substituting Eq. 2 into Eq. 1 yields $I_1 = -I_1 + I_3$, or

$$I_3 = 2I_1. \tag{4}$$

Substituting this expression for I_3 and Eq. 2 into Eq. 3 yields

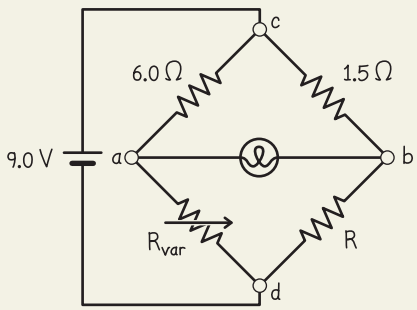
$$-2I_1R - I_1R + \mathscr{E} = 0.$$

Solving for I_1 then gives me

$$I_1 = \frac{\mathscr{E}}{3R}, \tag{5}$$

and substituting $\mathscr{E} = 9.0$ V and $R = 300\ \Omega$, I get

$$I_1 = \frac{9.0\text{ V}}{900\ \Omega} = 0.010\text{ A}.$$



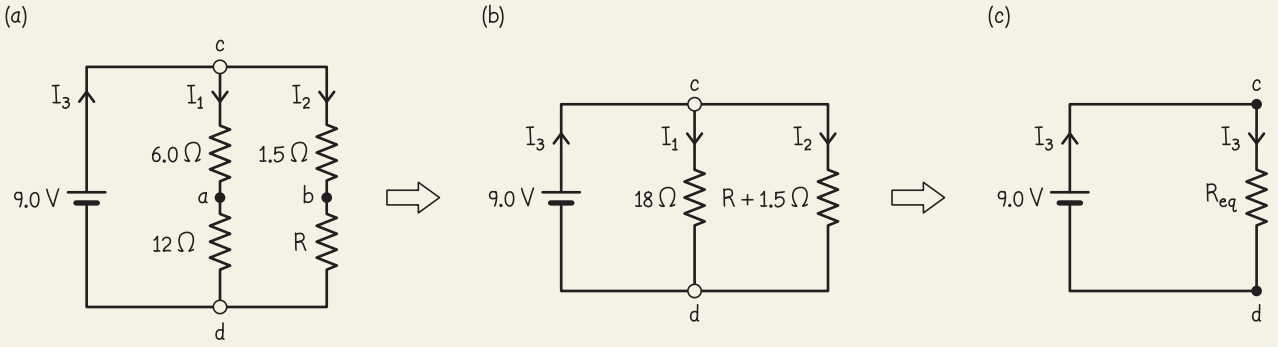
The magnitude of the potential difference across the resistor with resistance R_1 is therefore $|-I_1R_1| = (0.010\text{ A})(300\ \Omega) = 3.0$ V. ✔

❹ **EVALUATE RESULT** I can use my expression for I_1 to determine the potential difference between positions b and e. Going through branch efab, I have $V_{eb} = V_{ef} + V_{fa} + V_{ab} = -I_1R + \mathscr{E} + 0$. Substituting my expression for I_1 (Eq. 5), I get $V_{eb} = \frac{2}{3}\mathscr{E} = +6.0$ V. Going through branch egb, I have $V_{eb} = V_{eg} + V_{gb} = +I_2R + \mathscr{E}$. Because $I_2 = -I_1$ (Eq. 2), this expression gives the same result, $V_{eb} = +6.0$ V. Going through branch edcb and using Eq. 4, I get $V_{eb} = 0 + I_3R + 0 = +2I_1R$. Substituting Eq. 5, I obtain $V_{eb} = \frac{2}{3}\mathscr{E} = +6.0$ V. Because I obtain the same value for the potential difference each time, I am confident that my result for I_1 is correct.

EXAMPLE 31.11 Wheatstone bridge

The circuit shown in **Figure 31.44** includes a variable resistor, the resistance R_{var} of which can be adjusted, and a resistor of unknown value R. A circuit with such a network of resistors is called a *Wheatstone bridge* and can be used to determine the value of the unknown resistance R by adjusting the variable resistor so that the light bulb does not glow. The light bulb is initially glowing when R_{var} is set to 20 Ω, but it goes out when R_{var} is adjusted to 12 Ω. Determine the current in the battery when the light bulb is out.

Figure 31.44 Example 31.11.



❶ **GETTING STARTED** The bulb glows when there is a current in it and stops glowing when the current in it is zero. In the latter case, it doesn't matter whether the bulb is connected or not, so I can omit it from the circuit and simplify the circuit diagram, as shown in **Figure 31.45*a*** on the next page. Because R_{var} is set to 12 Ω, I use that value rather than R_{var}. I use the label I_1 for the current in the branch containing the variable resistor, I_2 for the current in the branch containing R, and I_3 for the current in the battery, which is the current I need to determine.

❷ **DEVISE PLAN** In order for the current in the bulb to be zero, junctions a and b in Figure 31.44 must be at the same potential, and I must have $V_{ca} = V_{cb}$ and $V_{ad} = V_{bd}$. I can then use Ohm's law to express these two conditions in terms of the unknown resistance R and the currents I_1 and I_2, and solve the resulting set of equations for R. Once I know R, I can further simplify the circuit by replacing the sets of resistors connected in series in each branch by a single equivalent resistor. This yields the circuit shown in Figure 31.45*b*. To determine the current in the battery, I can then replace the two parallel resistors by a single equivalent resistor as in Figure 31.45*c*, and use Eq. 31.34 to determine its resistance.

(Continued)

QUANTITATIVE TOOLS

Figure 31.45

❸ **EXECUTE PLAN** Rearranging the Ohm's law equation (Eq. 31.11) to $V = IR$ and applying it to the two conditions $V_{ca} = V_{cb}$ and $V_{ad} = V_{bd}$, I have, when I travel clockwise in the circuit,

$$-(6.0\ \Omega)I_1 = -(1.5\ \Omega)I_2 \qquad (1)$$

$$-(12\ \Omega)I_1 = -RI_2. \qquad (2)$$

Solving Eq. 1 for I_1 gives me $I_1 = I_2/4$, and substituting this result into Eq. 2 and solving for R give me

$$R = 3.0\ \Omega.$$

With this value of R the resistance in the rightmost branch in Figure 31.45*b* becomes 4.5 Ω. The equivalent resistance of the two parallel resistors is, from Eq. 31.34,

$$R_{eq} = \frac{(18\ \Omega)(4.5\ \Omega)}{18\ \Omega + 4.5\ \Omega} = 3.6\ \Omega.$$

The current in the battery is then

$$I_3 = \frac{\mathscr{E}}{R_{eq}} = \frac{9.0\ \text{V}}{3.6\ \Omega} = 2.5\ \text{A}. \checkmark$$

❹ **EVALUATE RESULT** I can verify that $V_{ca} = V_{cb}$ by calculating I_1 and I_2 and substituting these values in Eq. 1. Applying the junction rule to junction c, I have $I_3 = I_1 + I_2$. I know that $I_1 = I_2/4$, so $I_2 = \frac{4}{5}I_3 = 2.0$ A and $I_1 = \frac{1}{5}I_3 = 0.5$ A. Using these values, I get $V_{ca} = -(6.0\ \Omega)(0.5\ \text{A}) = -3.0$ V and $V_{cb} = -(1.5\ \Omega)(2.0\ \text{A}) = -3.0$ V, so junctions a and b are at the same potential, as I expect when there is no current in the bulb.

Example 31.11 illustrates an alternative to our standard procedure for analyzing circuits. For circuits that contain many junctions and loops, it is sometimes easier to simplify the circuit by replacing part of it with a single equivalent resistance, as I did in Figure 31.45*b* of the example. When you do this, think about what question you ultimately want to answer about the circuit and about which parts of the circuit can be simplified without interfering with solving the problem. In Example 31.11, because what I wanted to determine was the current in the battery, I could replace everything outside the battery by a single equivalent resistor. However, if I had been asked to determine the currents at, say, junction b when the bulb was not glowing, I would have stopped simplifying the circuit at the stage shown in Figure 31.45*b*. Simplifying the circuit to just a single resistor and battery would have made it impossible to determine the current at b because the branch in which junction b is located would be gone from the circuit.

31.17 If R_{var} in Figure 31.44 is adjusted to a little less than 12 Ω, what is the direction of the current in the light bulb?

31.8 Power in electric circuits

At the beginning of this chapter, we gave an operational description of a single-loop circuit as converting electric potential energy from a power source to some other form of energy by driving a current in a load. We also found that the loop rule, which essentially embodies the idea of conservation of energy, is a powerful tool for analyzing circuits.

QUANTITATIVE TOOLS

Let us examine how rapidly the power source in **Figure 31.46** can deliver energy to its load. From Chapter 25 we know that the electrostatic work done on a charge carrier carrying charge q in a time interval Δt as it passes through the load from point a to point b is the negative of the potential difference across the load multiplied by q (Eq. 25.17):

$$W_q(\text{a} \rightarrow \text{b}) = -qV_{\text{ab}}. \tag{31.40}$$

Because V_{ab} is negative, the work done by the power source on the charge carrier is positive, increasing its energy. While it travels through the load, however, this energy is converted to other forms, and so the amount of energy converted in the load is given by

$$\Delta E = -qV_{\text{ab}}. \tag{31.41}$$

To determine the rate at which energy is converted, we substitute this expression into the expression for the average power (time rate of change of energy, Eq. 9.29). We are considering a steady-state situation, average and instantaneous power are the same, so we can drop the subscript av:

$$P \equiv \frac{\Delta E}{\Delta t} = \frac{-qV_{\text{ab}}}{\Delta t} = -IV_{\text{ab}}. \tag{31.42}$$

The form of energy to which the electric potential energy in a circuit is converted depends on the type of load. When the load is a light bulb, for example, the conversion is from electric potential energy to light and thermal energy. When the load is an electric motor, the conversion is to kinetic energy as, say, the blades of a fan start rotating. Here we're interested in circuits in which the load is a resistor, in which case the conversion is to thermal energy. Substituting $V_{\text{ab}} = -IR$ in Eq. 31.42 gives us, for the rate at which energy is dissipated in a resistor,

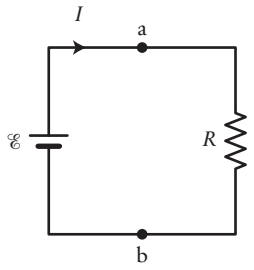
$$P = I^2R. \tag{31.43}$$

It can also be useful to know the rate at which energy is dissipated in terms of the potential difference across the resistor. Substituting $-V_{\text{ab}}/R$ for I in Eq. 31.43 yields

$$P = \frac{V_{\text{ab}}^2}{\text{R}}. \tag{31.44}$$

Keep in mind that although Eq. 31.42 is valid for any electrical device, we have derived Eqs. 31.43 and 31.44 using Ohm's law for resistors, in which electric potential energy is converted to thermal energy.

We can apply a similar reasoning to the power source. Let's consider the case of a battery as the power source. When a charge carrier carrying charge q moves from the negative terminal to the positive terminal inside the battery, its electric potential energy increases at a rate given by



$$P = \frac{q\mathscr{E}}{\Delta t} = I\mathscr{E}. \tag{31.45}$$

For an ideal battery $\mathscr{E} = IR$ (Eq. 31.24), and so Eq. 31.45 becomes

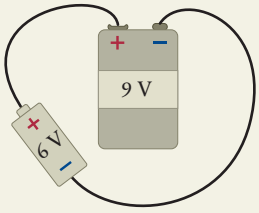
$$P = I\mathscr{E} = I^2R. \tag{31.46}$$

Comparing Eqs. 31.46 and 31.43, we see that the rate at which electric potential energy increases in the battery is equal to the rate at which

Figure 31.46 A battery delivers energy to a load connected to it.

electric potential energy is dissipated in the load. For a nonideal battery, some energy is dissipated inside the battery. As we have seen in Example 31.9, we can account for this dissipation by attributing an internal resistance R_{batt} to the battery. This internal resistance decreases the potential difference across the terminals: $V_{ba} = \mathscr{E} - IR_{batt}$, so $\mathscr{E} = V_{ba} + IR_{batt}$. Substituting this expression and $V_{ba} = IR$ into Eq. 31.45 yields

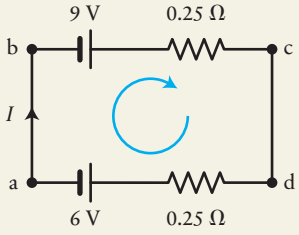
$$P = I\mathscr{E} = IV_{ba} + I^2R_{batt} = I^2R + I^2R_{batt}. \tag{31.47}$$



So for a nonideal battery the rate at which chemical energy is converted is equal to the sum of the rates at which energy is dissipated in the load and inside the battery, as we would expect.

31.18 The SI units of power suggested by Eqs. 31.42 and 31.43 are A · V and $A^2 \cdot \Omega$, respectively. Show that these SI units are equivalent to the derived SI unit for power, the watt.

EXAMPLE 31.12 Battery to battery



A 9.0-V and a 6.0-V battery are connected to each other (Figure 31.47). Each battery has an internal resistance of 0.25 Ω. At what rate is energy dissipated in the 6.0-V battery?

Figure 31.47 Example 31.12.

❶ **GETTING STARTED** I begin by drawing a circuit diagram for the two-battery combination, representing the internal resistance by two resistors in series with the batteries (Figure 31.48). I note that the negative terminals of the batteries are connected to each other, and the positive terminals are connected to each other. I arbitrarily choose clockwise both for the reference direction for the current and for my travel around the circuit.

Figure 31.48

❷ **DEVISE PLAN** Because this circuit contains only one loop and no junctions, the current is the same everywhere in the circuit. To determine the current, I apply the loop rule and solve the resulting equation for the current. I can then apply Eq. 31.43 to determine the rate at which energy is dissipated in the 6.0-V battery.

❸ **EXECUTE PLAN** As I travel clockwise around the circuit starting at a, the loop rule yields

$$9.0\ \text{V} - I(0.25\ \Omega) - I(0.25\ \Omega) - 6.0\ \text{V} = 0$$

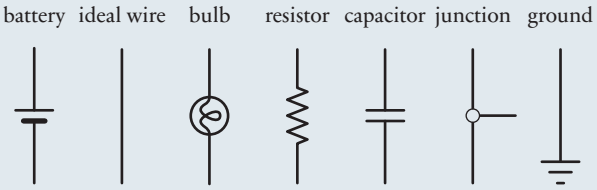
$$I = \frac{9.0\ \text{V} - 6.0\ \text{V}}{0.50\ \Omega} = \frac{3.0\ \text{V}}{0.50\ \Omega} = 6.0\ \text{A}.$$

The fact that I get a positive value for the current tells me that my assumed reference direction for the current (clockwise) is correct. Energy is dissipated in the 6.0-V battery as resistive losses in the internal resistance. Using Eq. 31.43 for the rate at which energy is dissipated in a resistor, I get

$$P = I^2R = (6.0\ \text{A})^2(0.25\ \Omega) = 9.0\ \text{W}. \checkmark$$

❹ **EVALUATE RESULT** Even though the internal resistance is small, this power is substantial because the current is large. The current is large because there is very little resistance in the circuit. It's not a good idea to connect two batteries of different emf values in this manner!

31.19 (*a*) In Example 31.12, how would the answer change if we had chosen a counterclockwise travel direction around the circuit? (*b*) At what rate is energy dissipated in the 9-V battery?



QUANTITATIVE TOOLS

Chapter Summary

The basic circuit (Section 31.1)

Concepts An **electric circuit** is an interconnection of electrical components (*circuit elements*). A **loop** is any closed conducting path through a circuit. A **power source** is any device that provides electric potential energy to an electric circuit. The potential difference across the terminals of the power source drives charge carriers through the circuit and thereby creates a current in the circuit. The **load** in an electric circuit is all the circuit elements connected to the power source. In the load, electric potential energy is converted to other forms of energy.

Quantitative Tools Standard representations of some common circuit elements used in circuit diagrams:

Current and resistance (Sections 31.2, 31.4, 31.5, 31.8)

Concepts A circuit is in **steady state** when the current has a constant value at all points in the circuit. The **current continuity principle** states that in steady state, the current is the same at all locations along a single-loop circuit.

The **resistance** of a circuit element is a measure of the potential difference across that element for a given current in it. The SI unit of resistance is the **ohm** Ω, where $1\Omega \equiv 1\ \text{V/A}$. The **conductivity** σ of a material is a measure of its ability to conduct charge carriers through the material and is measured in SI units of $\text{A}/(\text{V}\cdot\text{m})$.

When there is a current in a conductor, there must be an electric field in the conductor to cause the current. In a conductor of uniform cross section at steady state, this electric field has the same magnitude everywhere and is parallel to the walls of the conductor.

The **drift velocity** $\vec{v}_d$ of the charge carriers in a metal in which a current is present is the average velocity with which the carriers are moving.

The **current density** $\vec{J}$ in an electrical conductor is a vector whose direction is the same as the drift velocity direction when the charge carriers are positive and opposite the drift velocity direction when the charge carriers are negative.

Quantitative Tools The magnitude J of the **current density** is

$$J \equiv \frac{|I|}{A} = n|q|v_d, \tag{31.5}$$

where n is the number of charge carriers per unit volume of the conductor and v_d is the magnitude of the drift velocity of the charge carriers. If the electric field in a metal is $\vec{E}$, the **drift velocity** of the charge carriers (free electrons) is

$$\vec{v}_d = -\frac{e\vec{E}}{m_e}\tau, \tag{31.3}$$

where m_e is the mass of an electron and τ is the average time interval between collisions of the electrons with the metal ions.

The **conductivity** of a metal is

$$\sigma \equiv \frac{J}{E} = \frac{ne^2\tau}{m_e}. \tag{31.8, 31.9}$$

The **resistance** of any circuit element is

$$R \equiv \frac{V}{I}, \tag{31.10}$$

where V is the applied potential difference across the element and I is the resulting current in the element. If the curve of I versus V for a conductor is a straight line, the conductor obeys **Ohm's law**, $I = V/R$ (Eq. 31.11), and we call it *ohmic*.

The resistance of a conductor of length ℓ and cross-sectional area A is

$$R = \frac{\ell}{\sigma A}. \tag{31.14}$$

The rate at which energy is dissipated in a resistor is

$$P = I^2R. \tag{31.43}$$

The rate at which a power source delivers energy is

$$P = I\mathscr{E}, \tag{31.45}$$

where $\mathscr{E}$ is the emf of the source.

Circuit loops (Sections 31.3, 31.6, 31.7)

Concepts A **junction** is a location in a circuit where more than two wires are connected. A **branch** in a circuit is a conducting path between two junctions that is not intercepted by another junction. According to the **branch rule,** the current in a branch of a multiloop circuit is the same throughout the branch.

Two or more circuit elements are connected in *series* if there is only a single current path through them and the charge carriers flow through one element after the other. The potential difference across circuit elements connected in series is equal to the sum of the individual potential differences across each circuit element.

Two or more circuit elements are connected in *parallel* if their ends are connected to the same two junctions. The potential differences across circuit elements connected in parallel are always equal.

Quantitative Tools By the **loop rule,** the sum of the emfs and the potential differences around any loop under steady-state conditions is zero:

$$\Sigma\mathscr{E} + \Sigma V = 0. \tag{31.21}$$

For a steady-state multiloop circuit, the **junction rule** states that the sum of the charge carriers going into a junction equals the sum of the carriers coming out of that junction:

$$I_{\text{in}} = I_{\text{out}}. \tag{31.27}$$

See the Procedure boxes "Applying the loop rule in single-loop circuits" and "Analyzing multiloop circuits."

The **equivalent resistance** of resistors *in series* is given by

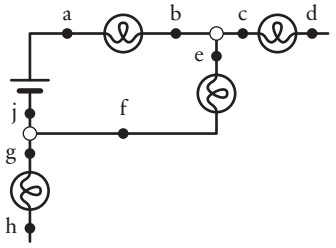
$$R_{\text{eq}} = R_1 + R_2 + R_3 + \cdots. \tag{31.26}$$

The **equivalent resistance** of resistors *in parallel* is given by

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots. \tag{31.33}$$

Questions and Problems

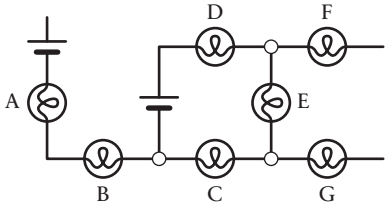
For instructor-assigned homework, go to Mastering Physics



Dots indicate difficulty level of problems: • = *easy,* •• = *intermediate,* ••• = *hard;* CR = *context-rich problem.*

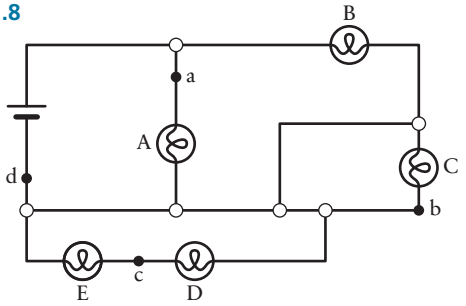
Unless instructed otherwise, assume all batteries and all wires in circuits are ideal and thus have zero (internal) resistance.

31.1 The basic circuit



1. A battery that initially contains 3.0×10^{24} electrons is used to power a light bulb for some time interval, pumping 1.1×10^{24} electrons through the bulb during that interval. How many electrons remain in the battery? •
2. How can the energy conversions in an electric circuit be represented in terms of two generalized circuit elements? •
3. A battery and four identical light bulbs are arranged in the circuit of Figure P31.3. Rank the current magnitudes at the nine lettered locations from greatest to smallest. •

Figure P31.3

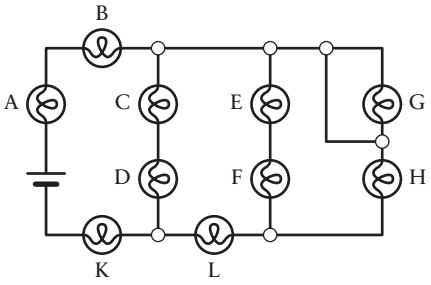


4. Which of the seven identical light bulbs in the circuit of Figure P31.4 light up? •

Figure P31.4

5. You have a light bulb, a battery, and one wire (which you cannot cut into two pieces). Draw the four ways of connecting these elements so that the bulb lights up. ••
6. Name any devices other than the three mentioned in Section 31.1—battery, solar cell, and electric generator—that can act as a power source in an electric circuit. ••
7. Draw a circuit diagram for a typical home hair dryer. To which form (or forms) of energy is electric potential energy converted when you use the dryer? ••
8. Figure P31.8 shows five identical light bulbs A–E connected to a battery. Initially, some of the bulbs light up

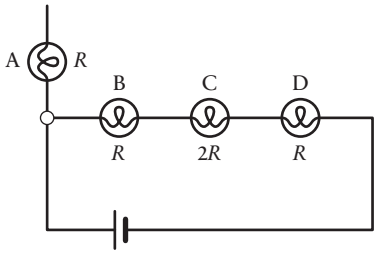
Figure P31.8



because the two terminals of each bulb are connected to opposite terminals of the battery. If any wire in the circuit is cut, some bulbs may go out. Which bulbs, if any, go out when a single cut is made at (*a*) location a, (*b*) location b, (*c*) location c, and (*d*) location d? •••

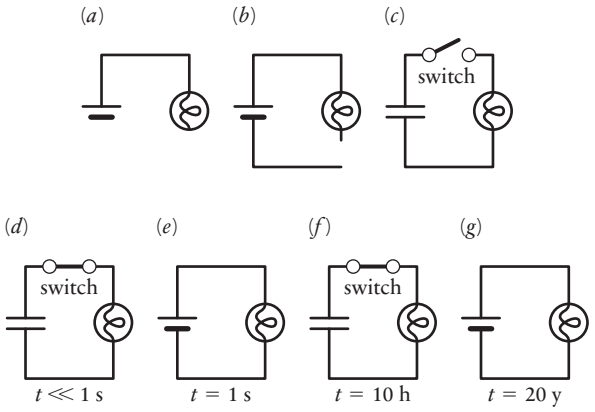
9. You and a colleague want to light a light bulb using a parallel-plate capacitor as a power source. Your colleague objects to this design, stating that the bulb cannot light up if the circuit is not continuous and the circuit is not continuous because the air gap between the capacitor plates constitutes a break in the circuit. He argues that charge carriers do not jump across the gap, so how can there be any current? What is your counterargument? •••

31.2 Current and resistance



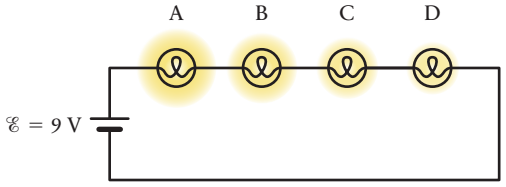
10. Which of the light bulbs (if any) in Figure P31.10 are connected in series to each other? •

Figure P31.10



11. (*a*) In the circuit of Figure P31.11, do all four bulbs light up? (*b*) Rank the bulbs according to how brightly they light up, brightest first. •

Figure P31.11



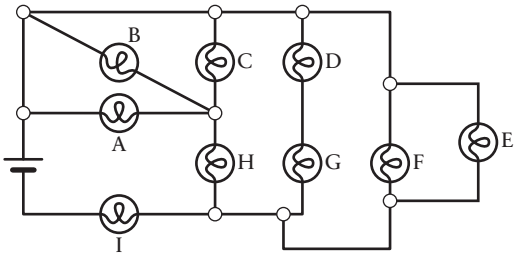
12. All the power sources (batteries or capacitors) in Figure P31.12 start with a potential difference of 9.0 V between their terminals, and all of them run down (decrease in potential difference) over time. Rank the brightness of these identical light bulbs from least bright to most bright. The *t* values in parts *d* through *g* refer to the time interval that has passed since the power source was connected to the load. ••

Figure P31.12

13. In Figure P31.13, bulb A is brighter than bulb B, B is brighter than C, and C is brighter than D. Is it possible for the potential difference across bulb C to be (*a*) 3 V and (*b*) 2 V? ••

Figure P31.13

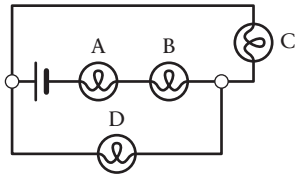
14. When light bulbs A and B are connected in series to a battery, bulb A glows brightly and bulb B glows dimly. You remove bulb B so that the circuit contains just the battery and bulb A, and you connect bulb B to an identical battery. With the two bulbs connected to identical batteries but in separate circuits, do the bulbs glow equally brightly now? ••



15. The bulbs A, B, C, and D are connected in series with a 12.0-V battery, and the steady current through bulb A is 1.0 A. Bulbs B and C, respectively, produce twice and three times as much light and thermal energy as bulb A and bulb D produces the same as bulb B. In 2.0 s, how much energy is dissipated as light and thermal energy by each bulb? •••

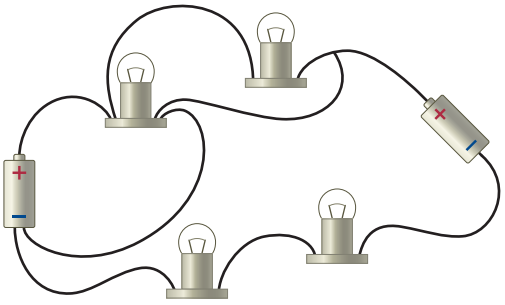
31.3 Junctions and multiple loops

16. Wires A, B, C, D, and E meet at a junction point O. The current in wire D and E is twice as in wire A and four times as in C, respectively. The current in wire A is 4.2 mA into the junction, and the current in wire C is 5.6 mA out of the junction. What is the current in wire B, and in what direction—into or out of the junction—is the current? •



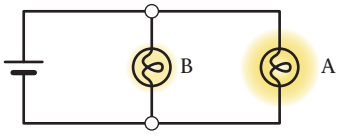
17. Which (if any) of the light bulbs in Figure P31.17 are connected to other bulbs in parallel? •

Figure P31.17



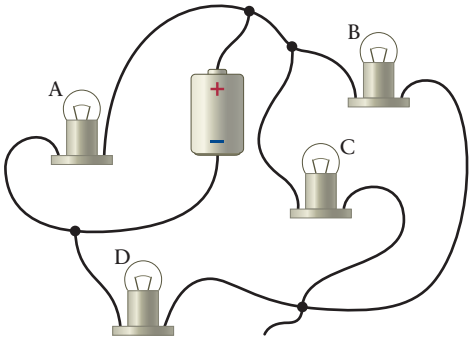
18. Which of the light bulbs in Figure P31.18 are connected to each other in series? Which are connected to each other in parallel? •

Figure P31.18



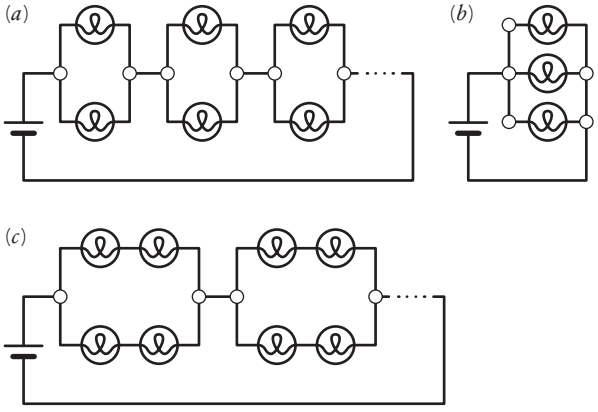
19. Draw a circuit diagram for the circuit of Figure P31.19. ••

Figure P31.19



20. In the circuit of Figure P31.20, bulb A is bright and bulb B is dim. Which bulb (*a*) has the greater potential difference across it, (*b*) carries the greater current, and (*c*) has the greater resistance? ••

Figure P31.20

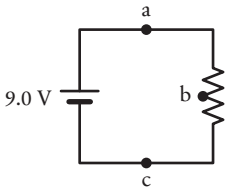


21. (*a*) Draw a circuit diagram for the circuit shown in Figure P31.21, which consists of a battery and four identical light bulbs. (*b*) Do all the bulbs light up? (*c*) Which bulb is brightest? Dimmest? (*d*) Which bulbs are connected to each other in parallel? Which are connected in series? ••

Figure P31.21

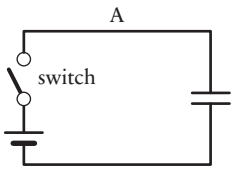
22. Decades ago, holiday lights were wired in series, so that if one bulb in a string burned out, all the lights in the string went dark because the burned-out bulb interrupted the circuit. Today's lights are wired at least partially in parallel, so that if one light goes out, many others in the string remain lit. In which circuits in Figure P31.22 does one bulb burning out leave all other bulbs lit? In which does one bulb burning out cause one or more of the other bulbs to go out? ••

Figure P31.22



23. Are the lights in a house wired in series, in parallel, or a combination of the two? •••

31.4 Electric fields in conductors



24. In Figure P31.24, the wire connecting the positive battery terminal to the top end of the resistor is 100 mm long, and the wire connecting the negative battery terminal to the bottom end of the resistor is also 100 mm long. If the resistor is 10 mm long, what are the electric field magnitudes at locations a, b, and c? •

Figure P31.24

25. Once the switch in the circuit in Figure P31.25 is closed, the circuit can be used to charge the capacitor. Sketch the electric field inside wire A (*a*) when the switch is open, (*b*) at the instant just after the switch is closed, and (*c*) at some instant long after the switch is closed. •

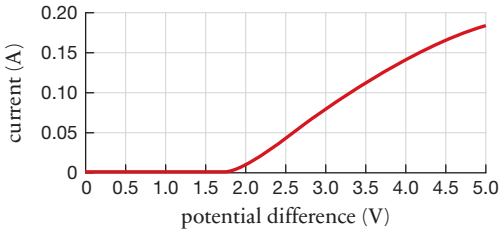
Figure P31.25

26. (*a*) Given a copper wire with radius 850 μm carrying a uniform current of 25 mA, calculate the magnitude of electric field applied to this wire. (*b*) We have given two types of wire made up of copper and aluminum. If these wires are of the same length, radius, and carry same current, which wire has higher electric field? ••

27. You want to use a length of insulated rigid metal rod to discharge the plates of a parallel-plate capacitor without allowing the electric field in the rod to exceed 1000 N/C. The area A of each square plate is 1.00 m^2, the plate separation distance is $d = 100$ mm, and there is no dielectric material between the plates. Initially, each plate holds a charge of magnitude 4.51×10^{-8} C. If one end of the rod is attached to the center of one edge of plate 1, describe all the positions on plate 2 to which the other end of the rod could be attached. Illustrate your answer with a sketch. •••

31.5 Resistance and Ohm's law

28. Given a copper wire of length 100 cm, radius 0.8 mm, and resistivity $1.68 \times 10^{-8}\ \Omega \cdot$m, find its resistance and current through the wire if connected to a 20.0-V battery. If the wire is stretched uniformly to 4 times its original length, what will be its new resistance? •



29. To connect two devices, you need a 40 m long copper wire. If the needed resistance of the wire is 0.5 Ω, then what should be the diameter of the wire? If the voltage drop across the wire is 10.0-V, then what is the current flow to each device? [$\rho_{\text{copper}} = 1.68 \times 10^{-8}\ \Omega \cdot$m] •

30. Determine the current density when 5.0 A of current is flowing through a copper wire of radius 0.6 mm. By what amount does current density change if the wire's radius is doubled?

31. How strong must an electric field in a metal be in order for electrons in the field to have a drift speed of 10 mm/s if the time interval between electron-ion collisions is 1.0×10^{-14} s? •

32. Figure P31.32 is a graph of the current through a light-emitting diode as a function of the potential difference across the diode. What is the resistance of the diode at a potential difference of 3.0 V? ••

Figure P31.32

33. *Gauge* is a term used to describe the size of a wire: The greater the gauge, the smaller the wire diameter. At room temperature, 6-gauge wire has a diameter of 4.115 mm, and 22-gauge wire has a diameter of 0.644 mm. For copper, how long would a wire of each gauge need to be to have a resistance of 0.5 Ω [$\sigma_{\text{copper}} = 5.9 \times 10^7\ \text{A}/(\text{V} \cdot \text{m})$]? ••

34. Two wires are made of the same material. If both are at the same temperature, but one has twice the diameter and three times the length of the other, which has the greater resistance, and by what factor? ••

35. When a potential difference of 1.00 V is maintained between opposing faces of a metal that has a charge carrier number density of $n = 6.60 \times 10^{28}$ charge carriers/m^3, the cube carries current $I = 6.10 \times 10^5$ A. What is the average time interval τ between collisions in this metal if each side of the cube is 10.0 mm long? ••

36. What is the magnitude of the applied electric field inside an aluminum wire of radius 1.0 mm that carries a 4.0-A current [$\sigma_{\text{aluminum}} = 3.6 \times 10^7\ \text{A}/(\text{V} \cdot \text{m})$]? ••

37. For each of these changes in a metal, predict whether the average time interval between collisions of an electron with a lattice ion increases or decreases: (*a*) spatial density of the lattice ions is increased, (*b*) size of the lattice ions is decreased, (*c*) charge of the lattice ions is increased. ••

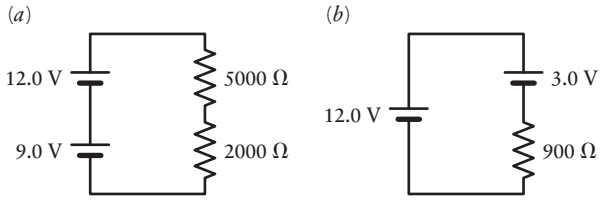
38. In a copper wire that has a diameter of 1.63 mm, the drift velocity is 7.08×10^{-4} m/s. If we assume one free electron per copper atom, what are (*a*) the current in the wire and (*b*) the current density? (*c*) This wire connects a light bulb, power source, and switch in a circuit, and the distance between the switch and bulb is 3.00 m. How long does it take for an electron initially at the switch to reach the bulb? ••

39. In a particle accelerator, the particles in a beam of protons are traveling toward a target at a speed equal to $0.100c_0$. If the beam has a radius of 0.100 μm and carries a current of 2.00 nA, how many protons strike the target in 1.00 s? Assume the target is large enough to intercept the entire beam. •

40. When you step on the brake pedal in your car, charge carriers flow from the battery to the rear brake lights. Suppose the wire connecting the switch at the pedal to the brake lights is made of copper and has a diameter of 1.1 mm. If the current through the wire is 2.0 A, how long on average does it take an electron to travel from the switch at the pedal to one of the brake lights? The number density of free electrons in copper is $n = 8.4 \times 10^{28}$ electrons/m^3. ••

41. Even though silver is a better electrical conductor than copper, most electrical cables are made from copper. The main reason is cost: The per-kilogram price of silver is about 100 times the per-kilogram price of copper. If you want a length ℓ of wire to have a resistance R, by what factor does the cost of silver exceed that of copper? (The mass density of silver is $\rho_S = 10{,}490$ kg/m^3, and that of copper is $\rho_C = 8960$ kg/m^3.) ••

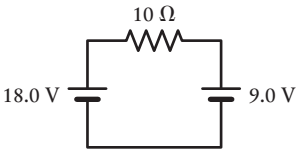
42. You have a piece of copper wire and a piece of carbon rod, each 1.5 m long and each having a cross-sectional area of 8.0×10^{-6} m^2. When you connect the copper wire to the terminals of a 9.0-V battery, the current in the wire is I. If you want to connect the carbon rod to another battery and



have the same current I in the wire, what must the potential difference of the battery be [$\sigma_{copper} = 5.9 \times 10^7$ A/(V·m), $\sigma_{carbon} = 7.3 \times 10^4$ A/(V·m)]? ●●

43. An electric field of magnitude 4.50×10^2 V/m is created in a wire that is 300 mm long and has a radius of 1.00 mm. The number density of the charge carriers in the wire is 1.20×10^{27} charge carriers/m^3. How much energy is gained by the lattice of metal ions in the time interval it takes for the average electron to travel the length of the wire? ●●●

31.6 Single-loop circuits



44. What are the magnitude and direction of the current in each circuit in Figure P31.44? ●

Figure P31.44

45. What are the magnitude and direction of the current in the circuit in Figure P31.45? ●

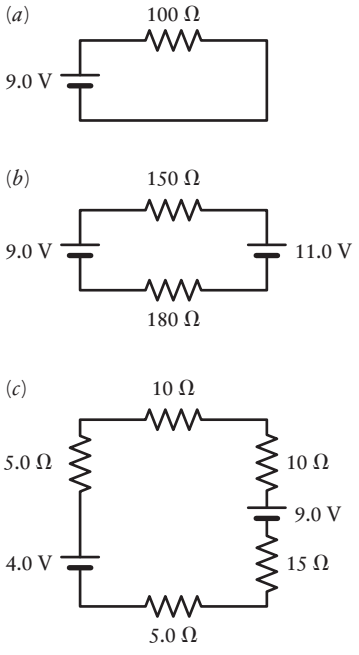


Figure P31.45

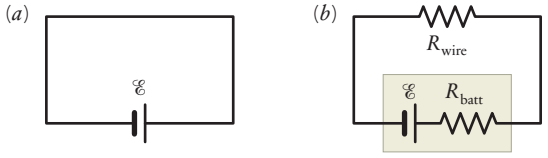
46. Three resistors are connected in series to a battery providing an emf of 24 V. If the resistances are $R_1 = 8\ \Omega$, $R_2 = 5\ \Omega$, and $R_3 = 3\ \Omega$, what is the current that flows through the 8-Ω resistor (*a*) if the battery is ideal and (*b*) if the battery has an internal resistance of 2.0 Ω? ●

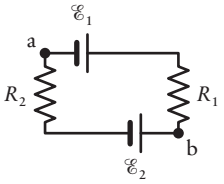


47. What are the magnitude and direction of the current in each circuit in Figure P31.47? ●●

Figure P31.47

48. When using the loop rule, what problems do you encounter with the circuit in Figure P31.48*a*? What do you expect for the current in the more realistic circuit in Figure P31.48*b*, which includes a small nonzero resistance in the wire and internal resistance in the battery? ●●

Figure P31.48



49. A nonideal battery connected to a resistor R_1 in a circuit results in the current I_1, if the same battery connected to a resistor R_2 gives current I_2. (*a*) What should be the value of R_2 for which the internal resistance is zero? (*b*) If $R_2 = 2R_1$ and $I_1 = 2I_2$, calculate the emf of the battery in terms of R_1 and I_1. ●●

50. List all the different resistances one can obtain using three resistors, each of value 50 Ω. ●●

51. The potential difference between positions a and b in Figure P31.51 is 6 V, and $R_1 = 4.0\ \Omega$, $\mathscr{E}_1 = 10.0$V, and $\mathscr{E}_2 = 5.0$ V. What is the value of the resistance R_2? ●●

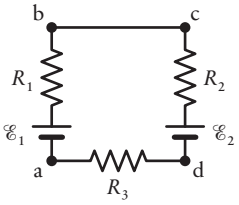


Figure P31.51

52. A typical car battery can be modeled as an ideal source $\mathscr{E}$ connected in series with an internal resistance R_{batt}. Using a good battery of this design to "jump start" a dead one can be dangerous if done incorrectly. (*a*) If you want to connect a good battery to a dead one in such a way that you have the smallest possible current through the dead one, should you connect them in series (+ to − and − to +) or in parallel (+ to + and − to −)? Assume you have a good battery for which $\mathscr{E}_{good} = 12.0$ V and $R_{batt,\,good} = 0.0200\ \Omega$ and a dead one for which $\mathscr{E}_{dead} = 11.0$ V and $R_{batt,\,dead} = 0.200\ \Omega$. Calculate the current through the batteries connected (*b*) in series and (*c*) in parallel. ●●

53. For the circuit shown in Figure P31.53, calculate (*a*) the magnitude and direction of the current and (*b*) the potential differences V_{ab}, V_{bc}, V_{cd}, and V_{da}. Use these values: $R_1 = 4.0\ \Omega$, $R_2 = 2.0\ \Omega$, $R_3 = 6.0\ \Omega$, $\mathscr{E}_1 = 4$ V, and $\mathscr{E}_2 = 8$ V. ●●

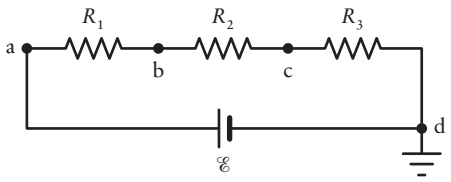

Figure P31.53

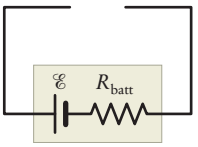
54. The internal resistance of a battery is relatively small when the battery is new but increases as the battery ages. When a new 12.0-V battery is attached to a 100-Ω load, the potential difference across the load is 11.9 V. After the circuit has operated for a while, the potential difference across the load is 11.5 V. By how much has the internal resistance of the battery changed? ••

55. (*a*) What is the equivalent resistance of the circuit in Figure P31.55? Use the values $R_1 = 10\ \Omega$, $R_2 = 60\ \Omega$, and $R_3 = 5\ \Omega$. (*b*) What is the current in the circuit? Assume $\mathscr{E} = 15$ V. (*c*) The electric potential at location d is defined to be 0, because the negative terminal of the battery is attached to ground. What is the electric potential at locations *a*, *b*, and *c*? ••

Figure P31.55



56. Resistors 1 and 2—$R_1 = 40\ \Omega$, $R_2 = 70\ \Omega$—are connected in series to a 4.5-V battery. (*a*) What is the potential difference across resistor 1? (*b*) If you decrease the value of R_1, what happens to the current in the circuit and to the potential difference across resistor 1? ••

57. A light bulb has resistance $R_{\text{bulb}} = 5.0\ \Omega$ and should be operated at a potential difference of $V_{\text{bulb}} = 3.0$ V. If you must use this bulb in a circuit powered by a battery of emf $\mathscr{E} = 9.0$ V, how much resistance must you add in series to the circuit in order to have a 3.0-V potential difference across the bulb? ••

58. You must complete the circuit of Figure P31.58 in such a way that it draws a current of 0.300 A from the battery. The battery maintains a potential difference of 10.0 V with no load, but has an internal resistance of $R_{\text{batt}} = 18.0\ \Omega$. The only material you have is 20.0 mm^3 of nichrome, and you must use all of it. If your plan is to form the nichrome into a cylindrical resistor, what must the cylinder length and cross-sectional area be? [The conductivity of nichrome is $6.7 \times 10^5\ \text{A/(V·m)}$.] •••

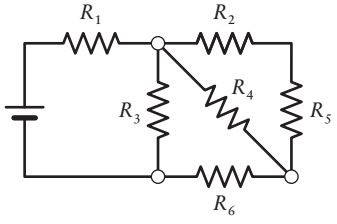


Figure P31.58

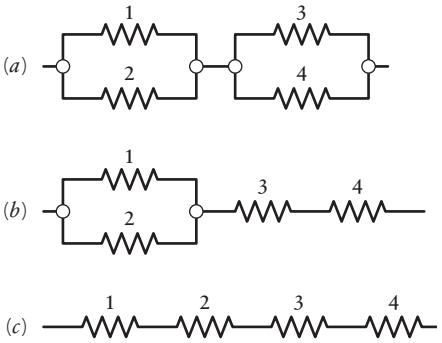
31.7 Multiloop circuits



59. What is the equivalent resistance of the circuit in Figure P31.59? Use the values $R_1 = 4.0\ \Omega$, $R_2 = 2.0\ \Omega$, $R_3 = 1.0\ \Omega$, $R_4 = 3\ \Omega$, $R_5 = 1.0\ \Omega$, and $R_6 = 2.5\ \Omega$. •

Figure P31.59

60. Figure P31.60 shows three circuits containing four identical resistors, each having resistance *R*. Which circuit has the smallest equivalent resistance? Which has the greatest equivalent resistance? •

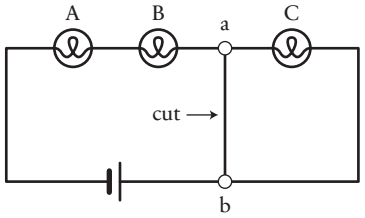


Figure P31.60

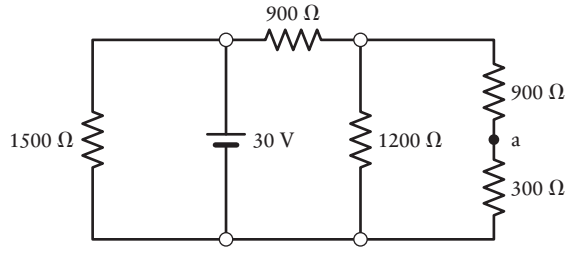
61. A nonideal ammeter that has an internal resistance of 0.503 Ω is connected in series with a 3.00-V battery and a 40.0-Ω resistor. By what percentage does the measured current differ from that of the same circuit with no ammeter? •

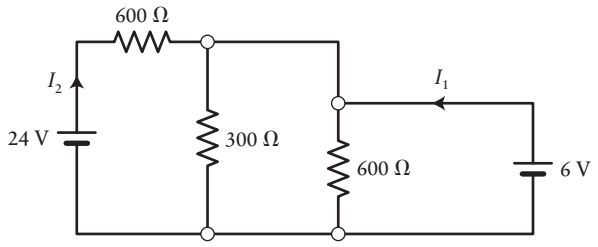
62. In Figure P31.62, the brightness of each bulb depends on the magnitude of the current through it. Rank these identical bulbs according to brightness, brightest first, (*a*) before the wire ab connecting the two junctions is cut and (*b*) after the wire is cut. (*c*) Does cutting the wire increase or decrease the brightness of A? Of B? Of C? ••

Figure P31.62



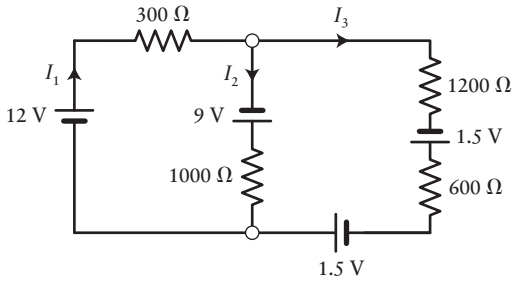
63. Using only 10.0-Ω resistors (but as many as you like), build a circuit that has a resistance of 27.5 Ω. ••

64. A copper wire has a diameter of 0.20 mm and is $\ell_{\text{wire}} = 10$ m long. (*a*) What is the resistance of the wire? (*b*) The wire is cut into *N* identical pieces, and the pieces are connected in parallel to form a single resistor. What is the minimum value of *N* that gives this resistor a resistance smaller than $R_{\text{resistor}} = 1.0\ \Omega$? [The conductivity of copper is $5.9 \times 10^7\ \text{A/(V·m)}$.] ••



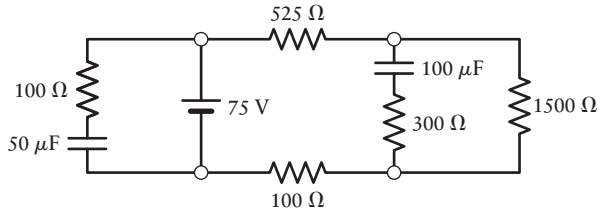
65. For the circuit in Figure P31.65, take the electric potential to be zero at the negative terminal of the battery. Calculate (*a*) the equivalent resistance of the circuit, (*b*) the electric potential at position a, and (*c*) the magnitude and direction of the current through each resistor. ••

Figure P31.65



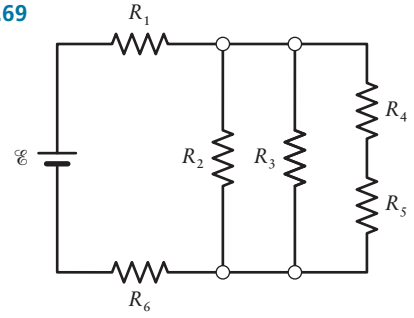
66. In Figure P31.66, determine the magnitude of current I_1. ●●

Figure P31.66



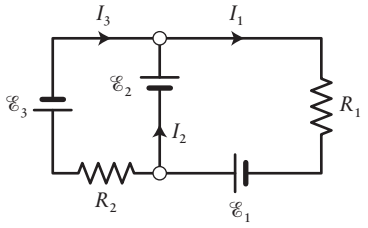
67. In Figure P31.67, calculate the magnitudes of currents I_1, I_2, and I_3. ●●

Figure P31.67



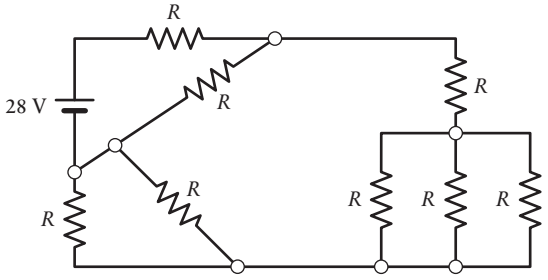
68. In Figure P31.68, the circuit has been completed for several minutes. Calculate (*a*) the current through each resistor and (*b*) the magnitude of charge on each capacitor plate. ●●

Figure P31.68



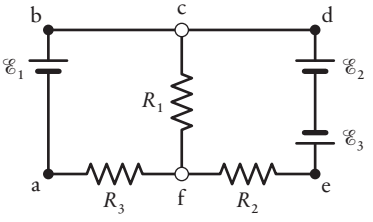
69. In Figure P31.69, calculate (*a*) the equivalent resistance of the circuit and (*b*) the magnitude of the current through each resistor. Use these values: $R_1 = 1.2\ \Omega$, $R_2 = 2.0\ \Omega$, $R_3 = 2.0\ \Omega$, $R_4 = 1.0\ \Omega$, $R_5 = 3.0\ \Omega$, $R_6 = 1.0\ \Omega$, and $\mathscr{E} = 12$ V. ●●

Figure P31.69



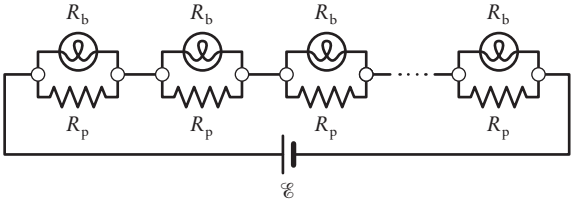
70. In Figure P31.70, determine the magnitudes of the currents I_1, I_2, and I_3 and whether the direction shown for each current is correct or should be reversed. Assume that $R_1 = 3.0\ \Omega$, $R_2 = 6.0\ \Omega$, $\mathscr{E}_1 = 12.0$ V, $\mathscr{E}_2 = 9.0$ V, and $\mathscr{E}_3 = 6$ V. ●●

Figure P31.70



71. The eight resistors in Figure P31.71 are identical to one another, all having resistance $R = 200\ \Omega$. What is the magnitude of the current drawn from the battery? ●●

Figure P31.71



72. In Figure P31.72, $\mathscr{E}_1 = 5.0$ V, $\mathscr{E}_2 = 5.0$ V, $\mathscr{E}_3 = 1.5$ V, $R_1 = 50\ \Omega$, $R_2 = 50\ \Omega$, and $R_3 = 50\ \Omega$. What are (*a*) the current in each branch of the circuit and (*b*) the potential differences V_{ab}, V_{bc}, V_{cd}, V_{de}, V_{ef}, and V_{fa}? ●●

Figure P31.72

73. A string of winter holiday lights consists of N bulbs, each having resistance R_b (Figure P31.73). Wired in parallel with each bulb is a resistor of resistance R_p. What is the resistance of the string? If one of the bulbs burns out, what happens to the other $N - 1$ bulbs? ●●

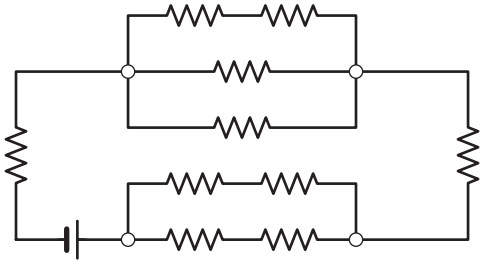


Figure P31.73

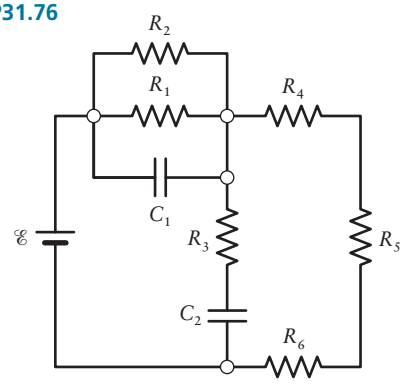
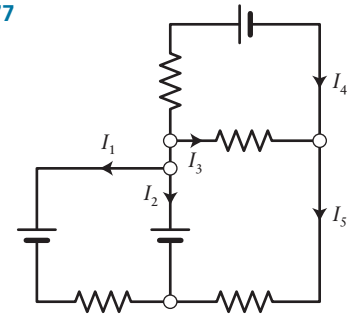
74. An ammeter that has internal resistance $R_{am} = 0.504\ \Omega$ is designed to measure a maximum current of $I_{max} = 100$ mA. You want to use this ammeter to measure the current in a circuit that consists of a 3.00-V battery and a resistor that has a resistance of 4.00 Ω. (*a*) What problem do you encounter? (*b*) How can you overcome this problem by inserting a second resistor into the circuit and rescaling the meter readout (that is, by multiplying the readout value by some constant)? ••



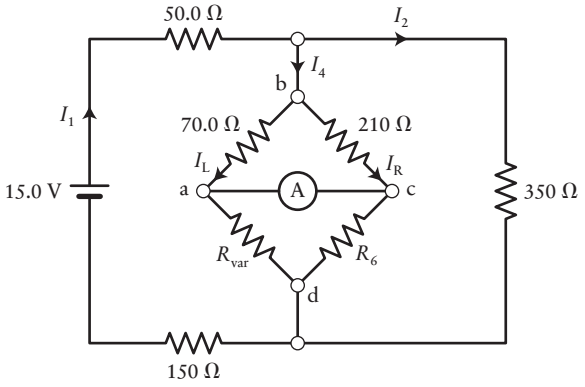
75. If each resistor in Figure P31.75 has resistance $R = 5.0\ \Omega$, what is the equivalent resistance of the combination? ••

Figure P31.75



76. In Figure P31.76, $R_1 = 2.0\ \Omega$, $R_2 = 1.5\ \Omega$, $R_3 = 2.0\ \Omega$, $R_4 = 1.0\ \Omega$, $R_5 = 2.0\ \Omega$, $R_6 = 1.0\ \Omega$, $C_1 = 20\ \mu$F, $C_2 = 40\ \mu$F, and $\mathscr{E} = 12.0$ V. Assume that the circuit has been connected for several minutes. (*a*) Calculate the current through the battery and through each resistor. (*b*) Compute the magnitude of charge on each plate of both capacitors. •••

Figure P31.76



77. In Figure P31.77, each of the three batteries supplies an emf of 6.0 V and each of the four resistors has a resistance of 3.0 Ω. Calculate the magnitudes of the five currents I_1–I_5. •••

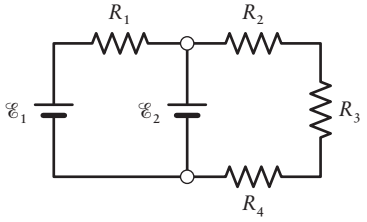
Figure P31.77

78. If the ammeter in the Wheatstone bridge of Figure P31.78 measures zero current when the resistance R_{var} of the variable resistor is set to 185 Ω, what is the current I_L through the left side of the bridge? •••

Figure P31.78

31.8 Power in electric circuits

79. If a light bulb has a resistance of 5.5 Ω and is dissipating energy at a rate of 9.0 W, what are (*a*) the current through the bulb and (*b*) the potential difference across its terminals? •



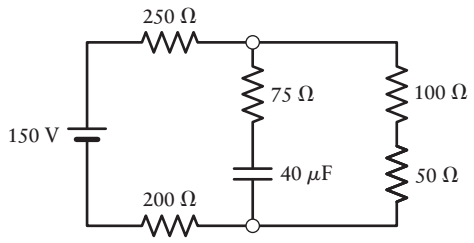
80. Three resistances R, $2R$, and $3R$ are connected in parallel in an electric circuit. Find the ratio of energy dissipation in R, $2R$, and $3R$. •

81. Two light bulbs 1 and 2 are connected in parallel to an 8.00-V battery. (*a*) If the bulb resistances are $R_1 = 4.0\ \Omega$ and $R_2 = 6.0\ \Omega$, what is the rate at which each bulb consumes energy? (*b*) At what rate does the circuit consume energy? (*c*) Calculate the same three power values for the bulbs connected in series rather than in parallel. •

82. A car battery is labeled "12 V 40 Ah." You forget to switch off the light in your glove compartment, which draws 0.80 A. How long until the battery is drained? •

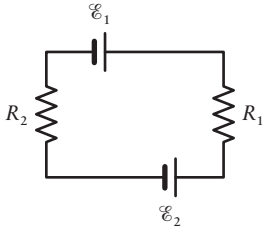
83. (*a*) Determine the current through and the potential difference across each resistor in Figure P31.83. Assume that $R_1 = R_2 = R_3 = R_4 = 3.0\ \Omega$, $\mathscr{E}_1 = 9.0$ V, and $\mathscr{E}_2 = 4.5$ V. (*b*) At what rate is energy dissipated in each resistor? (*c*) What is the power of each battery, and is energy used by or supplied by each battery? ••

Figure P31.83



84. The current through a 60-W light bulb is 2 A when connected to a nonideal battery with emf $\mathscr{E} = 120$ V. Determine the bulb's resistance and internal resistance of the battery. ••

85. Determine the current through each resistor and the magnitude of the charge on either capacitor plate after



the circuit in Figure P31.85 has been connected for a few minutes. ••

Figure P31.85

86. If the rate at which energy is dissipated by resistor 1 in Figure P31.86 is 2.5 W, and $R_1 = 10\ \Omega$, $\mathscr{E}_1 = 12$ V, and $\mathscr{E}_2 = 6$ V, (*a*) what is the value of R_2? (*b*) At what rate is energy dissipated in resistor 2? (*c*) Which battery supplies energy to the circuit, and at what rate does it do so? (*d*) At what rate is energy used by the other battery? ••

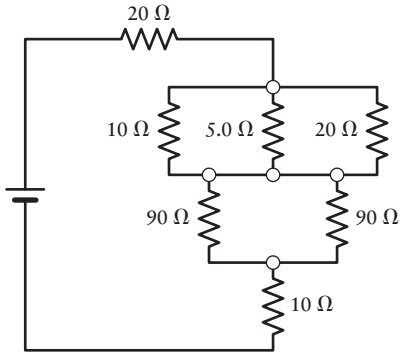


Figure P31.86

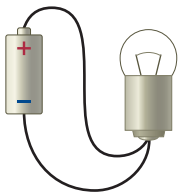
87. We have two types of wire made up of copper and aluminum. (*a*) If these wires are of same length, radius, and carry same current, which wire has higher rate of energy loss? (*b*) For same rate of energy loss, length, and radius for both types of wires, calculate the current in aluminum wire, if 15 A of current flows in the copper wire. ••

88. In Figure P31.88, in which resistor is energy dissipated (*a*) at the greatest rate and (*b*) at the smallest rate? •••

Figure P31.88

89. At what rate is energy either delivered by or delivered to each battery in Figure P31.67? At what rate is energy dissipated in each resistor? Does the power summed over all the elements make sense? •••



90. A physics student who needs a magnetic field for a project makes a solenoid coil from "magnet wire," which is copper wire coated with a very thin enamel insulation. (The insulation is so thin that you can ignore its thickness.) He chose 28-gauge wire, which is 0.321 mm in diameter, and winds a solenoid that is 50 mm in diameter and 0.20 m long. He then runs a 3.0-A current through the solenoid but is disappointed at how small the magnetic field magnitude is and horrified at how hot the magnet gets after a few minutes. Calculate the magnetic field magnitude and the rate at which energy is lost as thermal energy as the coil heats up. What would you suggest the student do to get a greater magnetic field and less thermal energy loss? •••

Additional Problems

91. Consider a strip of material that has a rectangular cross-section with height 310 μm and width 4.2 mm and which carries a uniform current of 5.5 mA. (*a*) What is the current density in the strip? (*b*) If the number density of the charge carrier (conduction electron) is $3.5 \times 10^{23}\ \text{m}^{-3}$, then calculate the drift speed in the strip. •

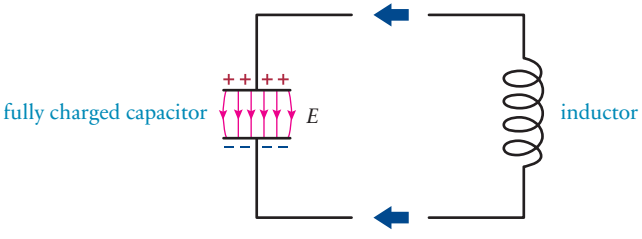
CONCEPTS

QUANTITATIVE TOOLS

In the preceding chapter, we discussed electric circuits in which the current is steady. As noted in that chapter, the steady flow of charge carriers in one direction only is called *direct current*. Batteries and other devices that produce static electrical charge, such as van de Graaff generators, are sources of direct current. Although direct current has many uses, it has several limitations as well. For example, in order to produce substantial currents, direct-current sources must be quite large and are therefore cumbersome. More important, steady currents do not generate any electromagnetic waves, which can be used to transmit information and energy through space, as we saw in Chapter 30.



Because of these and many other factors, most electric and electronic circuits operate with **alternating currents** (abbreviated AC)—currents that periodically change direction. The current provided by household outlets in the United States, for instance, alternates in direction, completing 60 cycles per second (that is, with a frequency of 60 Hz), and the currents in computer circuits change direction billions of times per second. It is no understatement to say that contemporary society *depends* on alternating currents.

In this chapter we discuss the basics of both household currents and the electronics that lie at the heart of computers.

32.1 Alternating currents

We have already encountered one example of an electrical device that produces a changing current: a capacitor that is either charging or discharging. Let's consider what happens when we connect an inductor to a charged capacitor (**Figure 32.1**). A circuit that consists of an inductor and a capacitor is called an *LC* circuit. As soon as the two circuit elements are connected, positive charge carriers begin to flow clockwise through the circuit. The magnitude of the current increases from its initial value of zero (**Figure 32.2a**) to a nonzero value (Figures 32.2*b*–*d*). The capacitor discharges through the inductor, and the current causes a magnetic field in the inductor. As the current in the inductor increases, the magnetic field also increases, causing an induced emf (see Section 29.7) that opposes this increase and prevents the current from increasing rapidly. Consequently, the capacitor discharges more slowly than it would if we had connected it to a wire.

Figure 32.1 What happens when we connect an inductor (represented as a coil in circuit diagrams) to a charged capacitor?

32.1 (*a*) Just before the inductor is connected to the charged capacitor, what type of energy is contained in the system comprising the two elements? (*b*) Once the two elements are connected to each other, what happens to that energy? (*c*) Once the capacitor is completely discharged, in what form is the energy in the circuit?

As you saw in Checkpoint 32.1, when the capacitor is completely discharged, all of the energy in an *LC* circuit is contained in the magnetic field and this field reaches its maximum magnitude (Figure 32.2*c*). Because the magnetic energy is proportional to the square of the current in the inductor (Eq. 29.25), the current, too, reaches its maximum value at this instant. Once the magnetic field and the current reach their maximum values, the current begins to charge the capacitor in the opposite direction (Figure 32.2*d*), and the charge on the capacitor increases as the magnetic field in the inductor decreases. When the magnetic field in the inductor is zero, the current is also zero and the capacitor has again maximum charge but with the opposite polarity (Figure 32.2*e*). The process then repeats itself with the current in the opposite direction (Figures 32.2*f*–*h*) until the capacitor is restored to its starting configuration. Then the cycle begins again.

Figure 32.3 shows the time dependence of the electric potential energy U^E stored in the capacitor and the magnetic potential energy U^B stored in the inductor. In the absence of dissipation, the energy in the circuit, $U^E + U^B$, must stay constant. Therefore, when the capacitor is not charged and U^E drops to zero, U^B must reach its maximum value, U_{max}.

There is always some dissipation in a circuit. Resistance in the connecting wires gradually converts electrical energy to thermal energy. Consequently, the oscillations decay in the same manner as the damped mechanical oscillations we considered in Section 15.8. Resistance therefore plays the same role in oscillating circuits as damping does in mechanical oscillators.

Throughout this chapter we work with time-dependent potential differences and currents. To make the notation as concise as possible, we represent time-dependent quantities with lowercase letters. In other words, v_C is short for $V_C(t)$ and i is short for $I(t)$. We also need a symbol for the maximum value of an oscillating quantity—its *amplitude* (see Section 15.1). For this we use a capital letter without the time-dependent marker (t); thus V_C is the maximum value of the potential difference across a capacitor, and I is the maximum value of the current in a circuit.

Unlike their counterparts in DC circuits, the potential difference across the capacitor, v_C, and the current in the *LC* circuit, i, change sign periodically. So, when analyzing AC circuits, we must carefully define what we mean by the sign of these quantities. To analyze the *LC* circuit in Figure 32.2, for example, we choose a reference

CONCEPTS

Figure 32.2 A series of "snapshots" showing what happens when we connect an inductor to a charged capacitor.

direction for the current i and let the potential difference v_C be positive when the top capacitor plate is at a higher potential than the bottom plate (**Figure 32.4*a*** on the next page). Note that both of these choices are arbitrary.

Figure 32.4*b* shows graphs for v_C and i with these choices. The potential difference across the capacitor v_C is initially positive, representing the situation at Figure 32.2*a*. During the first quarter cycle (Figure 32.2*b*), the capacitor is discharging and positive charge carriers travel away from the top plate of the capacitor in the chosen reference direction, and so i is positive. In the part of the cycle represented by Figure 32.2*f*, where the capacitor is again discharging, v_C is negative (because the top plate is negatively

CONCEPTS

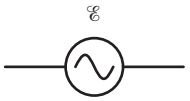

Figure 32.4 For the *LC* circuit shown in Figure 32.2, graphs of the time-dependent potential difference across the capacitor (defined to be positive when the top plate is at the higher potential) and the current in the circuit (defined to be positive when positive charge carriers travel away from the top plate of the capacitor). One cycle is completed in a time interval T (the *period*).

charged) and i is negative (because the direction of current is opposite the chosen reference direction), as shown in the time interval $\frac{1}{2}T < t < \frac{3}{4}T$ in Figure 32.4*b*. (See if you can work out the signs during the time intervals when the capacitor is charging.) Both v_C and i vary sinusoidally in time, with v_C at its maximum when i is zero, and vice versa.

Because of dissipation, the *LC* circuit in Figure 32.1 is not a practical source of alternating current; instead, generators are widely used to produce sinusoidally alternating emfs in a circuit (see Example 29.6). The symbol for a source that generates a sinusoidally alternating potential difference and/or current is shown in **Figure 32.5**; such a source is called an **AC source**. The time-dependent emf an AC source produces across its terminals is designated $\mathscr{E}$, and its amplitude is designated $\mathscr{E}_{max}$.

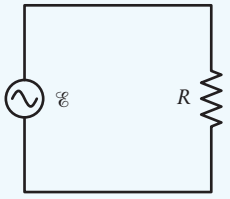

Figure 32.5 Symbol that represents an AC source in an electric circuit. The AC source produces a sinusoidally varying emf $\mathscr{E}$ across its terminals.

EXERCISE 32.1 AC source and resistor

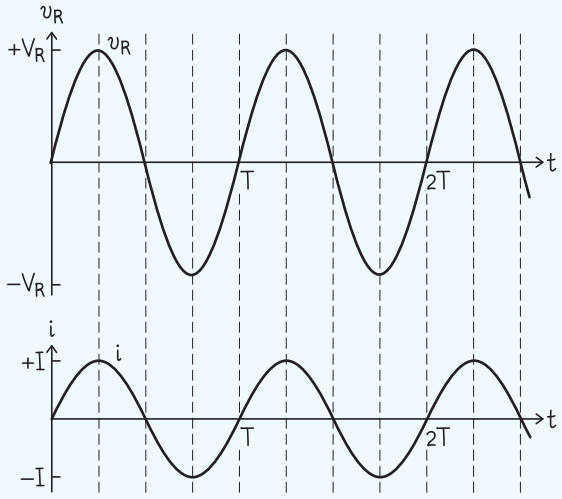

Figure 32.6 shows a circuit consisting of an AC source and a resistor. The emf produced by the generator varies sinusoidally in time. Sketch the potential difference across the resistor as a function of time and the current in it as a function of time.

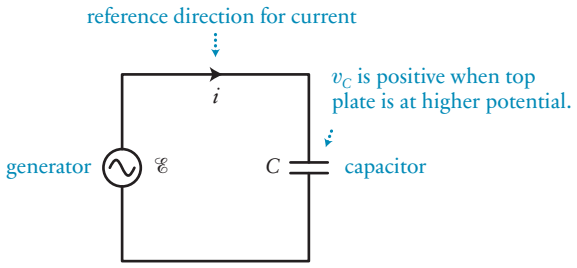
Figure 32.6 Exercise 32.1.

SOLUTION Ohm's law, the junction rule, and the loop rule (see Chapter 31) apply to alternating-current circuits just as they do to direct-current circuits. All I need to remember here is that the potential differences and currents are time dependent. Applying the loop rule to this circuit requires the time-dependent potential difference across the resistor v_R to equal the emf $\mathscr{E}$ of the AC source at every instant, so that the sum of the potential differences around the circuit is always zero. Consequently, v_R oscillates just as $\mathscr{E}$ oscillates, as shown in **Figure 32.7**; V_R is the maximum value of the potential difference across the resistor.

Figure 32.7

Ohm's law requires the time-dependent current i in the resistor to be proportional to v_R, which means that i also oscillates, with the current at its maximum when v_R is maximum. ✔



32.2 (*a*) Is energy dissipated in the resistor in the circuit of Figure 32.6? (*b*) If so, why doesn't the amplitude of the oscillations of v_R and i (shown in Figure 32.7) decrease with time?

32.2 AC circuits

The circuit discussed in Exercise 32.1 is an alternating current, or AC circuit. Such circuits exhibit more complex behavior when they contain elements that do not obey Ohm's law, so that the current is not proportional to the emf of the source. For example, let's consider the current in the circuit shown in **Figure 32.8**.

CONCEPTS

Figure 32.8 AC circuit with a capacitor connected to an AC source.

To analyze the circuit we choose a reference direction for the current i and let the potential difference v_C again be positive when the top capacitor plate is at a higher potential than the bottom plate (Figure 32.8). Because the capacitor is connected directly to the AC source, the time-dependent potential difference across the capacitor v_C equals the emf of the AC source at any instant. What is the current in the circuit? Let's begin considering what happens when the capacitor is uncharged. As v_C increases, the charge on the top plate of the capacitor increases. This means that positive charge carriers are moving toward the top plate, in the same direction as the chosen reference direction for the current, and so the current is positive (**Figure 32.9*a***). When v_C reaches its maximum, the capacitor reaches its maximum charge and the current is instantaneously zero. As v_C decreases, the charge on the top plate of the capacitor decreases. Positive charge carriers now move away from the top plate and the current is negative (Figure 32.9*b*). At some instant the top plate becomes negatively charged (Figure 32.9*c*); v_C continues to decrease until it reaches its minimum value and the current is instantaneously zero. At that instant the capacitor again reaches its maximum charge but with the opposite polarity. As v_C begins to increase again, positive charge carriers flow toward the top plate and the current is positive again (Figure 32.9*d*). When both plates are uncharged again, the cycle is complete.

Figure 32.9 The charging and discharging of the capacitor in the circuit of Figure 32.8.

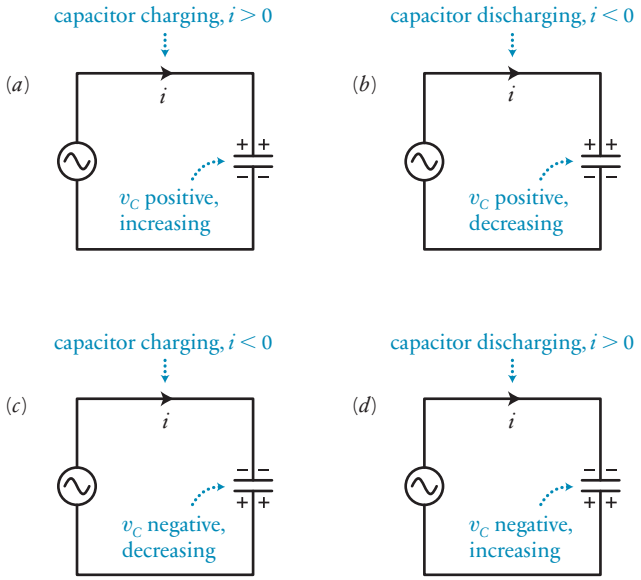


Figure 32.10 Time-dependent current in the circuit and potential difference across the capacitor for the circuit of Figure 32.9.

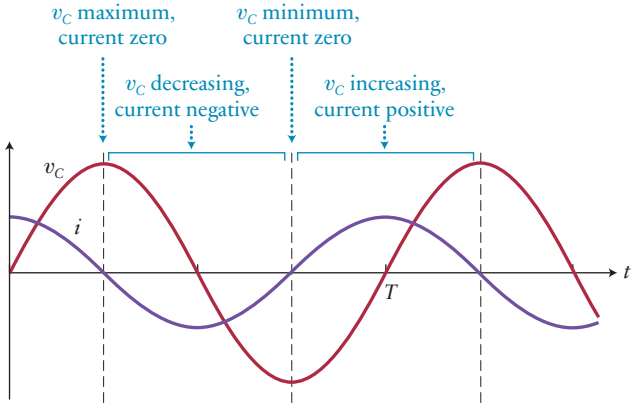

Figure 32.10 shows the time dependence of i and v_C in Figure 32.9. Note that i and v_C are not simply proportional to one another. Instead, the current maximum occurs one-quarter cycle before the potential difference maximum. For this reason, the current is said to *lead* the potential difference:

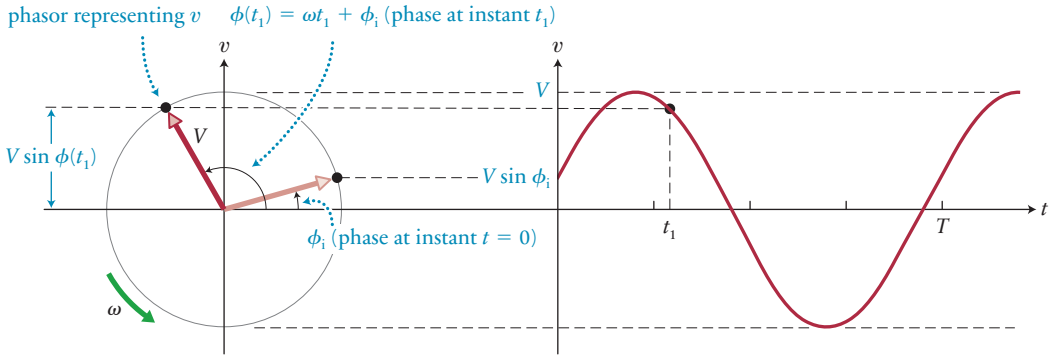

> **In an AC circuit that contains a capacitor, the current in the capacitor leads the potential difference by 90° (a quarter of an oscillation cycle).**

To describe the time dependence of a sinusoidally oscillating quantity, we must specify both the angular frequency of oscillation ω and the instant at which the oscillating quantity equals zero. As discussed in Chapter 15, a sinusoidally time-dependent quantity (such as the circuit potential difference we are looking at here) can be written in the form $v = V\sin(\omega t + \phi_i)$. The argument of the sine, $\omega t + \phi_i$, is the *phase*. At $t = 0$ the phase is equal to the *initial phase* ϕ_i (Chapter 15). When the phase of an oscillating quantity is zero, $\omega t + \phi_i = 0$, the quantity is zero as well because $\sin(0) = 0$.

We can analyze phase differences in AC circuits with lots of algebra, but the underlying physics is much clearer (and the analysis much simpler!) if we use the phasor notation developed in Chapter 15 to describe oscillatory motion. Following the approach of Section 15.5, we can represent an oscillating potential difference v by a phasor rotating in a reference circle (**Figure 32.11** on the next page). Because the length of the phasor equals the amplitude (maximum value) of v, the phasor is labeled V. The phasor rotates counterclockwise at angular frequency ω. The magnitude of v at any instant is given by the vertical component of the phasor; as the phasor rotates, that component oscillates sinusoidally in time, as shown in Figure 32.11. The angle measured counterclockwise from the positive horizontal axis to the phasor is the phase $\omega t + \phi_i$.

CONCEPTS

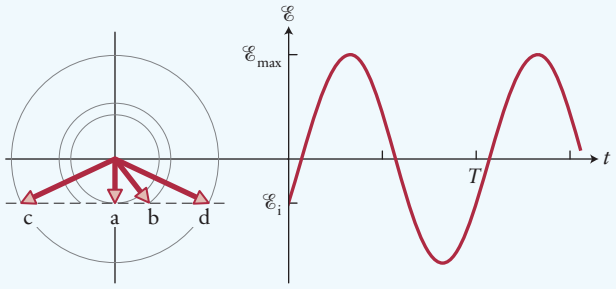

Figure 32.11 Phasor representation of a sinusoidally varying potential difference v. The phasor rotates counterclockwise at the same angular frequency at which v oscillates. The instantaneous value of v equals the length of the vertical component of the phasor.

EXAMPLE 32.2 Phasors

Consider the oscillating emf represented in the graph of **Figure 32.12**. Which of the phasors a–d, each shown at $t = 0$, correspond(s) to this oscillating emf?

Figure 32.12 Example 32.2.

1 GETTING STARTED I begin by observing from the graph that the emf is negative at instant $t = 0$ and increases until it reaches a maximum value $\mathscr{E}_{max}$.

2 DEVISE PLAN To identify the correct phasor or phasors, I can use the following information: (1) the length of the phasor is equal to the amplitude of the oscillation, (2) the value of the emf at any instant corresponds to the vertical component of the phasor, and (3) the phasor rotates counterclockwise around the reference circle.

3 EXECUTE PLAN The amplitudes of phasors a and b are too small and so I can rule these two out. The fact that the emf starts out negative at $t = 0$ and then increases tells me that the phasor representing it must be in the fourth quadrant (below the horizontal axis and to the right of the vertical axis), meaning the correct phasor must be d. ✔

4 EVALUATE RESULT I can verify my answer by tracing out the projection of the phasor on the vertical axis as the phasors rotates counterclockwise. The initial value of the projection, initial phase, and amplitude all agree with the values of these variables represented in the graph.

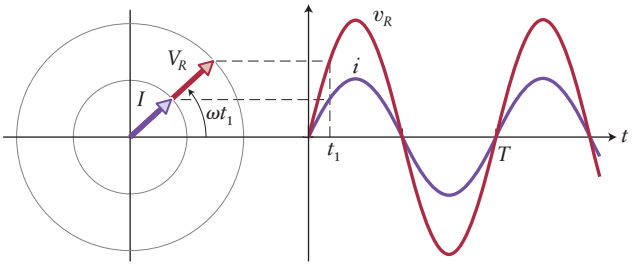
32.3 Construct a phasor diagram for the time-dependent current and potential difference at $t = 0$ in the AC source-resistor circuit of Figure 32.6.

We can generalize the result of this checkpoint to represent i and v_R from Figure 32.7 at an arbitrary instant t_1. Because i and v_R are in phase for a resistor, the two phasors for i and v_R always have the same phase and so overlap (**Figure 32.13**). Note that the initial phase ϕ_i is zero because i and v_R are zero at $t = 0$ (at that instant both phasors point to the right along the horizontal axis).

The relative lengths of the I and V_R phasors are meaningless because the units of i and v_R are different. However, for circuits with multiple elements (resistors, inductors, or capacitors), the relative lengths of phasors showing the potential differences across different elements are meaningful and will prove very useful in analyzing the circuit.

Phasors are most useful when we need to represent quantities that are not in phase. **Figure 32.14** shows the phasor diagram that corresponds to Figure 32.10 (at the instant represented by Figure 32.9*a*). As the phasor

Figure 32.13 Phasor diagram and graph showing time dependence of v_R and i from Figure 32.7.



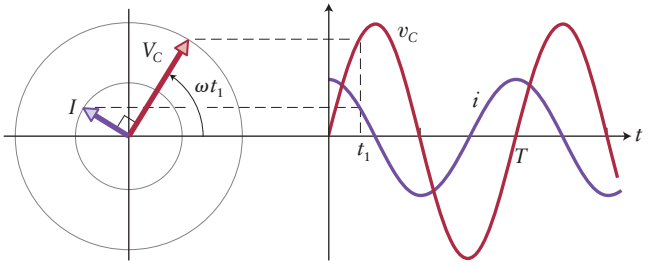


Figure 32.14 Phasor diagram and graph showing time dependence of i and v_C corresponding to Figure 32.10.

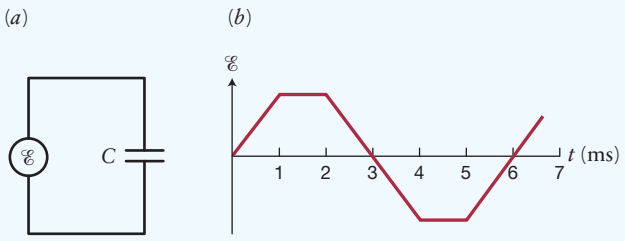


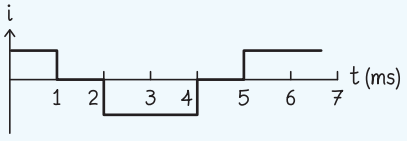
CONCEPTS

diagram shows, the angle between V_C and I is 90°, and so the phase difference between the two phasors is $\pi/2$. Because the phasors rotate counterclockwise, we see that current phasor I is ahead of the potential difference phasor V_C, in agreement with our earlier conclusion that the current in a capacitor leads the potential difference across the capacitor.

EXAMPLE 32.3 Nonsinusoidal AC circuit

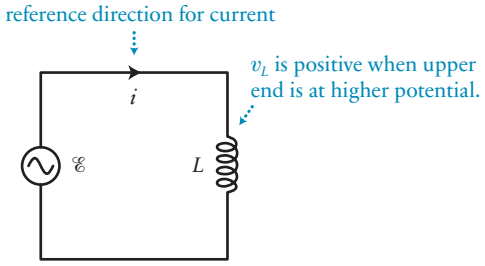
When a certain capacitor is connected to a nonsinusoidal source of emf as in **Figure 32.15a**, the emf varies in time as illustrated in Figure 32.15*b*. Sketch a graph showing the current in the circuit as a function of time.

Figure 32.15 Example 32.3.



❶ **GETTING STARTED** From Figure 32.15*b* I see that the emf has five distinct parts during the time interval shown. During each part, the emf either is changing at a constant rate or is constant.

❷ **DEVISE PLAN** I know that the current is proportional to the rate at which the charge on the capacitor plates changes over time. I also know that the emf is proportional to the charge on the plates, and so the current is proportional to the derivative of the emf with respect to time.



❸ **EXECUTE PLAN** Between $t = 0$ and $t = 1$ ms, the emf increases at a constant rate, so $i = Cd\mathscr{E}/dt$ is constant and positive. Between $t = 1$ ms and $t = 2$ ms, the emf is constant, so $i = Cd\mathscr{E}/dt = 0$. Between $t = 2$ ms and $t = 4$ ms, the emf decreases at a constant rate, so $i = Cd\mathscr{E}/dt$ is constant and negative. Because the rate of decrease between $t = 2$ ms and $t = 4$ ms is the same as the rate of increase between $t = 0$ and $t = 1$ ms, the magnitude of the current between $t = 2$ ms and $t = 4$ ms should be the same as that between $t = 0$ and $t = 1$ ms. The current is zero again during the next millisecond ($t = 4$ ms to $t = 5$ ms) because here the emf is again constant. After $t = 5$ ms, the emf increases again at the same constant rate as between $t = 0$ and $t = 1$ ms, so the current has the same positive value as between $t = 0$ and $t = 1$ ms. The graph representing these current changes is shown in **Figure 32.16**. ✔

Figure 32.16

❹ **EVALUATE RESULT** When the current is positive, the emf is increasing; when the current is negative, the emf is decreasing; and when the current is zero, the emf is constant, as it should be.

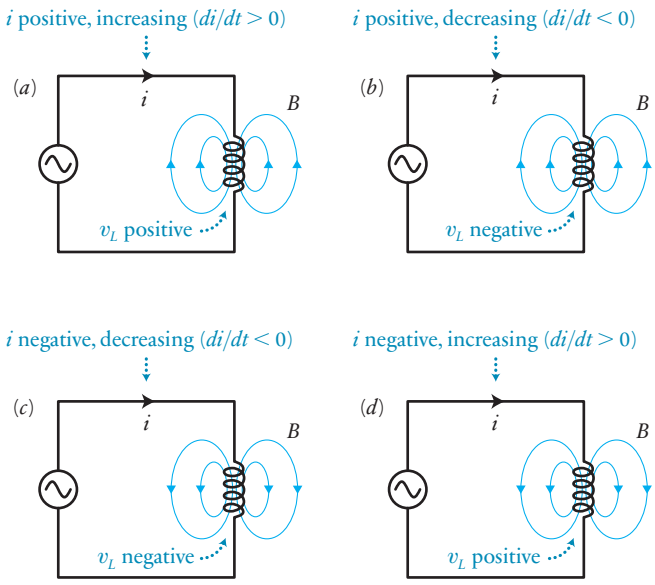


Figure 32.17 AC circuit consisting of an inductor connected across the terminals of an AC source.

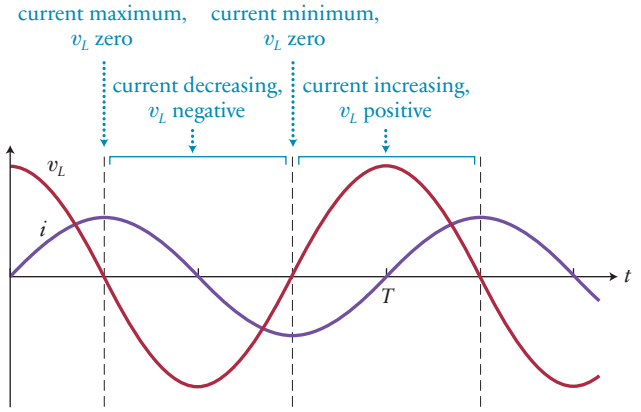
Now let's examine the behavior of an inductor connected to an AC generator (**Figure 32.17**). When the current in the circuit is changing, an emf is induced in the coil, in a direction to oppose this change (see Section 29.7). The potential difference between the ends of the inductor, which we'll denote by v_L, is proportional to the rate di/dt at which the current changes (Eq. 29.19). If the current is increasing in the reference direction for current indicated in Figure 32.17, the upper end of the inductor must be at a higher potential than the lower end to oppose the increase in current. If we take v_L to be positive when the upper end of the coil is at a higher potential, v_L must therefore be positive when the current is increasing in the reference direction for the current. This situation is represented in **Figure 32.18a**.



When the current reaches its maximum value in the cycle, v_L is instantaneously zero. After this instant, the current begins to decrease and the lower end of the inductor must be at a higher potential than the upper end to oppose this decrease in current. The potential difference v_L is now negative (Figure 32.18*b*). In the

Figure 32.18 Current and magnetic field oscillations through the inductor of Figure 32.17.

CONCEPTS

Figure 32.19 Graph of time-dependent current in the circuit and potential difference across the inductor for the circuit in Figure 32.17.

second half of the cycle, the current is in the opposite direction. As in the first part of the cycle, v_L has the same sign as di/dt (Figures 32.18*c* and *d*).

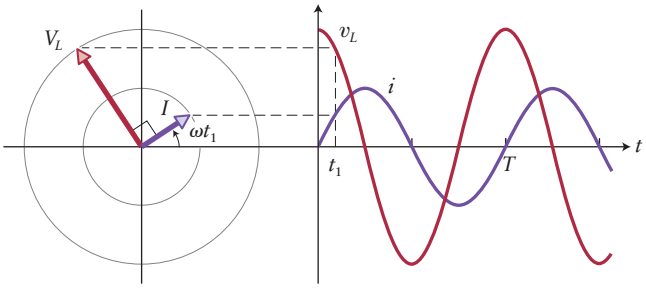
Figure 32.19 illustrates the time dependence of i and v_L in Figure 32.18. Note that the current maximum occurs one-quarter cycle after the potential difference maximum. For this reason, the current is said to *lag* the potential difference:

> **In an AC circuit that contains an inductor, the current in the inductor lags the potential difference by 90°.**

Figure 32.20 shows the phasor diagram that corresponds to Figure 32.19 (at the instant represented by Figure 32.18*a*). Just as with the capacitor, the angle between V_L and I is 90° and so the phase difference is $\pi/2$, but in this case the current phasor I is behind the potential difference phasor V_L, in agreement with our earlier conclusion that the current in an inductor lags the potential difference across the inductor.

32.4 What are the initial phases for the phasors in Figures 32.13 and 32.20?

Figure 32.20 Phasor diagram and graph showing time dependence of i and v_L corresponding to Figure 32.19.



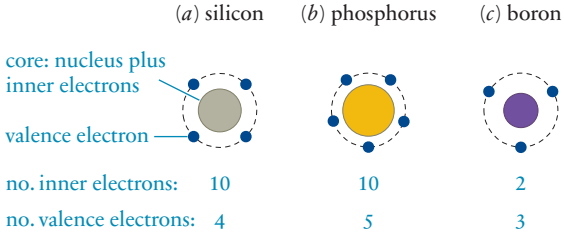


Figure 32.21 Schematic depiction of silicon, phosphorus, and boron atoms, shown as an inner core surrounded by valence electrons.

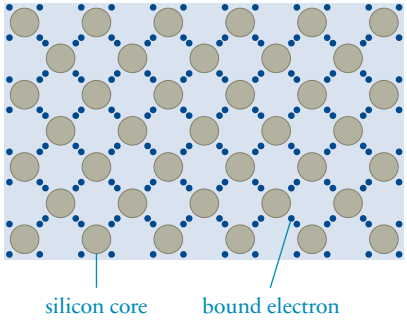
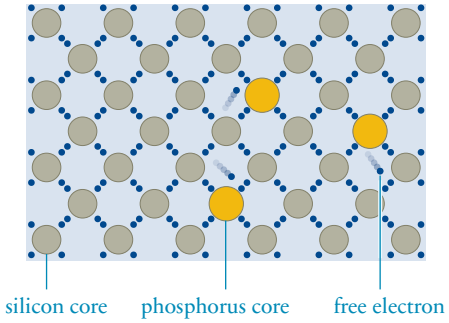


32.3 Semiconductors

Most modern electronic devices are made from a class of materials called **semiconductors**. Semiconductors have a limited supply of charge carriers that can move freely; consequently, their electrical conductivity is intermediate between that of conductors and that of insulators. Semiconductors are widely used in the manufacture of electronic devices such as transistors, diodes, and computer chips because their conductivity can be tailored chemically for particular applications layer by layer, even within a single piece of semiconductor.



Semiconductors are of two main types: intrinsic and extrinsic. *Intrinsic semiconductors* are chemically pure and have poor conductivity. *Extrinsic* or *doped semiconductors* are not chemically pure, have a conductivity that can be finely tuned, and are widely used in the microelectronics industry. The most widely used semiconductor is silicon, a nonmetallic element that makes up more than one-quarter of Earth's crust. **Figure 32.21*a*** shows a schematic of a silicon atom, which consists of a nucleus surrounded by fourteen electrons. Ten of these electrons are tightly bound to the nucleus—we'll refer to these electrons plus the nucleus as the *core* of the atom. The remaining outermost four electrons are called the atom's *valence electrons*. Each valence electron can form a covalent bond with a valence electron of another silicon atom. These bonds hold many identical silicon atoms together in a crystalline lattice (**Figure 32.22**). The electrons in a covalent bond are not free to move; consequently, pure

Figure 32.22 Schematic of a crystalline lattice of silicon atoms, showing electrons participating in silicon-silicon bonds. (A real silicon crystal exists in three dimensions, and not all of the silicon-silicon bonds lie in a plane; this diagram illustrates only the essential idea that all of the valence electrons participate in covalent bonds.)

CONCEPTS

Figure 32.23 Schematic depiction of a crystalline lattice of silicon atoms doped with phosphorus atoms. The only charge carriers that are free to move in the crystal are the free electrons supplied by the phosphorus dopant atoms.

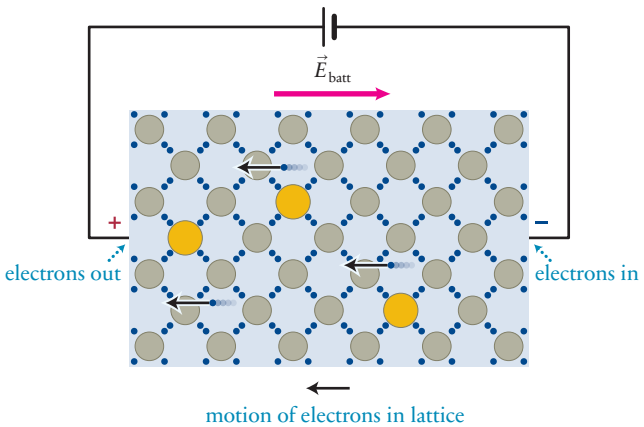
silicon has a very low electrical conductivity because all of its valence electrons form covalent bonds.

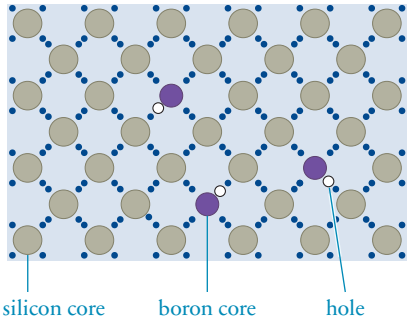
In extrinsic silicon, other types of atoms, such as boron or phosphorus, replace some of the atoms in the silicon lattice, introducing freely moving charge carriers into the lattice. The substituted atoms are called either *impurities* or *dopants*. For example, phosphorus has five valence electrons (Figure 32.21*b*). Because the silicon lattice structure requires only four bonds from each atom, the fifth electron from a phosphorus atom dopant is not involved in a bond and is free to move through the solid (**Figure 32.23**).

If an electric field is applied to the doped semiconductor of Figure 32.23, the free electrons move, creating a current in the semiconductor (**Figure 32.24**). As free electrons leave the semiconductor from one side, other free electrons enter it on the opposite side. Because the semiconductor must remain electrically neutral, the number of free electrons in the semiconductor at any given instant is always the same and it is equal to the number of phosphorus atoms in the material.

If boron atoms, which have three valence electrons (Figure 32.21*c*), are substituted for some silicon atoms

Figure 32.24 In an applied electric field, the free electrons in a phosphorus-doped silicon semiconductor can move in the direction opposite the field direction. Free electrons leave the semiconductor at the left, travel through the circuit wire, and re-enter at the right.





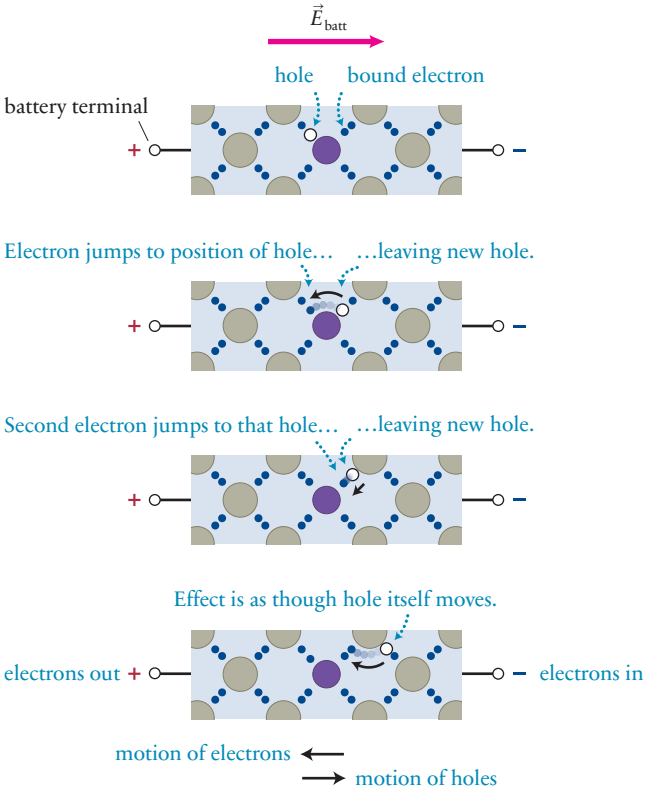


Figure 32.25 Schematic of crystalline lattice of silicon atoms with some boron atoms substituted for silicon, showing both bonding electrons and holes (missing electrons). The only free charge carriers in the crystal are the holes caused by the boron impurities.

in a silicon lattice, the "missing" fourth electron at each boron leaves behind what is called a **hole**—an incomplete bond (**Figure 32.25**). These holes behave like *positive* charge carriers and are free to move through the lattice. The holes therefore increase the ability of the silicon to conduct current, just as do the free electrons in phosphorus-doped silicon.

Keep in mind that the motion of holes involves electrons moving to fill existing holes, leaving new holes in the previous positions of the electrons (**Figure 32.26**).

Figure 32.26 Sequence of four snapshots showing how holes "move" through a crystal by trading places with bonding electrons. In the presence of an electric field, holes move in the direction of the field (opposite to the directions in which the electrons move). To maintain continuity, free electrons from attached metal wires enter at the right, recombining with holes that accumulate there, and leave at the left.

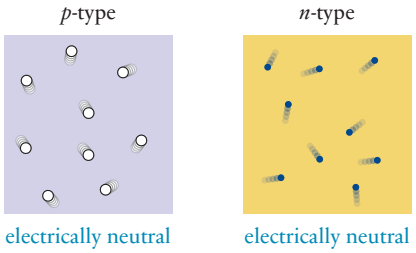
CONCEPTS

The boron cores do not move! In the presence of an electric field, the positively charged holes move in the direction of the field as the negatively charged electrons move in the opposite direction. If the semiconductor is attached to metal wires on either side, as in Figure 32.26, free electrons travel into the semiconductor from the right (eliminating holes that reach the right edge) and travel out of the semiconductor on the left (producing holes on the left edge). Electrons thus flow from right to left, making holes travel in the opposite direction. Unlike the electrons, however, the holes never leave the semiconductor.

Doped semiconductors are classified according to the nature of the dopant. In a *p-type* semiconductor, the dopant has fewer valence electrons than the host atoms, contributing positively charged holes as the free charge carriers (thus the *p* in the name). In an *n-type* semiconductor, the dopant has more valence electrons than the host atoms, contributing negatively charged electrons as the free charge carriers (thus the *n* in the name). Substituting as few as ten dopant atoms per million silicon atoms produces conductivities appropriate for most electronic devices.

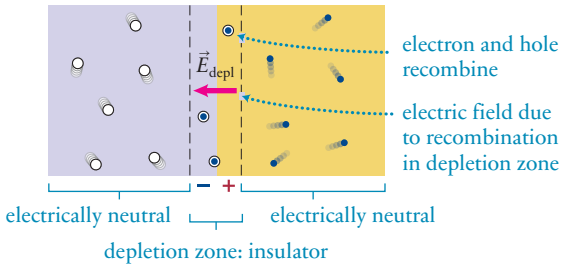
32.5 Is a piece of *n*-type silicon positively charged, negatively charged, or neutral?

32.4 Diodes, transistors, and logic gates



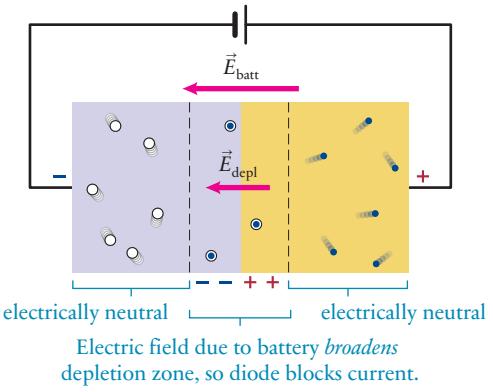
Although tailoring the conductivity of a single piece of semiconductor can be a useful procedure, the most versatile semiconductor devices combine doped layers that have different types of charge carriers. The simplest such device is a **diode**, made by bringing a piece of *p*-type silicon into contact with a piece of *n*-type silicon (**Figure 32.27a**). Near the junction where the two pieces meet, free electrons from the *n*-type silicon wander into the *p*-type material, where they end up filling holes. This *recombination* process turns free electrons into bound electrons (that is, electrons not free to roam around in the material) and eliminates the holes. Likewise, some of the holes in the *p*-type silicon wander into the *n*-type silicon, where they recombine with free electrons.

As recombination events take place, a thin region containing no free charge carriers (neither free electrons nor holes), called the **depletion zone**, develops at the junction. Although there are no *free* charge carriers in this zone, the trapping of electrons on the *p*-side of the junction causes negative charge carriers that are nonmobile to accumulate there. Similarly, positive nonmobile charge carriers accumulate on the *n*-side of the junction. As a result, the depletion zone consists of a negatively charged region and a positively charged region, and an electric field points across the depletion zone from the *n*-side to the *p*-side (Figure 32.27*b*).

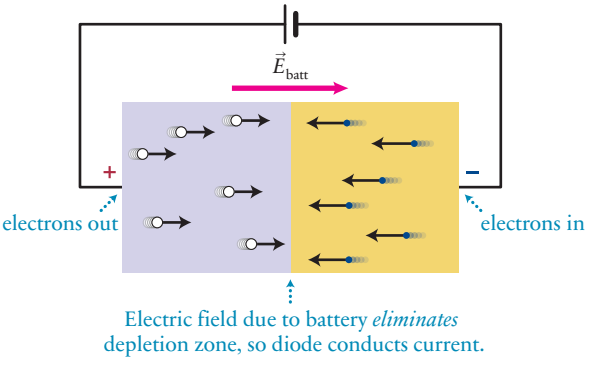


CONCEPTS

Figure 32.27 How a diode transmits current in one direction but blocks it in the other. If the battery is connected as shown in part *d* and produces a sufficiently strong electric field to compensate for the electric field of the depletion zone, there is a steady flow of both electrons and holes. (Remember, though: The holes never leave the semiconductor. Only the electrons enter and leave the semiconductor.)



(*a*) Pieces of *p*- and *n*-type doped silicon



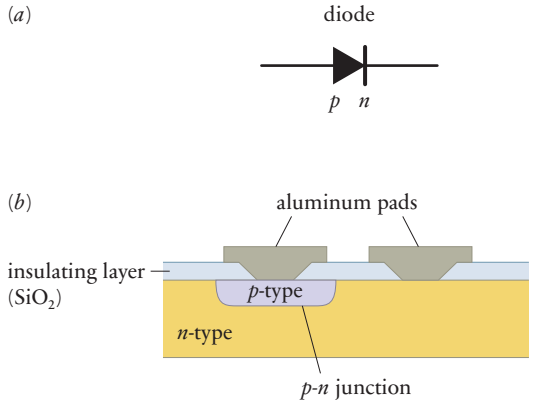
(*b*) When the two are put in contact, a diode is formed

(*c*) Battery connected so as to produce electric field in *same* direction as electric field in depletion zone; diode blocks current

(*d*) Battery connected with the *opposite* polarity; diode conducts current

As this electric field in the depletion zone of the diode increases, it becomes more difficult for free electrons and holes to cross the junction and recombine because the electric field pushes free electrons back into the *n*-type silicon and pushes holes back into the *p*-type silicon. Consequently, the depletion zone stops growing. Typically this region is less than a micrometer wide. Because of the lack of free charge carriers in it,

the depletion zone acts as an electrical insulator.



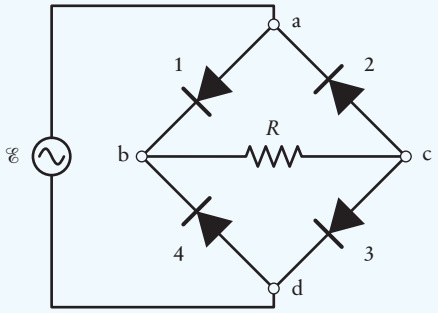
If we now connect the *n*-side of this diode to the positive terminal of a battery and the *p*-side to the negative terminal, the battery produces across the diode an electric field that points in the same direction as the electric field in the depletion zone (Figure 32.27*c*). The electric field of the battery pulls free electrons in the *n*-type silicon toward the positive terminal and pulls holes in the *p*-type silicon toward the negative terminal, broadening the (nonconducting) depletion zone. Connecting the battery in this manner therefore causes no flow of charge carriers in the diode.

When the battery is connected in the opposite direction, however, the depletion zone narrows as the battery's electric field pushes free electrons and holes toward the junction (Figure 32.27*d*). When the magnitude of the applied electric field created by the battery equals that of the electric field across the depletion zone, both types of free charge carriers can reach the junction, resulting in a current in the device carried both by free electrons and by holes.

As Figure 32.27 shows, a diode conducts current in one direction only: from the *p*-type side to the *n*-type side. The symbol for a diode is shown in **Figure 32.28*a***; the triangle points in the direction in which the diode conducts current (from the *p*-side to the *n*-side).

32.6 In the diode of Figure 32.28*a*, which way do holes travel? Which way do electrons travel?

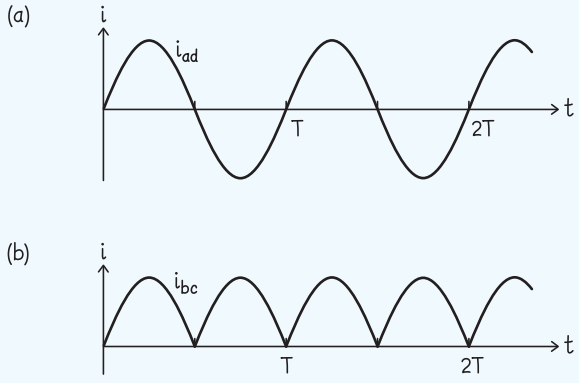
Figure 32.28 (*a*) Circuit symbol for a diode. (*b*) Schematic of a diode made using integrated-circuit technology.



An *ideal diode* acts like a short circuit for current in the permitted direction and like an open circuit for current in the opposite direction. (That is not exactly how a diode behaves, but it's pretty close.)

32.7 Suppose a sinusoidally varying potential difference is applied across a diode connected in series with a resistor. Sketch the potential difference across the diode as a function of time, and then, on the same graph, sketch the current in the resistor as a function of time.

EXAMPLE 32.4 Rectifier



Consider the arrangement of ideal diodes shown in **Figure 32.29**. This arrangement, called a *rectifier*, converts alternating current (AC) to direct current (DC). Sketch a graph showing, for a sinusoidally alternating source, the current in the resistor in the direction from b to c as a function of time.

Figure 32.29 Example 32.4.

❶ **GETTING STARTED** Because the source is alternating, the current in the circuit periodically reverses direction. During part of the cycle the charge carriers creating the current flow clockwise through the source, and during another part of the cycle they flow counterclockwise. The diodes, however, conduct current in one direction only. I begin by making a sketch of the current between a and d, taking the direction from a to d to be positive (**Figure 32.30*a***).

Figure 32.30

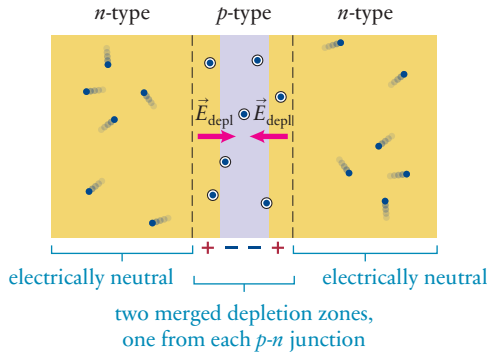
❷ **DEVISE PLAN** In an ideal diode, the charge carriers can flow only in the direction in which the triangle in the diode symbol points. I shall determine which diodes allow charge

(Continued)

CONCEPTS

carriers to flow when the current direction is clockwise and when it is counterclockwise. I can then determine in each case which way the charge carriers flow through the resistor.

3 EXECUTE PLAN When the current in the circuit is clockwise, only diodes 1 and 3 are conducting, so the current direction is abcd. When the current in the circuit is counterclockwise ($i_{ad} < 0$), only diodes 2 and 4 are conducting, so the current direction is dbca. At all instants, the current in the resistor points in the same direction: from b to c. This means that i_{bc} is positive regardless of whether i_{ad} is positive or negative. Whenever i_{ad} is negative, the diodes reverse the direction of the current in the resistor, so i_{bc} is always positive and my graph is as shown in Figure 32.30*b*. ✔



4 EVALUATE RESULT The arrangement of diodes keeps the current from b to c always in the same direction, even though the current from a to d alternates in direction. It makes sense, then, that this arrangement of diodes is called a *rectifier*.

Figure 32.28*b* shows how a diode may be constructed as part of an integrated circuit (a computer chip, for example). An aluminum pad (part of the metal wire connecting the diode to the rest of the circuit) is in contact with a small *p*-type region of silicon, which is surrounded by a larger *n*-type region that is in contact with a second aluminum pad. The *p*-*n* junction forms at the interface between the *p*- and *n*-type regions. A thin layer of silicon oxide (SiO_2) insulates the aluminum from the underlying silicon except where electrical contact is needed. On a modern computer chip, the entire device is only a few micrometers wide.

Another important circuit element in modern electronics is the **transistor,** a device that allows current control that is more precise than the on/off control of a diode. A transistor consists of a thin layer of one type of doped semiconductor sandwiched between two layers of the opposite type of doped semiconductor. **Figure 32.31**, for example, shows an *npn-type bipolar transistor*—a thin layer of *p*-type silicon sandwiched between two thicker regions of *n*-type silicon.* If the *p*-type layer is thin, the depletion zone formed at the left *p*-*n* junction merges with the depletion zone formed at the right *p*-*n* junction. The merged depletion zones form one wide depletion zone.

When a potential difference is applied across such a transistor (**Figure 32.32*a***), the depletion zone across junction 1 disappears, but that across junction 2 grows, shifting the depleted region toward the positive terminal of the battery. While charge carriers can now cross junction 1 where the depletion zone has disappeared, the (shifted) depletion zone that still exists prohibits their movement, which means no current in the transistor. For historical reasons, the *n*-type region connected to the negative terminal is called the *emitter*, the *n*-type region connected to the positive terminal is called the *collector*, and the *p*-type layer is called the *base*. If the direction of the applied potential difference is reversed, the roles of the emitter and the collector are also reversed, and there is still no current in the transistor.

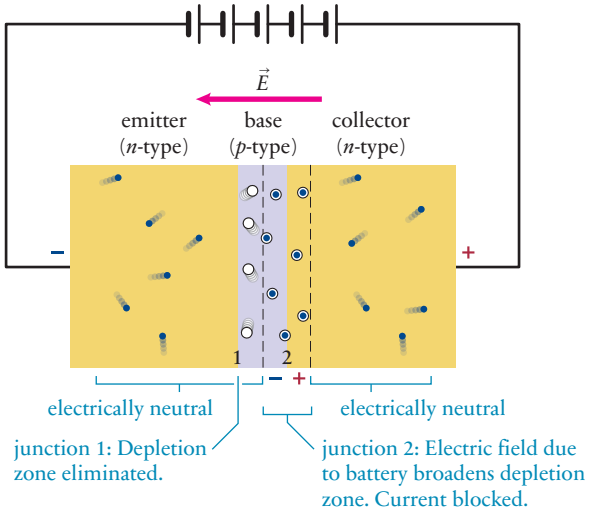


Figure 32.31 Schematic of an *npn*-type bipolar transistor, showing charge distribution and depletion zones for both *p*-*n* junctions.

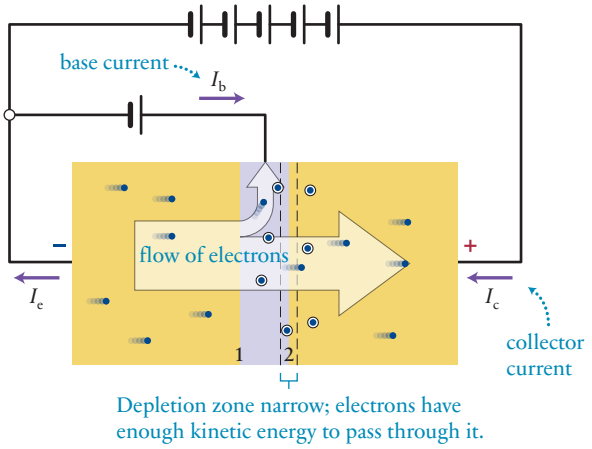


*Transistors in which a thin layer of *n*-type silicon is sandwiched between pieces of *p*-type silicon, called *pnp*-type bipolar transistors, are also used.

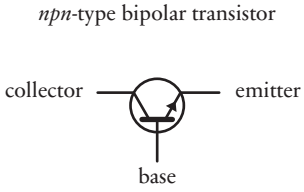
Figure 32.32 How an *npn*-type bipolar transistor works.

(*a*) Potential difference applied from collector to emitter only

(*b*) Potential difference also applied from base to emitter

CONCEPTS

Figure 32.33 Circuit symbol for an *npn*-type bipolar transistor.



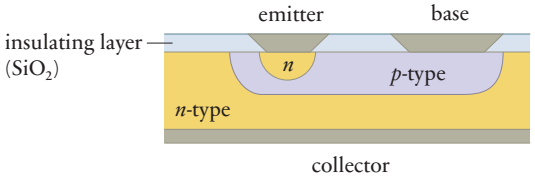


Figure 32.35 Schematic of an *npn*-type bipolar transistor made using integrated-circuit technology.

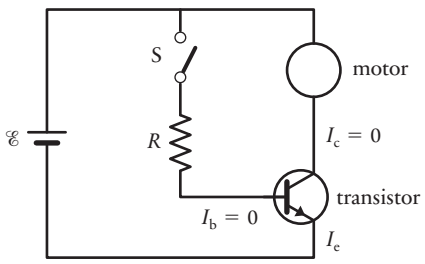


The situation changes drastically when, in addition to the potential difference between the emitter and the collector, a small potential difference is applied between the emitter and the base (Figure 32.32*b*). Adding this potential difference, called a *bias* or *bias potential difference*, makes the depletion zone much thinner than it is in Figure 32.32*a* because the formerly negatively charged region of this zone is brought to a positive potential, restoring mobile holes to that region. Because the emitter-base junction is conducting (remember, the depletion zone at junction 1 has disappeared), electrons now start flowing from the emitter toward the base. Once in the base, three things happen: (1) a small fraction of the electrons recombine with holes in the base, (2) electrons are attracted by the positive charge on the collector and have sufficient kinetic energy to pass straight through the very thin depletion zone, producing a collector current I_c, and (3) electrons diffuse through the base toward the positively charged end of the base, causing a small base current I_b. In a typical bipolar transistor, the collector current is 10 to 1000 times greater than the base current.

The circuit symbol for an *npn*-type bipolar transistor is shown in **Figure 32.33**.

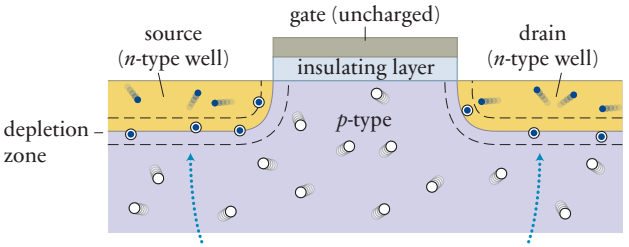
Transistors are ubiquitous in modern electronics. In most applications, the transistor functions as either a switch or a current amplifier. If we consider I_b to be the input current and I_c the output current, the transistor acts as a switch in which I_b turns on and controls I_c. As a current amplifier, a small current I_b produces a much larger current I_c.

For electrical devices that draw large currents, it is useful to switch the device on and off with a mechanical switch wired in parallel with the device, rather than in series, so that the current in the device does not have to pass through the switch. **Figure 32.34** shows a circuit that utilizes such switching. When switch S is open, the base current is zero, and so the collector current (and therefore the current in the device) is zero. When switch S is closed, the small current from base to emitter causes a large current from collector to emitter that turns on the motor.

Figure 32.34 Circuit in which a bipolar transistor is used to turn a motor on and off.

32.8 In a bipolar transistor, what relationship, if any, exists among I_b, I_c, and the emitter current I_e?

Figure 32.35 shows how an *npn*-type bipolar transistor can be fabricated. A drawback of this type of transistor, however, is that a continuous small current through the base is required to make the transistor conducting. For this reason, another type of transistor, called the *field-effect transistor*, is used much more frequently. **Figure 32.36*a*** on the next page shows the configuration of one. Two *n*-type wells are made in a piece of *p*-type material. The *p*-type material between the two wells is covered with a nonconducting oxide layer (typically SiO_2) and then with a metal layer called the *gate*. The two *n*-type wells are called the *source* and the *drain* (the *n*-type well that is kept at a higher potential is the drain).



Because of the depletion zones between the *p*-type and *n*-type materials, no charge carriers can flow from the source to the drain (or vice versa). The nonconducting layer between the gate and the *p*-type material prevents charge carriers from traveling between the gate and the rest of the device.

If the gate is given a positive charge, as in Figure 32.36*b*, the (positively charged) holes just underneath the gate are pushed away, forming underneath the gate an additional depletion zone that connects the depletion zones around the two *n*-*p* junctions. If the positive charge is made large enough, electrons from the source and from the drain are pulled underneath the gate, forming an *n*-type channel below the gate (Figure 32.36*c*). This channel allows charge carriers to flow between the source and the drain. The gate thus controls the current between the source and the drain, just as the base in an *npn*-type bipolar transistor controls the current between the emitter and the collector. (The difference is that there is no current in the gate in a field-effect transistor.) Applying a positive charge to the gate is often referred to as putting a positive *bias* on the gate.

CONCEPTS

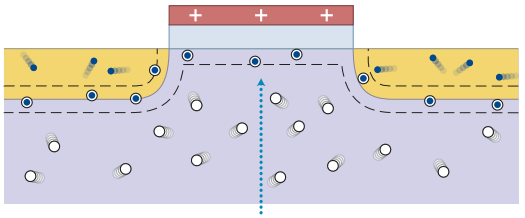


Figure 32.36 How a field-effect transistor works.

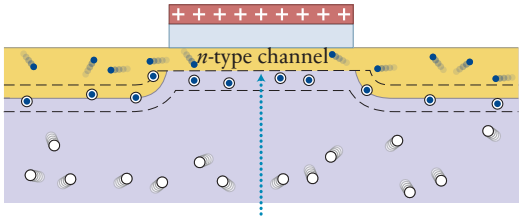
(*a*) Field-effect transistor with uncharged gate



Uncharged gate: Separate depletion zones at *p*-*n* junctions.

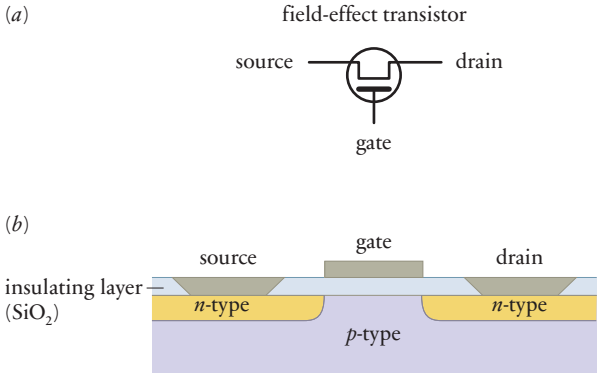
(*b*) Small positive charge on gate attracts electrons to gate and extends depletion zone below gate

Small gate charge causes depletion zone to extend beneath gate.

(*c*) Large positive charge on gate attracts more electrons to gate and causes *n*-type channel, which connects source and drain

Strong gate charge pushes depletion zone away; conducting *n*-type channel now connnects source and drain.

Figure 32.37 (*a*) Circuit symbol for a field-effect transistor. (*b*) Schematic of a field-effect transistor made using integrated-circuit technology.



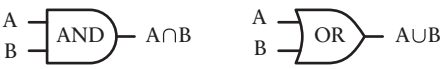


Figure 32.37*a* shows the circuit symbol for a field-effect transistor, and Figure 32.37*b* shows how this type of transistor can be realized in an integrated circuit. This type of transistor has two advantages over the bipolar transistor shown in Figure 32.35. First, all the terminals in the field-effect transistor are on the same side of the chip, making fabrication in integrated circuits much easier. Second, the current between the source and the drain is controlled by the charge on the gate, allowing a potential difference rather than a current to be used to control the source-drain current. Because no current is leaving the gate, no energy is required to keep current flowing from the source to the drain.

Field-effect transistors are widely used in devices called *logic gates*, which are the building blocks of computer processors and memory. A logic gate takes two input signals and provides an output after performing a logic operation on the input signals. For example, in a so-called AND gate, the output potential is nonzero with respect to ground only when both inputs are at positive potential with respect to ground. In an OR gate, the output potential is nonzero when either input potential is positive. The symbols used for these gates in circuit diagrams are shown in **Figure 32.38**; the inputs are on the left, and the output is on the right. In analyzing these circuits, we'll make the simplifying assumption that a transistor is just a switch that is open (off) when the potential of the gate is either at ground or negative with respect to ground and is closed (on) when the gate is at a positive potential.

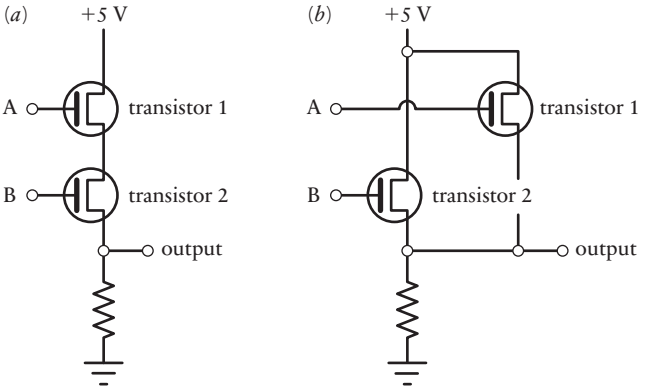

Figure 32.38 Circuit symbols for AND and OR logic gates.

CONCEPTS

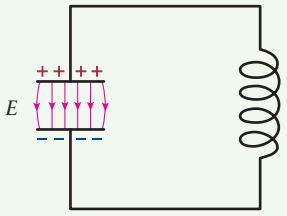
32.9 Circuit diagrams for two logic gates are shown in **Figure 32.39**. Which is the AND gate, and which is the OR gate? Explain briefly how each one works.

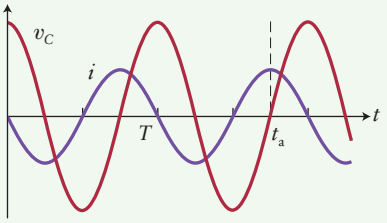
Figure 32.39 Checkpoint 32.9.

Self-quiz

1. At the instant shown in **Figure 32.40**, the potential difference across the capacitor is half its maximum value and the charge on the plates is increasing. Draw the direction of the current and sketch the magnetic field at this instant. Is the magnitude of current increasing or decreasing?
2. Construct a phasor diagram representing the current and potential difference in Figure 32.10 at $t = T/4$, $T/2$, and $3T/4$.
3. **Figure 32.41** shows the time-varying potential difference and current for the circuit of Figure 32.8. At the instant labeled t_a, what are the charge on the capacitor plates and the direction of the current?

Figure 32.40





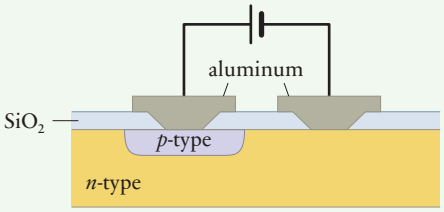


Figure 32.41

4. Is there any current in a diode connected as shown in **Figure 32.42**?

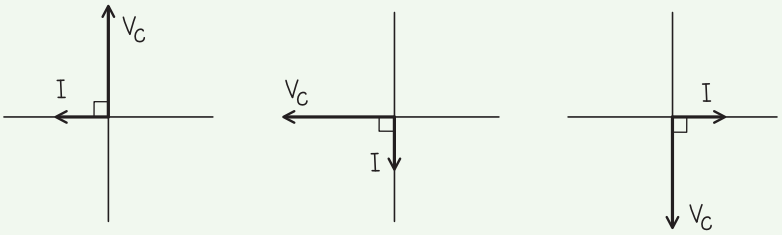

Figure 32.42

Answers

1. Your sketch should show the current directed counterclockwise. The magnetic field in the center of the coil points up the page according to the right-hand dipole rule (assuming we are looking down on the top of the coil in Figure 32.40). Because the current is zero when the capacitor has maximum charge, the magnitude of the current is decreasing at the instant shown in Figure 32.40.
2. See **Figure 32.43**. At $t = T/4$ the potential difference phasor V_C points along the positive y axis because the potential difference reaches its maximum positive value at this instant, and the current phasor I points along the negative x axis because it leads the current by 90°. Each quarter cycle both phasors rotate 90° counterclockwise.

Figure 32.43

3. Because the potential difference across the capacitor is zero at instant t_a, the charge on the plates must be zero. The current is a maximum at this instant and is directed clockwise.
4. Yes. The holes in the p-type material move away from the positive terminal, and the electrons move toward it. According to Figure 32.27*d*, this flow shrinks the depletion zone, the charge carriers can flow, and so there is a current.

32.5 Reactance

Let us now develop a mathematical framework for analyzing alternating-current circuits. The instantaneous emf supplied by an AC source is customarily written as

$$\mathscr{E} = \mathscr{E}_{\max} \sin \omega t, \tag{32.1}$$

where $\mathscr{E}_{\max}$ is the maximum value of the emf, typically called the *peak value* or *amplitude* (see Section 15.1), $\omega = 2\pi f$ is the angular frequency of oscillation in inverse seconds (Section 15.5), and f is the frequency in hertz. Most generators have frequencies of 50 Hz or 60 Hz. Audio circuits typically operate at kilohertz frequencies, radio transmitters at 10^8 Hz, for instance, and computer chips at 10^9 Hz. It's very important to remember to convert frequencies in hertz (cycles per second) to angular frequencies in s^{-1} when ω appears in the equations.

Note that the initial phase for the emf as written in Eq. 32.1 is zero. When we make this choice, the source emf serves as the reference for phase in the circuit.

Let's begin by revisiting the circuit from Exercise 32.1—a resistor connected to an AC source (**Figure 32.44**). At any instant, Ohm's law relates the potential difference across the resistor to the current in it, just as it does for DC circuits:

$$v_R = iR. \tag{32.2}$$

The only difference between Eq. 32.2 and Ohm's law for DC circuits (Eq. 31.11) is that the potential difference and the current in Eq. 32.2 oscillate in time.

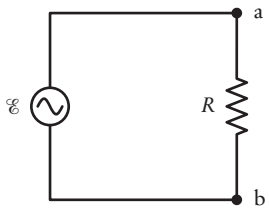
Applying the loop rule to this circuit gives the AC version of Eq. 31.23:

$$\mathscr{E} - iR = 0. \tag{32.3}$$

Equations 32.2 and 32.3 show that the potential difference across the load equals the emf supplied by the source (as we would expect):

$$v_R = \mathscr{E} = \mathscr{E}_{\max} \sin \omega t. \tag{32.4}$$

Figure 32.44 AC circuit consisting of a resistor connected across the terminals of an AC source.



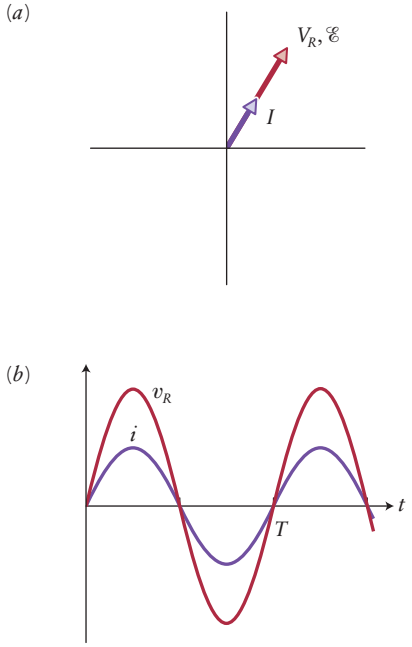


Figure 32.45 (*a*) Phasor diagram and (*b*) graph showing time dependence of i and v_R for the circuit shown in Figure 32.44.

32.10 (*a*) In Figure 32.44, is the potential at point a higher or lower than the potential at b when the current direction is clockwise through the circuit? (*b*) If we define such a current to be positive, is $\mathscr{E}$ positive or negative? Express v_R in terms of the potential at a and the potential at b. (*c*) Half a cycle later, when the current is negative, is $\mathscr{E}$ positive or negative? Express v_R again in terms of the potential at a and the potential at b.

Using Eqs. 32.2 and 32.4, we can write the current in the resistor as

$$i = \frac{v_R}{R} = \frac{\mathscr{E}_{\max} \sin \omega t}{R} = I \sin \omega t, \tag{32.5}$$

where $I = \mathscr{E}_{\max}/R$ is the amplitude of the current. Note that the current and the potential difference both oscillate at angular frequency ω and are in phase, as we concluded in Exercise 32.1. If we write $v_R = V_R \sin \omega t$, we see that the amplitudes of the current and the potential difference satisfy the relationship

$$V_R = IR. \tag{32.6}$$

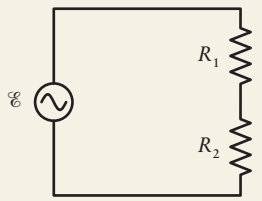

Figure 32.45 shows the corresponding phasor diagram and time dependence of v_R and i.

QUANTITATIVE TOOLS

EXERCISE 32.5 AC circuit with two resistors

In **Figure 32.46**, the resistances are $R_1 = 100\ \Omega$ and $R_2 = 60\ \Omega$, the amplitude of the emf is $\mathscr{E}_{max} = 160$ V, and its frequency is 60 Hz. (*a*) What is the amplitude of the potential difference across each resistor? (*b*) What is the instantaneous potential difference across each resistor at $t = 50$ ms?

Figure 32.46 Exercise 32.5.

SOLUTION I analyze this circuit just as I would analyze a DC circuit containing two resistors, except now I must keep in mind that the current and potential differences are oscillating. The resistance of the load is

$$R_{load} = R_1 + R_2,$$

and the instantaneous current in the load is

$$i = \frac{\mathscr{E}}{R_{load}} = \frac{\mathscr{E}}{R_1 + R_2}.$$

(*a*) Because the current and the emf are in phase, they reach their maximum values at the same instant. As a result, the amplitude (maximum value) of the current is given by the amplitude of the emf divided by the resistance:

$$I = \frac{\mathscr{E}_{max}}{R_1 + R_2} = 1.0\ \text{A}.$$

The potential differences across the resistors are in phase with the current, and so I calculate the amplitude of the potential differences from the amplitude of the current using Eq. 32.6:

$$V_{R_1} = IR_1 = (1.0\ \text{A})(100\ \Omega) = 100\ \text{V}$$

$$V_{R_2} = IR_2 = (1.0\ \text{A})(60\ \Omega) = 60\ \text{V}. \checkmark$$

(*b*) I can use Eq. 32.5 to calculate the instantaneous value of the current:

$$i = (1.0\ \text{A})\sin(2\pi \cdot 60\ \text{Hz} \cdot 0.050\ \text{s}) = 0.$$

(In 50 ms, three full cycles at 60 Hz take place.) Because the current is zero at 50 ms, the potential differences v_{R_1} and v_{R_2} at 50 ms are also zero. ✔

Next consider a capacitor connected to an AC source (**Figure 32.47**). Because the capacitor and the source are connected to each other, we have

$$\mathscr{E} = v_C, \tag{32.7}$$

and so the potential difference across the capacitor is

$$v_C = \mathscr{E}_{max} \sin \omega t = V_C \sin \omega t. \tag{32.8}$$

At any instant the potential difference across the capacitor and the charge on the upper plate are related by (see Eq. 26.1)

$$\frac{q}{v_C} = C, \tag{32.9}$$

where the potential difference v_C and the charge q on the plate oscillate in time. The charge on the upper capacitor plate is thus

$$q = Cv_C = CV_C \sin \omega t, \tag{32.10}$$

and the current is the rate of change of the charge on the plate:

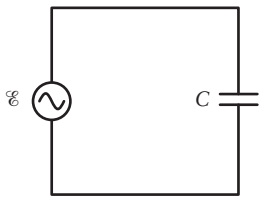
$$i = \frac{dq}{dt} = \frac{d}{dt}(CV_C \sin \omega t) = \omega CV_C \cos \omega t. \tag{32.11}$$

Using the identity $\cos \alpha = \sin\left(\alpha + \frac{\pi}{2}\right)$, we can rewrite this as

$$i = \omega CV_C \sin\left(\omega t + \frac{\pi}{2}\right) = I \sin\left(\omega t + \frac{\pi}{2}\right). \tag{32.12}$$

We now see that v_C and i are not in phase: i reaches its maximum value one-quarter period before v_C reaches its maximum value (**Figure 32.48** on the next page), as we found in Section 32.2.

Figure 32.47 AC circuit consisting of a capacitor connected across the terminals of an AC source.



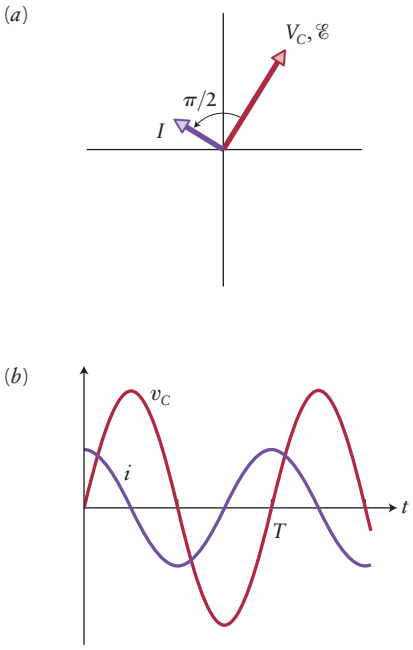


Figure 32.48 (*a*) Phasor diagram and (*b*) graph showing time dependence of i and v_C for the circuit of Figure 32.47. The phasor diagram shows the relative phase of i and v_C.

The current in the capacitor of Figure 32.47 is not simply proportional to the potential difference across the capacitor because the two are out of phase. However, the *amplitude* of the current is proportional to the amplitude of the potential difference: $I = \omega C V_C$. Rewriting this to express V_C in terms of I gives

$$V_C = \frac{I}{\omega C}. \tag{32.13}$$

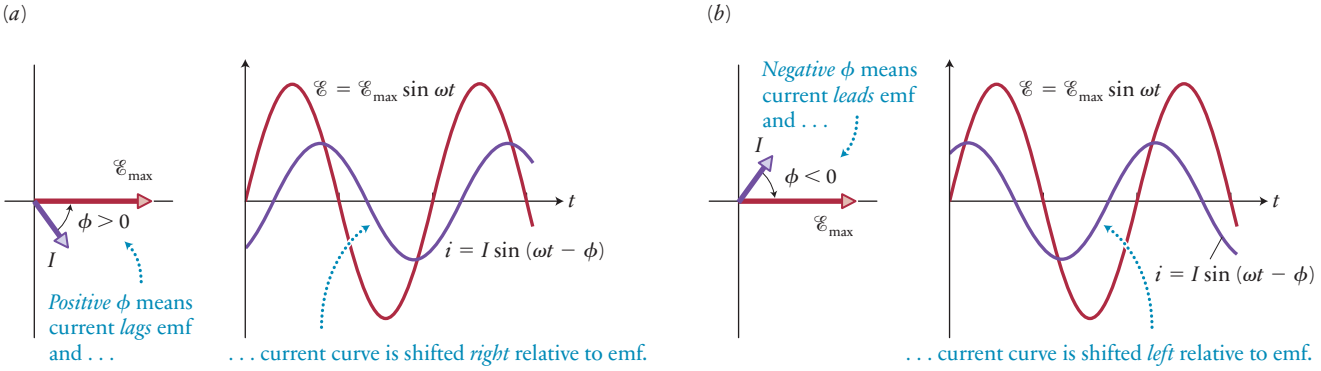
Note how this expression differs from the expression for a circuit that consists of only an AC source and a resistor, $V_R = IR$ (Eq. 32.6), where R is the proportionality constant between V and I. In Eq. 32.13, the proportionality constant is no longer a resistance (though it still has units of ohms). In circuits that contain capacitors and/or inductors, we use the general name **reactance** for the proportionality constant between the potential difference amplitude and the current amplitude. From Eq. 32.13 we see that this proportionality constant for a circuit that contains a capacitor is $1/\omega C$, and we call this constant the *capacitive reactance* X_C:

$$X_C \equiv \frac{1}{\omega C}, \tag{32.14}$$

so Eq. 32.13 becomes

$$V_C = IX_C. \tag{32.15}$$

Reactance is a measure of the opposition of a circuit element to a change in current. Unlike resistance, reactance is frequency dependent. At low frequency, the capacitive reactance X_C is large, which means that the amplitude of the current is small for a given value of V_C. At zero frequency, the current $I = \omega C V_C$ is zero, as it should be. (There is no direct current in a capacitor because the capacitor is just like an open circuit!) The higher the frequency of the source, the smaller the capacitive reactance and the greater the current (the less the capacitor opposes the alternating current).



Often, when analyzing AC circuits, the only things we are interested in are the amplitudes of the currents and potential differences. The capacitive reactance allows us to calculate the amplitude of the current in the capacitor directly from the amplitude of the potential difference across it—in this case, the emf of the source.

It is conventional to write the current in an AC circuit in the form

$$i = I \sin(\omega t - \phi), \tag{32.16}$$

where ϕ is called the **phase constant.** The negative sign in front of the phase constant is chosen so that a positive ϕ corresponds to shifting the curve for the current to the right, in the positive direction along the time axis, and a negative ϕ corresponds to shifting the curve to the left, in the negative direction along this axis (**Figure 32.49**).

Figure 32.49 Positive and negative phase constant.

QUANTITATIVE TOOLS

The phase constant represents the phase difference between the source emf and the current. It is measured from the current phasor to the source emf phasor with the counterclockwise direction being positive (Figure 32.49). As a result, when the current leads the source emf, ϕ is negative; when the current lags the source emf, ϕ is positive.

Comparing Eqs. 32.12 and 32.16, we see that for the capacitor-AC source circuit of Figure 32.47, $\phi = -\pi/2$, as shown in Figure 32.48*a*. The negative phase constant means that the current leads the source emf. The curve for i is shifted to the left relative to the curve for v_C, as shown in Figure 32.48*b*. As you can see from the figure, when the capacitor has maximum charge (v_C maximum), the current is zero because at that instant the current reverses direction as the capacitor begins discharging. The current reaches its maximum value when the capacitor is completely discharged ($v_C = 0$).

32.11 As in the *LC* circuit discussed in Section 32.1, the current in the circuit of Figure 32.47 oscillates. If we think of v_C as corresponding to the position of the simple harmonic oscillator described in Section 15.5, what property of the circuit of Figure 32.47 corresponds to the velocity of the oscillator?

Finally, consider an inductor connected to an AC source (**Figure 32.50**). Because the inductor and the source are connected to each other, we have

$$\mathscr{E} = v_L, \tag{32.17}$$

so the potential difference across the inductor is

$$v_L = \mathscr{E}_{\max} \sin \omega t = V_L \sin \omega t. \tag{32.18}$$

In Chapter 29 we saw that a changing current in an inductor causes an induced emf (Eq. 29.19):

$$\mathscr{E}_{\text{ind}} = -L\frac{di}{dt}. \tag{32.19}$$

The negative sign in this expression means that the potential decreases across the inductor in the direction of increasing current. Consequently, in Figure 32.50, the potential at b is lower than the potential at a when the current is increasing clockwise around the circuit. However, for consistency with Eq. 32.3, we always measure the potential difference v_L from b to a, just as we did with the AC source-resistor circuit of Figure 32.44. Therefore the sign of the potential difference across the inductor is the opposite of the sign in Eq. 32.19:

$$v_L = L\frac{di}{dt}. \tag{32.20}$$

We obtain the current in the circuit by substituting Eq. 32.18 into Eq. 32.20:

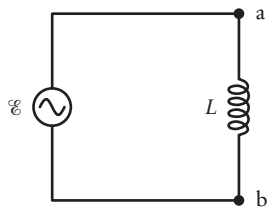
$$L\frac{di}{dt} = V_L \sin \omega t \tag{32.21}$$

$$di = \frac{V_L}{L} \sin \omega t \, dt. \tag{32.22}$$

To obtain the current, we integrate this expression:

$$i = \frac{V_L}{L}\int \sin \omega t \, dt = -\frac{V_L}{\omega L} \cos \omega t. \tag{32.23}$$

Figure 32.50 AC circuit consisting of an inductor connected across the terminals of an AC source.



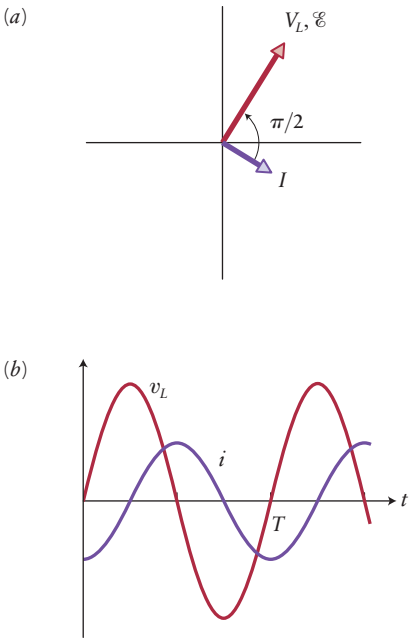


Figure 32.51 (*a*) Phasor diagram and (*b*) graph showing time dependence of i and v_L for the circuit of Figure 32.50. The phasor diagram shows the phase difference $\phi = \pi/2$ between i and v_L.

The amplitude of the current is thus

$$I = \frac{V_L}{\omega L}, \tag{32.24}$$

and using the identity $\cos \omega t = -\sin\left(\omega t - \frac{\pi}{2}\right)$, we get

$$i = I \sin\left(\omega t - \frac{\pi}{2}\right). \tag{32.25}$$

The phase constant is $\phi = +\pi/2$, which means the current lags the source by 90°, as shown in **Figure 32.51**.

Just as we defined a capacitive reactance for a circuit that contains a capacitor, we define the *inductive reactance* X_L for a circuit that contains an inductor as the constant of proportionality between the amplitudes V_L and I in the circuit. From Eq. 32.24 we see that this proportionality constant is ωL:

$$X_L \equiv \omega L, \tag{32.26}$$

so that

$$V_L = IX_L. \tag{32.27}$$

Inductive reactance, like capacitive reactance, has units of ohms and depends on the frequency of the AC source. However, X_L increases with increasing frequency, so, at a given potential difference, the amplitude of the current is greatest at zero frequency and decreases as the frequency increases. This makes sense because for a constant current, an inductor is just a conducting wire and does not impede the current; as the frequency of the AC source increases, the emf induced across the inductor increases.

EXAMPLE 32.6 Oscillating inductor

When a 3.0-H inductor is the only element in a circuit connected to a 60-Hz AC source that is delivering a maximum emf of 160 V, the current amplitude is I. When a capacitor is the only element in a circuit connected to the same source, what must the capacitance be in order to have the current amplitude again be I?

❶ **GETTING STARTED** I begin by identifying the information given in the problem statement: $\mathscr{E}_{max} = 160$ V, angular frequency $\omega = 2\pi(60\text{ Hz})$, and inductance $L = 3.0$ H. The problem asks me to compare two circuits, one with an inductor connected to an AC source and the other with a capacitor connected to the same source. What I must determine is the capacitance value that makes the current amplitude the same in the two circuits.

❷ **DEVISE PLAN** For both circuits the potential difference across the load equals the source emf, so $\mathscr{E}_{max} = V_C = V_L$. I can use Eqs. 32.26 and 32.27 to get an expression for V_L in terms of I, from which I can express I in the inductor circuit in terms of V_L, ω, and L. Next I can use Eqs. 32.14 and 32.15 to get an expression for V_C in terms of I. I can then substitute this into my first expression for I and obtain an expression for C that contains only known quantities.

❸ **EXECUTE PLAN** Substituting the inductive reactance from Eq. 32.26, $X_L = \omega L$, into Eq. 32.27, $V_L = IX_L$, I get $V_L = I\omega L$, so the amplitude of the current is

$$I = \frac{V_L}{\omega L}. \tag{1}$$

Substituting the capacitive reactance from Eq. 32.14, $X_C = 1/\omega C$, into Eq. 32.15, $V_C = IX_C$, I get

$$V_C = \frac{I}{\omega C}. \tag{2}$$

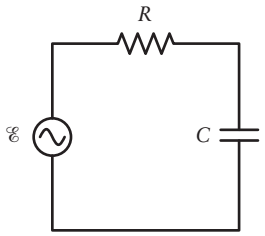
Solving Eq. 2 for C and substituting Eq. 1 for I give

$$C = \frac{I}{\omega V_C} = \frac{V_L}{\omega^2 V_C L} = \frac{1}{\omega^2 L}$$

$$= \frac{1}{(2\pi \cdot 60\text{ Hz})^2(3.0\text{ H})} = 2.3 \times 10^{-6}\text{ F}. \checkmark$$

❹ **EVALUATE RESULT** To check my answer, I can calculate the inductive and capacitive reactances from Eqs. 32.26 and 32.14, respectively: $X_L = \omega L = (2\pi \cdot 60\text{ Hz})(3.0\text{ H}) = 1.1\text{ k}\Omega$ and $X_C = 1/\omega C = 1/(2\pi \cdot 60\text{ Hz})(2.3 \times 10^{-6}\text{ F}) = 1.1\text{ k}\Omega$. The two reactances are identical, as I expect given that they yield the same current amplitude for the same AC source.

QUANTITATIVE TOOLS



32.12 For the three circuits discussed in this section (AC source with resistor, capacitor, or inductor), sketch for a given emf amplitude (*a*) the resistance or reactance as a function of angular frequency ω and (*b*) the current amplitude in the circuit as a function of ω. Explain the meaning of each curve on your graphs.

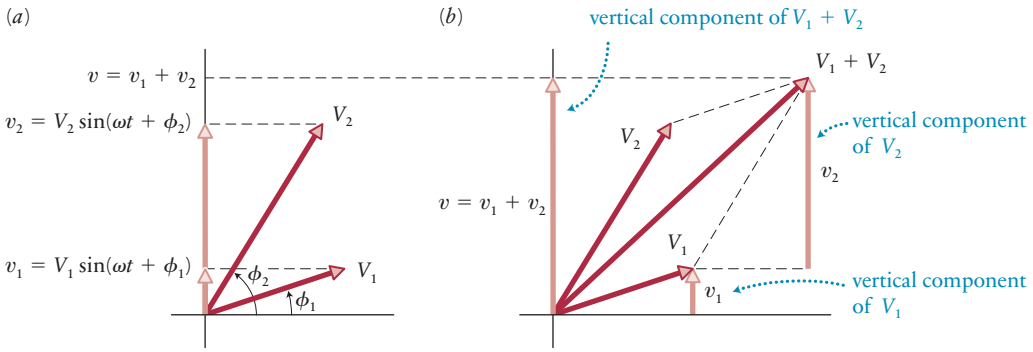
32.6 *RC* and *RLC* series circuits

When an AC source is connected to multiple circuit elements, either in series or in parallel, applying the loop rule becomes more complicated than for DC circuits because we need to add several oscillating potential differences that may be out of phase with one another. For example, suppose we have a resistor and a capacitor in series with an AC source (**Figure 32.52**), known as an *RC series circuit*. The loop rule states that

$$\mathscr{E} = v_R + v_C. \tag{32.28}$$

Figure 32.52 An *RC* series circuit, consisting of a resistor and a capacitor in series across the terminals of an AC source.

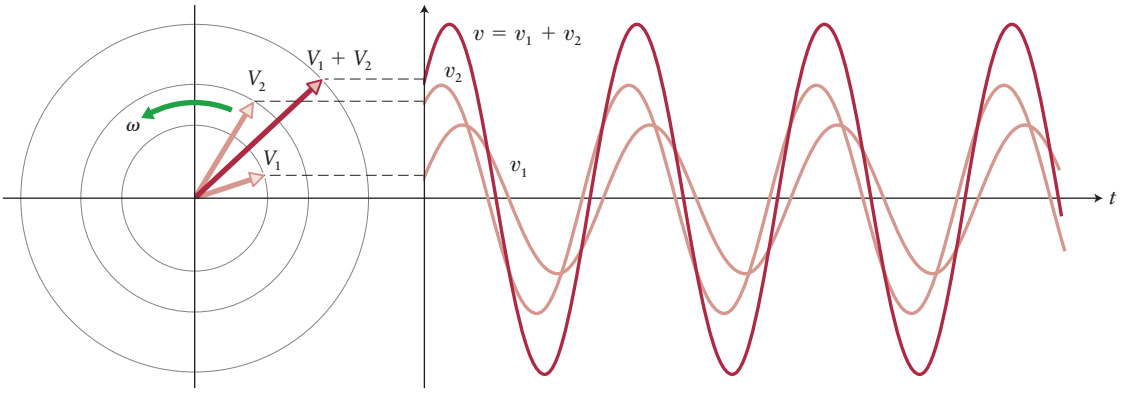
To compute the sum on the right side of this equation, we must add potential differences that vary sinusoidally at the same angular frequency ω but are out of phase. The combined potential difference v of two potential differences v_1 and v_2 that oscillate at the same angular frequency is



$$v = V_1 \sin(\omega t + \phi_1) + V_2 \sin(\omega t + \phi_2), \tag{32.29}$$

where ϕ_1 and ϕ_2 are the initial phases of the two potential differences. Calculating this sum algebraically gets very messy, but using phasors to calculate it simplifies things greatly.

Figure 32.53*a* shows the phasors that correspond to the two terms on the right in Eq. 32.29. Recall that the instantaneous value of the quantity represented by a rotating phasor equals the vertical component of the phasor (see Figure 32.11). Therefore, v at any instant equals the sum of the vertical components of the phasors that represent v_1 and v_2. This sum is equal to the vertical component of the vector sum $V_1 + V_2$ of the phasors, as shown in Figure 32.53*b*.



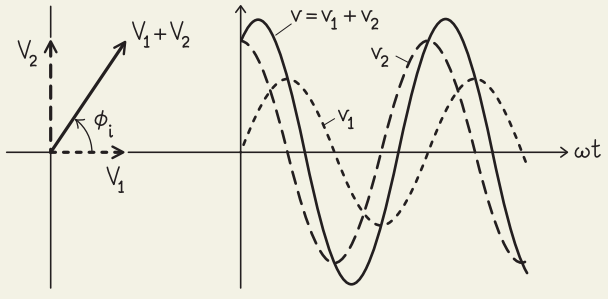
Note that the combined potential difference v oscillates at the same angular frequency as the two potential differences v_1 and v_2. Consequently, the three phasors V_1, V_2, and $V_1 + V_2$ rotate as a unit at angular frequency ω, as

Figure 32.53 (*a*) Phasor diagram for a system of two oscillating potential differences v_1 and v_2. (*b*) Vector diagram indicating that the vertical component of the vector sum of the phasors equals the sum of the vertical components of the individual phasors.

QUANTITATIVE TOOLS

Figure 32.54 Phasor diagram and graph showing time dependence of v_1, v_2, and $v = v_1 + v_2$ from Figure 32.53. All three phasors rotate as a unit at angular frequency ω.

shown in **Figure 32.54**. The phase relationship among the three phasors is constant, as is the phase relationship among the potential differences.



The next example shows how to apply these principles to a specific situation. To convince yourself that the phasor method is worthwhile, try adding the two original trigonometric functions algebraically after solving the problem using phasors!

EXAMPLE 32.7 Adding phasors

Use phasors to determine the sum of the oscillating potential differences $v_1 = (2.0\ \text{V}) \sin \omega t$ and $v_2 = (3.0\ \text{V}) \cos \omega t$.

❶ **GETTING STARTED** I begin by making a graph showing the time dependence of v_1 and v_2, and I draw the corresponding phasors V_1 and V_2 to the left of my graph (**Figure 32.55**). I add to my phasor diagram the phasor $V_1 + V_2$, which is the phasor that represents the potential difference sum $v_1 + v_2$ that I must determine. Using phasor $V_1 + V_2$, I can sketch the time dependence of the sum $v_1 + v_2$ by tracing out the projection of phasor $V_1 + V_2$ onto the vertical axis of my $V(\omega t)$ graph as this phasor rotates counterclockwise from the starting position I drew.

Figure 32.55

❷ **DEVISE PLAN** To obtain an algebraic expression for $v_1 + v_2$, I first write the oscillating potential differences in the form $v_1 = V_1 \sin(\omega t + \phi_1)$ and $v_2 = V_2 \sin(\omega t + \phi_2)$. Comparing these expressions with the given potential differences, I see that $V_1 = 2.0$ V, $\phi_1 = 0$, and $V_2 = 3.0$ V. In order to determine ϕ_2, I use the trigonometric identity $\cos(\omega t) = \sin(\omega t + \pi/2)$, and so my given information $v_2 = (3.0\ \text{V}) \cos \omega t = (3.0\ \text{V}) \sin(\omega t + \pi/2)$ tells me that $\phi_2 = \pi/2$. The sum $v_1 + v_2$ is a sinusoidally varying function that can be written as $v_1 + v_2 = A \sin(\omega t + \phi_i)$. The amplitude A is equal to the length of the phasor $V_1 + V_2$, and from my sketch I see that the initial phase ϕ_i is given by the angle between $V_1 + V_2$ and V_1.

❸ **EXECUTE PLAN** The length of the phasor $V_1 + V_2$ is given by the Pythagorean theorem applied to the right triangle containing ϕ_i in my phasor diagram:

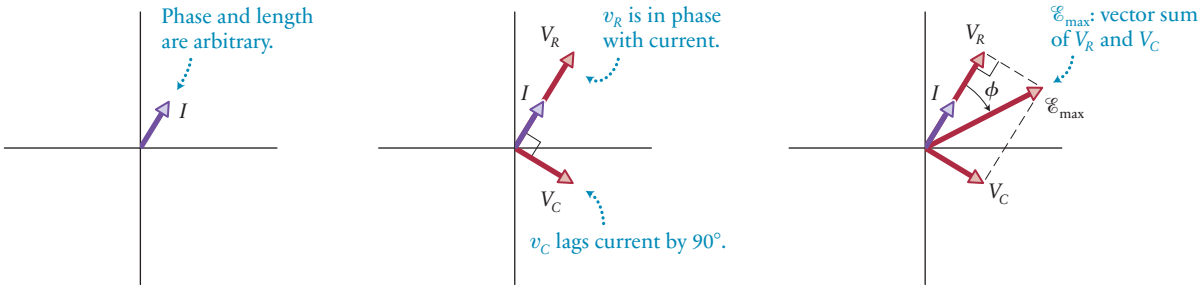
$$A = \sqrt{V_1^2 + V_2^2} = \sqrt{(3.0\ \text{V})^2 + (2.0\ \text{V})^2}$$
$$= \sqrt{13\ \text{V}^2} = 3.6\ \text{V}.$$

The tangent of the angle between $V_1 + V_2$ and V_1 is then

$$\tan \phi_i = \frac{V_2}{V_1} = \frac{3.0\ \text{V}}{2.0\ \text{V}} = 1.5,$$

so $\phi_i = \tan^{-1}(1.5) = 56°$.

Now that I have determined A and ϕ_i, I can write the sum of the two potential differences as



$$v_1 + v_2 = (3.6\ \text{V}) \sin(\omega t + 56°). \checkmark$$

❹ **EVALUATE RESULT** The amplitude of the sinusoidal function I obtained is 3.6 V, which is greater than the larger of the two phasors I added, as I expect. My answer shows that the sum of the two potential differences reaches its maximum when $\omega t + \phi_i = 90°$, or when $\omega t = 90° - \phi_i = 34°$. This conclusion agrees with my phasor diagram: The phasor $V_1 + V_2$ reaches the vertical position after it rotates through an angle of $90° - \phi_i = 90° - 56° = 34°$. (I could also verify my answer by adding the two original sine functions algebraically, but the trigonometry needed in that approach is tedious.)

QUANTITATIVE TOOLS

Figure 32.56 Steps involved in constructing a phasor diagram for the circuit in Figure 32.52. The diagram in part *c* indicates the phase of the current relative to the source emf.

(*a*) Draw current phasor (*b*) Add phasors for v_R and v_C (*c*) Add phasor for emf

32.13 Suppose you need to add two potential differences that are oscillating at *different* angular frequencies—say, 2 sin (ωt) and 3 cos ($2\omega t$). Can you use the phasor method described above to determine the sum? Why or why not?

Let us now return to the *RC* series circuit of Figure 32.52 and construct a phasor diagram in order to determine the amplitude and phase of the current in terms of the amplitude of the source emf and the resistance and capacitance of the circuit elements. From the current, we can calculate the potential differences across the circuit elements.

Because the circuit contains only one loop, the time-dependent current i is the same throughout. Therefore, we begin by drawing a phasor that represents i (**Figure 32.56*a***). We are free to choose the phase of this phasor because we have not yet specified the phase of any of the potential differences in the circuit. Also, the length we draw for phasor I is unimportant because it is the only current phasor for this circuit.

Next, we draw the phasors for v_R and v_C, the potential differences across the resistor and capacitor, respectively. We must get the relative phases right, and the lengths of the phasors must also be appropriately proportioned. Because the current is in phase with v_R (Figure 32.45*a*), we draw the corresponding phasor as shown in Figure 32.56*b*; its length is $V_R = IR$.

What about the phasor for v_C? We found previously that the current in a capacitor leads the potential difference across the capacitor by 90° (Figure 32.48*a*), which means we must draw the phasor for v_C 90° behind the phasor for i, as it is in Figure 32.56*b*. The length of this phasor is $V_C = IX_C$.

Finally, we need to draw the phasor for the emf supplied by the source. Phasor addition with the loop rule for this circuit (Eq. 32.28) tells us that the phasor $\mathscr{E}_{max}$ for the emf is the vector sum of the phasors V_R and V_C (Figure 32.56*c*). The amplitudes of the potential differences are related by

$$\mathscr{E}_{max}^2 = V_R^2 + V_C^2. \tag{32.30}$$

If we substitute $V_R = IR$ (Eq. 32.6) and $V_C = IX_C$ (Eq. 32.15), this becomes

$$\mathscr{E}_{max}^2 = (IR)^2 + (IX_C)^2 = I^2(R^2 + X_C^2) = I^2\left(R^2 + \frac{1}{\omega^2 C^2}\right). \tag{32.31}$$

Solving for I gives

$$I = \frac{\mathscr{E}_{max}}{\sqrt{R^2 + 1/\omega^2 C^2}}. \tag{32.32}$$

Remembering that $\mathscr{E}_{max} = V_{load}$, we see that even though this load includes both resistive and reactive elements, I is still proportional to V_{load}! The constant of proportionality is called the **impedance** of the load and is denoted by Z:

$$I = \frac{\mathscr{E}_{max}}{Z}. \tag{32.33}$$

The impedance of the load is a property of the entire load. It is measured in ohms and depends on the frequency for any load that contains reactive elements.

Impedance plays the same role in AC circuits that resistance plays in DC circuits. In fact, Eq. 32.33 can be thought of as the equivalent of Ohm's law for AC circuits. Equation 32.32 shows that, for an RC series circuit, Z depends on both R and C:

$$Z_{RC} \equiv \sqrt{R^2 + 1/\omega^2C^2} \quad (RC \text{ series combination}). \tag{32.34}$$

To express V_R and V_C in terms of $\mathscr{E}_{max}$, R, C, and ω, we use Eq. 32.32:

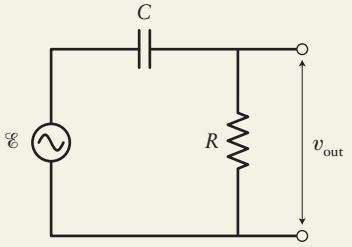
$$V_R = IR = \frac{\mathscr{E}_{max}R}{\sqrt{R^2 + 1/\omega^2C^2}} \tag{32.35}$$

$$V_C = IX_C = \frac{\mathscr{E}_{max}/\omega C}{\sqrt{R^2 + 1/\omega^2C^2}}. \tag{32.36}$$

To calculate the phase constant ϕ, the geometry shown in Figure 32.56*c* gives us, with Eqs. 32.6 and 32.15,

$$\tan\phi = -\frac{V_C}{V_R} = -\frac{IX_C}{IR} = -\frac{1}{\omega RC} \tag{32.37}$$

or



$$\phi = \tan^{-1}\left(-\frac{1}{\omega RC}\right) \quad (RC \text{ series circuit}). \tag{32.38}$$

The negative value of ϕ indicates that the current in an RC series circuit leads the emf, just as it does in an AC circuit with only a capacitor. As you can see in Figure 32.56*c*, however, the phase difference between the emf and the current in the RC series circuit is less than 90°.

EXAMPLE 32.8 High-pass filter

A circuit that allows emfs in one angular-frequency range to pass through essentially unchanged but prevents emfs in other angular-frequency ranges from passing through is called a *filter*. Such a circuit is useful in a variety of electronic devices, including audio electronics. An example of a filter, called a *high-pass filter*, is shown in Figure 32.57. Emfs that have angular frequencies above a certain angular frequency, called the *cutoff angular frequency* ω_c, pass through to the two output terminals marked v_{out}, but the filter attenuates the amplitudes of emfs that have frequencies below the cutoff value. (*a*) Determine an expression that gives, in terms of R and C, the cutoff angular frequency ω_c at which $V_R = V_C$. (*b*) Determine the potential difference amplitude v_{out} across the output terminals for $\omega \gg \omega_c$ and for $\omega \ll \omega_c$.

Figure 32.57 Example 32.8.

❶ **GETTING STARTED** This circuit is the same as the one in Figure 32.52, which I used to determine expressions for V_R (Eq. 32.35) and V_C (Eq. 32.36) in terms of R and C, so I can use those results. From Figure 32.57 I see that the

QUANTITATIVE TOOLS

potential difference v_{out} is equal to the potential difference across the resistor, so $V_{out} = V_R$.

2 DEVISE PLAN In order to determine the value of ω_c at which $V_R = V_C$, I equate the right sides of Eqs. 32.35 and 32.36. The resulting ω factor in my expression then is the cutoff value ω_c. For part *b*, I know that $V_{out} = V_R$. Therefore I can use Eq. 32.35 to determine V_{out} and then determine how V_{out} behaves in the limiting cases where $\omega \gg \omega_c$ and $\omega \ll \omega_c$.

3 EXECUTE PLAN (*a*) Equating the right sides of Eqs. 32.35 and 32.36, I get $R = 1/\omega C$. Solving for ω yields the desired cutoff angular frequency ω_c:

$$\omega_c = \frac{1}{RC}. \checkmark$$

(*b*) To obtain the values of V_{out} for $\omega \gg \omega_c$ and for $\omega \ll \omega_c$, I first rewrite Eq. 32.35 in a form that contains ω_c:

$$V_{out} = V_R = \frac{\mathscr{E}_{max} R}{\sqrt{R^2 + 1/\omega^2 C^2}} = \frac{\mathscr{E}_{max}}{\sqrt{1 + 1/R^2\omega^2 C^2}} = \frac{\mathscr{E}_{max}}{\sqrt{1 + \omega_c^2/\omega^2}}. \quad (1)$$

For $\omega \gg \omega_c$, the second term in the square root is equal to zero and Eq. 1 reduces to $V_{out} = \mathscr{E}_{max}$. ✔

For $\omega \ll \omega_c$, the second term in the square root dominates, so I can ignore the first term. Equation 1 then becomes

$$V_{out} = V_R = \frac{\mathscr{E}_{max}}{\sqrt{1 + \omega_c^2/\omega^2}} \approx \frac{\mathscr{E}_{max}}{\sqrt{\omega_c^2/\omega^2}} = \frac{\mathscr{E}_{max}\omega}{\omega_c} = \mathscr{E}_{max}\omega RC.$$

In the limit that the angular frequency ω approaches zero, V_{out} approaches zero as well. ✔

4 EVALUATE RESULT The name *high-pass filter* makes sense because this circuit allows emfs with an angular frequency higher than the cutoff angular frequency to pass through to the output but attenuates emfs of angular frequency lower than the cutoff angular frequency, preventing them from passing through to the output. It is the capacitor that does the actual passing or blocking. It blocks low-angular-frequency emfs because for these emfs the capacitive reactance, $X_C = 1/\omega C$, is very high. For high-angular-frequency emfs, X_C approaches zero, and so the capacitor passes the emf undiminished.

32.14 Interchange the resistor and the capacitor in Figure 32.57, and then show that the high-pass filter becomes a low-pass filter.

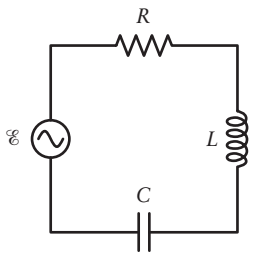
Filters can also be constructed by wiring an inductor and a resistor in series with an AC source. Such a circuit is called an *RL* series circuit and can be analyzed in exactly the manner we used to analyze an *RC* series circuit (as we shall see in Example 32.9).

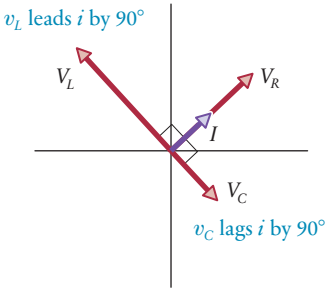
Finally, let's analyze an *RLC* series circuit: a resistor, a capacitor, and an inductor all in series with an AC source (**Figure 32.58**). As with the *RC* series circuit, the instantaneous current i is the same in all three elements, and the sum of all the potential differences equals the emf of the source:

$$\mathscr{E} = v_R + v_L + v_C. \quad (32.39)$$

The phasor diagram for this circuit is constructed in **Figure 32.59** for the case where $V_L > V_C$. As before, we begin with the phasors for i and v_R,

Figure 32.58 An *RLC* series circuit, consisting of a resistor, an inductor, and a capacitor in series across the terminals of an AC source.





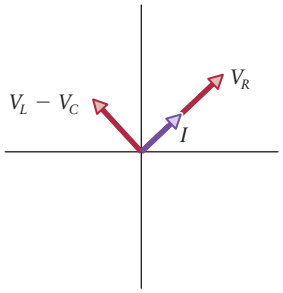


Figure 32.59 Steps involved in constructing a phasor diagram for the *RLC* series circuit in Figure 32.58. The diagram in part *c* indicates the phase of the current relative to the source emf.

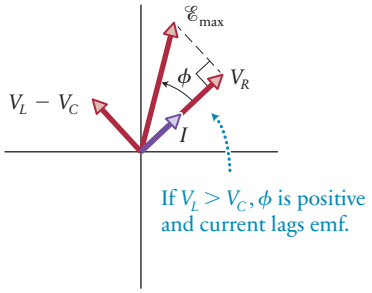


(*a*) Begin with phasors for i and v_R (in phase)

(*b*) Add V_C and V_L

(*c*) Add $V_L - V_C$ and V_R to obtain $\mathscr{E}_{max}$

and then note that v_C lags i by 90° and v_L leads i by 90° (Figure 32.59*a*). As a result, the phasors V_C and V_L can be added directly (Figure 32.59*b*). Finally, the loop rule (Eq. 32.39) requires the phasor for the emf to equal the vector sum of the phasors for the potential differences, as shown in Figure 32.59*c*. Consequently, the amplitudes V_R, V_L, and V_C must satisfy

$$\mathscr{E}_{\max}^2 = V_R^2 + (V_L - V_C)^2. \tag{32.40}$$

Rewriting Eq. 32.40 in terms of I, R (from Eq. 32.6), X_L (from Eq. 32.27), and X_C (from Eq. 32.15) gives

$$\mathscr{E}_{\max}^2 = I^2[R^2 + (X_L - X_C)^2] = I^2[R^2 + (\omega L - 1/\omega C)^2], \tag{32.41}$$

and thus

$$I = \frac{\mathscr{E}_{\max}}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}}. \tag{32.42}$$

The impedance of the RLC series combination (in other words, the constant of proportionality between I and $\mathscr{E}_{\max}$) is therefore

$$Z_{RLC} \equiv \sqrt{R^2 + (\omega L - 1/\omega C)^2} \quad (RLC \text{ series combination}). \tag{32.43}$$

Table 32.1 lists the impedances of various loads.

Figure 32.59*c* shows that the phase relationship between the current and the source emf depends on the relative magnitudes of V_L and V_C. The phase of the current relative to the emf is given by

$$\tan\phi = \frac{V_L - V_C}{V_R} = \frac{X_L - X_C}{R}$$

$$= \frac{\omega L - 1/\omega C}{R} \quad (RLC \text{ series circuit}). \tag{32.44}$$

If $V_L > V_C$, as it is in Figure 32.59, ϕ is positive, meaning that the current lags the source emf. Here the inductor dominates the capacitor, and as a result the series combination of the inductor and capacitor behaves like an inductor. If $V_L < V_C$, ϕ is negative, the inductor-capacitor combination is dominated by the capacitor, and the current leads the source emf, just as in an RC series circuit.

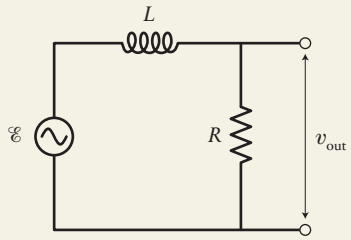
In general, when analyzing AC series circuits, follow the procedure shown in the Procedure box "Analyzing AC series circuits."

Table 32.1 Impedances of various types of loads (all elements in series)

Load	Z
R	R
L	ωL
C	$1/\omega C$
RC	$\sqrt{R^2 + (1/\omega C)^2}$
RLC	$\sqrt{R^2 + (\omega L - 1/\omega C)^2}$

Note that impedances do not simply add the way resistances do. However, the impedance of any simpler load can be found from the impedance of the RLC combination; for example, $Z_{RC} = Z_{RLC}$ without the term containing L.

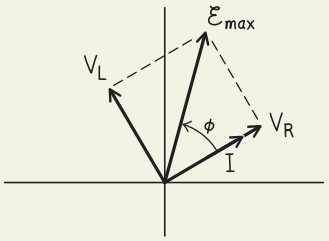
PROCEDURE: Analyzing AC series circuits



When analyzing AC series circuits, we generally know the properties of the various circuit elements (such as R, L, C, and $\mathscr{E}$) but not the potential differences across them. To determine these, follow this procedure:

1. To develop a feel for the problem and to help you evaluate the answer, construct a phasor diagram for the circuit.
2. Use Eq. 32.43 to determine the impedance of the load. If there is no inductor, then ignore the term containing L; if there is no capacitor, ignore the term containing C; and so on.
3. To determine the amplitude of the current in the circuit, you can now use Eq. 32.42; to determine the phase of the current relative to the emf, use Eq. 32.44.
4. Determine the amplitude of the potential difference across any reactive element using $V = XI$, where X is the reactance of that element. For a resistor, use $V = RI$.

EXAMPLE 32.9 *RL* series circuit



Consider the circuit shown in **Figure 32.60**. (*a*) Determine the cutoff angular frequency ω_c and the phase constant at which $V_R = V_L$. (*b*) Can this circuit be used as a low-pass or high-pass filter?

Figure 32.60 Example 32.9.

❶ **GETTING STARTED** This example is similar to Example 32.8, with the capacitor of that example replaced by an inductor here. As in Example 32.8, I see from the circuit diagram that the potential difference v_{out} is equal to the potential difference across the resistor, so $V_{out} = V_R$. I begin by drawing a phasor diagram for the circuit (**Figure 32.61**). I first draw phasors V_R and I, which I know from Figure 32.45*a* are in phase. I then add V_L, which leads I by 90° (Figure 32.51*a*). I make V_L have the same length as V_R because the problem asks about the circuit when $V_R = V_L$.

Figure 32.61

❷ **DEVISE PLAN** To determine the potential difference amplitudes V_L and V_R across the inductor and the resistor, I follow the procedure given in the Procedure box above. I then set these two amplitudes equal to each other in order to determine ω_c and the phase constant. To determine whether this circuit can be used as a low-pass or high-pass filter, I examine the behavior of V_{out} for $\omega \gg \omega_c$ and for $\omega \ll \omega_c$.

❸ **EXECUTE PLAN** (*a*) Ignoring the term containing C in Eq. 32.43 and substituting the result in Eq. 32.33, I get for the current amplitude

$$I = \frac{\mathscr{E}_{max}}{\sqrt{R^2 + (\omega L)^2}}.$$

I can now use Eq. 32.6 to calculate the amplitude of the potential difference across the resistor,

$$V_R = IR = \frac{\mathscr{E}_{max} R}{\sqrt{R^2 + (\omega L)^2}}, \tag{1}$$

and Eq. 32.27 to calculate the amplitude of the potential difference across the inductor,

$$V_L = IX_L = \frac{\mathscr{E}_{max} \omega L}{\sqrt{R^2 + (\omega L)^2}}, \tag{2}$$

where I have substituted ωL for X_L (Eq. 32.26). Equating the right sides of Eqs. 1 and 2 yields $R = \omega L$. Substituting ω_c for ω in this equation and solving for ω_c give me for the cutoff angular frequency value at which $V_R = V_L$:

$$\omega_c = \frac{R}{L}. \checkmark$$

To determine the phase constant for the condition $V_R = V_L$, I substitute V_R for V_L in Eq. 32.44 and set V_C equal to zero:

$$\tan\phi = \frac{V_L - V_C}{V_R} = \frac{V_R}{V_R} = 1,$$

so the phase constant is 45°. ✔

(*b*) Just as I did in Example 32.8, to obtain the limiting values of V_{out}, I first rewrite Eq. 1 in a form that contains ω_c:

$$V_{out} = V_R = \frac{\mathscr{E}_{max} R}{\sqrt{R^2 + (\omega L)^2}} = \frac{\mathscr{E}_{max}}{\sqrt{1 + (\omega L)^2/R^2}}$$

$$= \frac{\mathscr{E}_{max}}{\sqrt{1 + \omega^2/\omega_c^2}}. \tag{3}$$

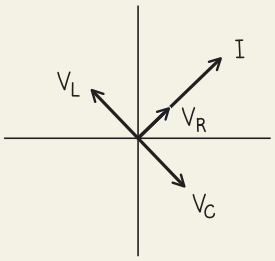
(Continued)

For $\omega \ll \omega_c$, the second term in the square root is equal to zero and Eq. 3 reduces to $V_{out} = \mathscr{E}_{max}$. For $\omega \gg \omega_c$ the second term in the square root dominates and we can ignore the first term. Equation 3 then becomes

$$V_{out} = V_R = \frac{\mathscr{E}_{max}}{\sqrt{1 + \omega^2/\omega_c^2}} \approx \frac{\mathscr{E}_{max}}{\sqrt{\omega^2/\omega_c^2}} = \frac{\mathscr{E}_{max}\omega_c}{\omega} = \frac{\mathscr{E}_{max}R}{\omega L}.$$

In the limit that the angular frequency ω becomes very large, V_{out} approaches zero. The circuit thus blocks high-frequency emfs and allows low-frequency ones to pass through to the output. Therefore it can be used as a low-pass filter. ✔

4 EVALUATE RESULT From my phasor diagram I see that the triangle that has V_R and V_L as two of its sides is an equilateral right-angle triangle, and so the phase constant ϕ must be 45°, as I obtained.



For part *b*, an emf is generated in the inductor whenever the current in it changes. This emf is proportional to the rate of change of the current in the inductor and it opposes the change in current (Eq. 29.19, $\mathscr{E}_{ind} = -L(di/dt)$). For a low-angular-frequency emf, di/dt is small, and the signal passes through the inductor essentially undiminished. For a high-angular-frequency signal, the inductive reactance $X_L = \omega L$ is high, and so the inductor essentially blocks the signal. It therefore makes sense that the arrangement in Figure 32.60 can serve as a low-pass filter.

EXAMPLE 32.10 *RLC* series circuit

Consider an *RLC* circuit, such as the one shown in Figure 32.58. The source emf has amplitude 160 V and frequency 60 Hz. The resistance is $R = 50\ \Omega$ and the inductance is $L = 0.26$ H. If the amplitudes of the potential difference across the capacitor and the inductor are equal, what is the current in the circuit?

1 GETTING STARTED I begin by drawing a phasor diagram for the circuit (**Figure 32.62**). I first draw phasors V_R and I, which are in phase, arbitrarily choosing the direction in which I draw them. I then add phasors V_C, which lags I by 90°, and V_L, which leads I by 90°.

Figure 32.62

2 DEVISE PLAN The current in the circuit depends on the impedance, which is given by Eq. 32.43. This equation contains *C*, however, and I am given no information about this variable. I am given, however, that $V_C = V_L$, and because both V_C and V_L are proportional to the current, I should be able to determine the current without knowing the capacitance in the circuit.

3 EXECUTE PLAN I know from Eq. 32.24 that $V_L = I\omega L$, and I also know that $V_C = I/\omega C$ (Eq. 32.13). Because $V_L = V_C$ in this problem, I can equate the terms on the right in these two equations to obtain

$$\omega L = \frac{1}{\omega C}. \qquad (1)$$

Substituting ωL for $1/\omega C$ in Eq. 32.43 yields $Z_{RLC} = R$. Now I can use Eq. 32.33 to determine the current in the circuit:

$$I = \frac{\mathscr{E}_{max}}{Z_{RLC}} = \frac{\mathscr{E}_{max}}{R} = \frac{160\ \text{V}}{50\ \Omega} = 3.2\ \text{A}. \checkmark$$

4 EVALUATE RESULT When the amplitudes of the potential differences across the inductor and the capacitor are equal, the lengths of the phasors V_C and V_L are equal. Because the phasors point in opposite directions (Figure 32.62), they add to zero, and so the impedance in the circuit is due to the resistor only. This means the current is essentially given by Ohm's law, $I = V/R$, or, in the version I obtained here, $I = \mathscr{E}_{max}/R$.

32.15 (*a*) Calculate the maximum potential difference across each of the three circuit elements in Example 32.10. (*b*) Is the sum of the amplitudes V_R, V_L, and V_C equal to the amplitude of the source emf? Why or why not?

32.7 Resonance

Consider again the *RLC* series circuit of Figure 32.58. Suppose that the amplitude $\mathscr{E}_{max}$ of the source emf is held constant, but we vary its angular frequency. What happens to the amplitude of the current I and to the phase constant ϕ? Combining Eqs. 32.42 and Eq. 32.43, we can say

$$I = \frac{\mathscr{E}_{max}}{Z} = \frac{\mathscr{E}_{max}}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}}. \qquad (32.45)$$

The current is at its maximum when the term in parentheses in the denominator is zero. When this term is zero, $V_L = V_C$ and the two potential

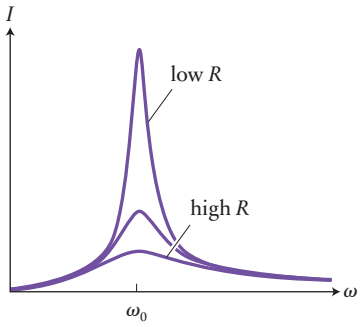
QUANTITATIVE TOOLS

differences are 180° out of phase. Therefore the effects of the inductor and the capacitor cancel each other and the circuit behaves as if only the resistor is present. The term in parentheses in Eq. 32.45 is zero when

$$\omega L = \frac{1}{\omega C}. \tag{32.46}$$

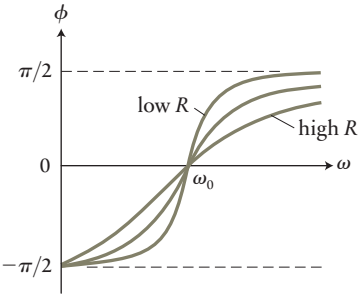
The angular frequency for which Eq. 32.46 is satisfied is called the **resonant angular frequency** ω_0 of the circuit:

$$\omega_0 = \frac{1}{\sqrt{LC}}. \tag{32.47}$$



The current amplitude and phase as a function of angular frequency are plotted in **Figure 32.63** for three values of R (with fixed values of $\mathscr{E}_{max}$, L, and C). Increasing or decreasing the angular frequency from ω_0 decreases the current amplitude. Changing R changes the maximum current that can be obtained and also changes how rapidly the current drops as the angular frequency increases or decreases from resonance.

Whenever an oscillating physical quantity has a peaked angular frequency dependence, the dependence is referred to as a *resonance curve*. The sharpness of the peak reflects the efficiency with which the source delivers energy to the system at or near resonance and depends on the amount of dissipation present in the system. A very tall, sharp peak corresponds to a system with low dissipation. In such a system, the source can pump an enormous amount of energy into the system at resonance. A short, broad peak corresponds to a system with high dissipation. Here, less energy goes into the system even at resonance, but that energy can be transferred in at angular frequencies farther from resonance. For the RLC series circuit, energy is dissipated via the resistor; high R values produce less current at ω_0 and a broader resonance curve, as Figure 32.63*a* shows.



Another system that exhibits resonance is a damped mechanical oscillator (see Section 15.8) driven by an external source. The damping in a mechanical oscillator is analogous to the resistance in the RLC series circuit.

Figure 32.63 Current and phase changes in the RLC circuit of Figure 32.58.

(*a*) Frequency dependence of the current at low, medium, and high R

(*b*) Frequency dependence of current phase relative to source emf as function of angular frequency at low, medium, and high R

32.16 How does the resonance curve in Figure 32.63 change if the value of C or L is changed?

In the RLC series circuit, the phase difference between the current and the driving emf also depends on the angular frequency of the AC source. The current can either lag or lead the emf (or be in phase with it), depending on the angular frequency. We found previously that the phase of the current relative to the source emf for an RLC series circuit is given by Eq. 32.44:

$$\tan\phi = \frac{\omega L - 1/\omega C}{R}. \tag{32.48}$$

Consider the limiting values of this expression for the relative phase by looking at the curves in Figure 32.63*b*. At resonance ($\omega = \omega_0$), $\phi = 0$ and the current and the source emf are in phase. When $\omega = 0$, $\tan\phi = -\infty$ and $\phi = -\pi/2$. When $\omega = \infty$, $\tan\phi = \infty$ and $\phi = +\pi/2$. Below resonance, $\phi < 0$, the capacitor provides the dominant contribution to the impedance, and the current leads the source emf. Above resonance, $\phi > 0$ and the inductor dominates, and the current lags the source emf.

32.17 In an RLC series circuit, you measure $V_R = 4.9$ V, $V_L = 6.7$ V, and $V_C = 2.5$ V. Is the angular frequency of the AC source above or below resonance?

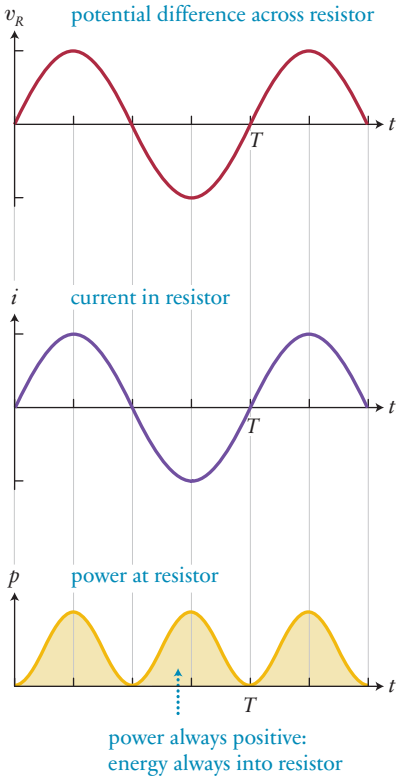


Figure 32.64 For an AC circuit consisting of a resistor connected across an AC source, time dependence of potential difference across the resistor, current in the resistor, and power dissipated at the resistor.

32.8 Power in AC circuits

At the beginning of this chapter, we saw that in alternating-current circuits, the energy stored in capacitors and inductors can oscillate. Consequently, for part of each cycle, these elements put energy back into the source rather than taking up energy from the source. Thus, unlike what we see in DC circuits, the source in an AC circuit does not simply deliver energy steadily to the circuit. Let's take a closer look at how to determine the rate at which an AC source delivers energy to a load.

In general, the rate at which the source delivers energy to its load—in other words, the power of the source—is the time-dependent version of the result we found for DC circuits (Eq. 31.42):

$$p = iv_{\text{load}}. \tag{32.49}$$

Because the current and the emf oscillate, this power varies with time and in principle can be either positive or negative. Let's first consider a load that consists of just one resistor. Ohm's law tells us that the instantaneous energy delivered to the resistor is

$$p = iv_R = i^2R = I^2R \sin^2 \omega t. \tag{32.50}$$

The time dependence of the potential difference, current, and power are shown in **Figure 32.64**. Because the current and potential difference are in phase, the power is always positive, and so the source always delivers energy to the resistor. This makes sense because the resistor dissipates energy regardless of the current direction. Consequently, the rate at which energy is dissipated in the resistor (the *power at the resistor*) is always positive and oscillates at *twice* the angular frequency of the emf.

For most applications, we are interested in the time average of the power at the resistor. Using the trigonometric identity $\sin^2\alpha = \frac{1}{2}(1 - \cos 2\alpha)$, we can rewrite Eq. 32.50 as

$$p = I^2R[\tfrac{1}{2}(1 - \cos 2\omega t)] = \tfrac{1}{2} I^2R - \tfrac{1}{2} I^2R \cos 2\omega t. \tag{32.51}$$

The first term on the right is constant in time. The second term on the right averages to zero over a full cycle because the area under the positive half of the cosine is equal to the area under the negative half. As a result, for time intervals much longer than the period of oscillation, the time average of the power at the resistor is

$$P_{\text{av}} = \tfrac{1}{2} I^2R. \tag{32.52}$$

For a sinusoidally varying current, the *root-mean-square* or *rms* value of the current is (Eqs. 19.21 and 30.39)

$$I_{\text{rms}} \equiv \sqrt{(i^2)_{\text{av}}} = \sqrt{\tfrac{1}{2}I^2} = \frac{I}{\sqrt{2}}. \tag{32.53}$$

and so

$$P_{\text{av}} = I_{\text{rms}}^2 R. \tag{32.54}$$

The advantage of writing the average power in terms of the rms current is that Eq. 32.54 is completely analogous to the expression for the rate of energy dissipation by a resistor connected to a DC source (Eq. 31.43). Similarly, we can introduce rms values of potential difference and source emf:

$$V_{\text{rms}} = \frac{V_R}{\sqrt{2}} \quad \text{and} \quad \mathscr{E}_{\text{rms}} = \frac{\mathscr{E}_{\text{max}}}{\sqrt{2}}. \tag{32.55}$$

QUANTITATIVE TOOLS

The rms value is a useful way to measure the average value of an oscillating current or emf because the strict time average of these quantities is zero. *Voltmeters* and *ammeters* typically measure the rms value of alternating potential differences and currents, respectively. Thus, for example, the wall potential difference in household electrical wiring in the United States is referred to as 120 V even though the amplitude is 170 V; the 120-V rating is the rms value.

Next let's look at a circuit made up of an AC source and a capacitor. How much power is delivered to the capacitor by the source? Now the current and the potential difference are out of phase (see Figure 32.48). Substituting from Eq. 32.8, $v_C = V_C \sin \omega t$, and Eq. 32.11, $i = \omega C V_C \cos \omega t$, into Eq. 32.49, we obtain

$$p = iv_C = (\omega C V_C \cos \omega t)(V_C \sin \omega t). \tag{32.56}$$

Using the trigonometric identity $\sin(2\alpha) = 2 \sin \alpha \cos \alpha$, we obtain

$$p = \tfrac{1}{2}\omega C V_C^2 \sin 2\omega t. \tag{32.57}$$

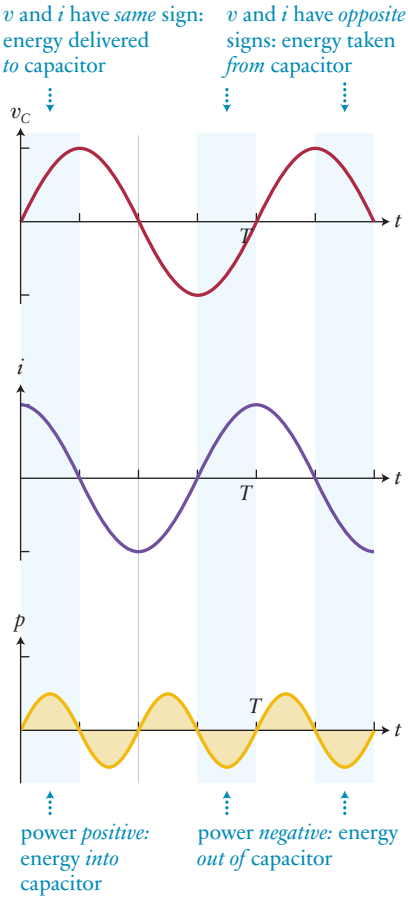
As in the resistor-only circuit, the power oscillates at twice the angular frequency of the source, but now the power is sometimes positive and sometimes negative, as shown in **Figure 32.65**. When v and i have the same sign, energy is transferred to the capacitor; when v and i have opposite signs, energy residing in the capacitor is transferred back to the source. The average power is zero, as it must be, because no energy is dissipated in a capacitor. The same is true for an inductor, except that in an inductor energy is stored as magnetic energy rather than electric energy; you can show this mathematically by converting Eqs. 32.56 and 32.57 to their V_L counterparts.

Finally, let's examine how power is delivered to the load in an *RLC* circuit. Although we could work out the power at each element, it's easier to consider the power for the entire load consisting of the *RLC* combination. The potential difference across the load is equal to the applied emf. Using Eq. 32.1, $\mathscr{E} = \mathscr{E}_{\max} \sin \omega t$, and Eq. 32.16, $i = I \sin(\omega t - \phi)$, we can write the instantaneous power as

$$p = vi = \mathscr{E}_{\max} I \sin \omega t \sin(\omega t - \phi). \tag{32.58}$$

Using the trigonometric identity $\sin(\alpha - \beta) = \sin \alpha \cos \beta - \cos \alpha \sin \beta$ to separate the ϕ and ω dependence and substituting $\sin \alpha \cos \alpha = \frac{1}{2} \sin 2\omega t$, we rewrite Eq. 32.58 in the form

$$\begin{aligned} p &= \mathscr{E}_{\max} I (\cos \phi \sin^2 \omega t - \sin \phi \sin \omega t \cos \omega t) \\ &= \mathscr{E}_{\max} I (\cos \phi \sin^2 \omega t - \sin \phi \tfrac{1}{2} \sin 2\omega t). \end{aligned} \tag{32.59}$$



The time average of $\sin^2 \omega t$ is 1/2, and the second term inside the parentheses averages to zero, leaving us with

$$P_{\text{av}} = \tfrac{1}{2} \mathscr{E}_{\max} I \cos \phi. \tag{32.60}$$

Writing this result using rms values (Eqs. 32.54 and 32.55) gives

$$P_{\text{av}} = \tfrac{1}{2}(\sqrt{2}\, \mathscr{E}_{\text{rms}})(\sqrt{2}\, I_{\text{rms}}) \cos \phi = \mathscr{E}_{\text{rms}} I_{\text{rms}} \cos \phi. \tag{32.61}$$

Figure 32.65 For an AC circuit consisting of a capacitor connected across an AC source, time dependence of potential difference across the capacitor, current in the capacitor, and power into or out of the capacitor.

We can rewrite this in a more physically insightful way if we note that $\mathscr{E}_{\text{rms}} = I_{\text{rms}} Z$ (Eq. 32.33) and note from Figure 32.59*c* that

$$\cos \phi = \frac{V_R}{\mathscr{E}_{\text{max}}} = \frac{RI}{ZI} = \frac{R}{Z}. \tag{32.62}$$

With these substitutions, Eq. 32.61 becomes

$$P_{\text{av}} = I_{\text{rms}} Z \, I_{\text{rms}} \frac{R}{Z} = I_{\text{rms}}^2 \text{R}. \tag{32.63}$$

This result tells us that all of the energy delivered to the circuit is dissipated as thermal energy in the resistor—as it must be, because neither the capacitor nor the inductor dissipates energy. This energy is dissipated at the same average rate as in a circuit made up of a single resistor connected to an AC source (Eq. 32.54).

The factor $\cos \phi$ that appears in Eqs. 32.60–32.62 is called the **power factor** which is a measure of the efficiency with which the source delivers energy to the load. At resonance, when the current and the emf are in phase ($\phi = 0$), the current and the power factor are greatest, and the maximum power possible is delivered to the load. At angular frequencies away from resonance, less power is delivered to the load.

32.18 Calculate the rate P_{av} at which energy is dissipated in the *RLC* series circuit of Example 32.10.

Chapter Summary

AC circuits (Sections 32.1, 32.2, 32.5)

Concepts **Alternating current** (AC) is current that periodically changes direction.

In an AC circuit that contains a capacitor, the current through the capacitor leads the potential difference by 90° (one-fourth of an oscillation).

In an AC circuit that contains an inductor, the current through the inductor lags the potential difference by 90°.

In any circuit that contains a capacitor and/or an inductor, **reactance** is the proportionality constant between the potential-difference amplitude and the current amplitude.

The **phase constant** ϕ for an AC circuit, which is the phase difference between the source emf and the current, is negative when the current leads the source emf and positive when the current lags the source emf.

Quantitative Tools The instantaneous emf supplied by an AC source is

$$\mathscr{E} = \mathscr{E}_{\max} \sin \omega t. \tag{32.1}$$

The instantaneous current in an AC circuit is

$$i = I \sin(\omega t - \phi), \tag{32.16}$$

where I is the amplitude (maximum value) of the current and ϕ is the **phase constant**.

In an AC circuit that contains a capacitor, the *capacitive reactance* is

$$X_C \equiv \frac{1}{\omega C}, \tag{32.14}$$

and the amplitude of the potential difference across the capacitor is

$$V_C = IX_C. \tag{32.15}$$

In an AC circuit that contains an inductor, the *inductive reactance* is

$$X_L \equiv \omega L, \tag{32.26}$$

and the amplitude of the potential difference across the inductor is

$$V_L = IX_L. \tag{32.27}$$

RC and *RLC* series circuits (Section 32.6)

Concepts The **impedance** of a load connected to an AC source is a proportionality constant between the amplitudes of the potential difference and the current through the load.

Quantitative Tools In an ***RC* series circuit,** the sum of all the instantaneous potential differences equals the emf of the source:

$$\mathscr{E} = v_R + v_C. \tag{32.28}$$

The current amplitude is

$$I = \frac{\mathscr{E}_{\max}}{Z}, \tag{32.33}$$

where Z is the **impedance** of the load. For an RC series circuit, the impedance is

$$Z_{RC} \equiv \sqrt{R^2 + 1/\omega^2 C^2}. \tag{32.34}$$

The amplitudes of the potential differences are

$$V_R = IR = \frac{\mathscr{E}_{\max} R}{\sqrt{R^2 + 1/\omega^2 C^2}} \tag{32.35}$$

$$V_C = IX_C = \frac{\mathscr{E}_{\max}/\omega C}{\sqrt{R^2 + 1/\omega^2 C^2}}, \tag{32.36}$$

and the **phase constant** for the circuit is

$$\phi = \tan^{-1}\left(-\frac{1}{\omega RC}\right). \tag{32.38}$$

In an ***RLC* series circuit,** the sum of all the instantaneous potential differences equals the emf of the source:

$$\mathscr{E} = v_R + v_L + v_C. \tag{32.39}$$

The **impedance** of the *RLC* series circuit is

$$Z_{RLC} \equiv \sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}, \tag{32.43}$$

and so the current amplitude is

$$I = \frac{\mathscr{E}_{\max}}{Z_{RLC}} = \frac{\mathscr{E}_{\max}}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}}. \tag{32.42}$$

The **phase constant** for the circuit is given by

$$\tan\phi = \frac{\omega L - 1/\omega C}{R}. \tag{32.44}$$

Resonance and power in AC circuits (Sections 32.7, 32.8)

Concepts At the **resonant angular frequency,** the current in a series *RLC* circuit is a maximum.

The **power factor** is a measure of the efficiency with which the source in an AC circuit delivers energy to the load.

Quantitative Tools The **resonant angular frequency** is

$$\omega_0 = \frac{1}{\sqrt{LC}}. \tag{32.47}$$

For a sinusoidally varying current, the *root-mean-square* current is

$$I_{\text{rms}} = \frac{I}{\sqrt{2}}, \tag{32.53}$$

and the root-mean-square potential difference is

$$V_{\text{rms}} = \frac{V}{\sqrt{2}} \qquad \mathscr{E}_{\text{rms}} = \frac{\mathscr{E}_{\max}}{\sqrt{2}}. \tag{32.55}$$

The average power is

$$P_{\text{av}} = \mathscr{E}_{\text{rms}} I_{\text{rms}} \cos\phi, \tag{32.61}$$

where the cosine term is the **power factor** for the circuit:

$$\cos\phi = \frac{R}{Z}. \tag{32.62}$$

Semiconductor devices (Sections 32.3, 32.4)

Concepts A **semiconductor** is a material that contains a limited number of charge carriers that can move freely and that has an electrical conductivity intermediate between that of electrical conductors and that of electrical insulators.

An *intrinsic* semiconductor is made of atoms of only one element. An *extrinsic* (*doped*) semiconductor contains, interspersed among the atoms of its main element, trace amounts of atoms of other elements. These *dopant* atoms alter the number of electrons that can move freely and so change the electronic properties of the semiconductor.

A **hole** is an incomplete bond in a semiconductor that behaves like a freely moving positive charge carrier.

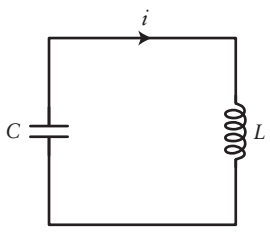
In a *p-type* semiconductor, holes are the free charge carriers. In an *n-type* semiconductor, electrons are the free charge carriers.

A **diode** is made by bringing a piece of *p*-type semiconductor into contact with a piece of *n*-type semiconductor. It behaves like a one-way valve for current.

The **depletion zone** in a diode is a thin insulating region at the junction between the *p*-type and *n*-type semiconductors where the positive and negative charge carriers have recombined and become immobile.

A **transistor** consists of a thin layer of one type of extrinsic semiconductor sandwiched between two layers of the opposite type of extrinsic semiconductor (such as *npn*). It behaves either like an on/off switch for current or like a current amplifier.

Questions and Problems



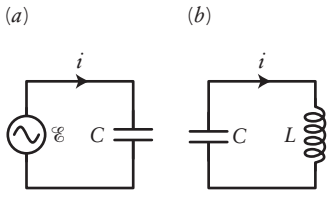
For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

32.1 Alternating currents

1. A fully charged parallel-plate capacitor is connected to an inductor with n turns of wire (Figure P32.1) What is the rms value of the magnetic field through the inductor, which has an rms current of I_{rms}? •

Figure P32.1



2. (*a*) If each vertical gray line in Figure 32.4*b* represents 0.020 s, what is the frequency of the oscillation? (*b*) What is the average potential difference across the capacitor in one cycle? •

3. For the circuit shown in Figure 32.4*a*, let the period T of the oscillation be 1.0 s and the emf be zero at $t = 0$. Identify the instant(s) at which the energy stored in the inductor reaches a maximum. •

4. (*a*) For the circuit shown in Figure P32.4*a*, draw (qualitative) curves showing the current as a function of time and the potential difference across the parallel-plate capacitor as a function of time. Assume that the capacitor is fully

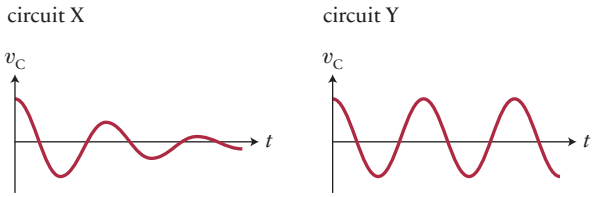


Figure P32.4

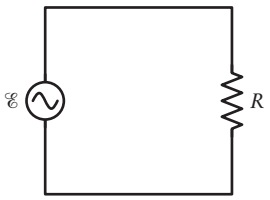
charged at $t = 0$ and that the potential is positive when the upper plate is positively charged, and use the current reference direction shown. (*b*) Repeat for the circuit in Figure P32.4*b*. ●●

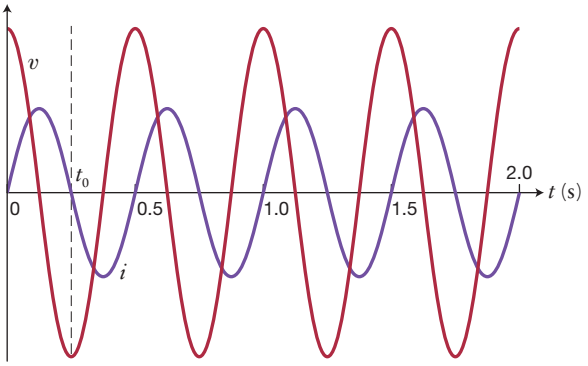


5. Two circuits X and Y each contain a parallel-plate capacitor and may contain other elements as well. The capacitors are identical, and the potential difference across each is shown in Figure P32.5. Which circuit—X, Y, or both—could contain a resistor, and under what circumstances could it/they contain a resistor? ●●

Figure P32.5

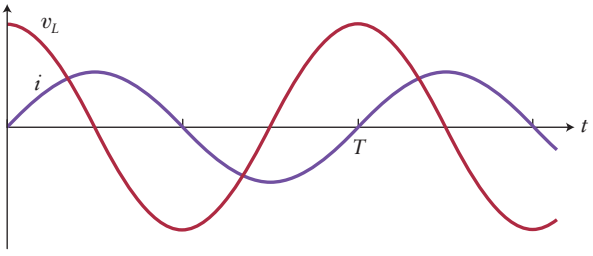
6. In an *LC* circuit like the one shown in Figure P32.1, which of these quantities simultaneously reach their maximum values: $|v_C|$, $|q_C|$, $|i|$, $|B|$, $|U^E|$, $|U^B|$? ●●
7. A parallel-plate capacitor is fully charged and connected in series to an inductor only. The capacitor initially stores charge q and electric potential energy U^E. Once the circuit is closed, charge carriers flow from the capacitor, producing a current in the circuit. When the charge on the capacitor has been reduced to $q/2$, what is the magnetic potential energy U^B stored in the inductor? Report your answer in terms of U^E. ●●
8. If the circuit in Figure P32.8 operates at 50 Hz with $\mathscr{E}_{max} = 120$ V and $R = 15.0\ \Omega$, how much energy is dissipated in the resistor in 1.5 s? ●●

Figure P32.8



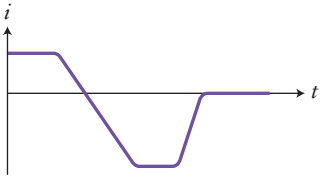
9. A circuit consists of a parallel-plate capacitor, an inductor, and a switch, which is initially open. The capacitor plates have an area of $1.00 \times 10^{-4}\ m^2$ and are held 0.100 mm apart by a thin layer of barium titanate. The capacitor is charged to a potential difference of 10 V, and then the switch is closed. How much charge remains on the capacitor at the instant the energy stored in the inductor has increased to 85% of its maximum? (See Table 26.1.) ●●●
10. In an *LC* circuit, there is always some energy dissipation as electrical energy is converted to thermal energy. (*a*) What property of the circuit is responsible for electrical energy being converted to thermal energy? (*b*) Describe the shape of a graph showing the charge on one capacitor plate as a function of time. (*c*) What sort of function would describe the rate at which energy is converted? [Hint: See the discussion of damped mechanical oscillators in Chapter 15.] ●●●

32.2 AC circuits



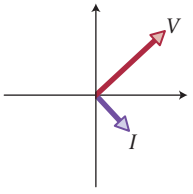
11. Draw a phasor diagram at instant t_0 for the circuit element whose instantaneous current and instantaneous potential difference are shown in Figure P32.11. ●

Figure P32.11



12. Draw a phasor diagram for the current and potential difference represented in Figure P32.12 at the instant $t = T$. Be sure to note which way it is rotating. ●

Figure P32.12



13. In a circuit consisting of an inductor connected to a nonsinusoidal AC source, the current varies as a function of time as shown in Figure P32.13. Sketch the potential difference across the inductor as a function of time. ●●

Figure P32.13

14. The phasor diagram in Figure P32.14 shows the potential difference across a circuit element and the current through the element at $t = 0$. (*a*) Is the element a resistor,

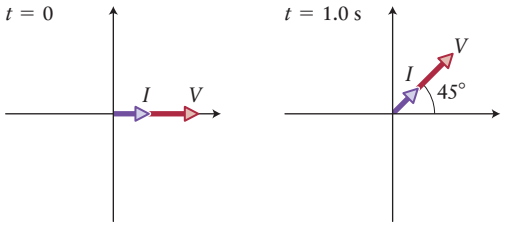


Figure P32.14

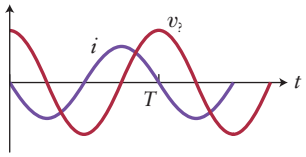
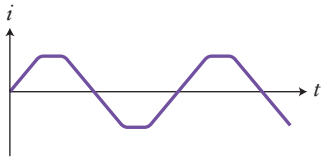
capacitor, or inductor? (*b*) On a single graph, sketch a curve showing v as a function of time and a curve showing i as a function of time. ●●



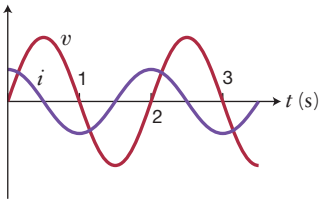
15. Figure P32.15 shows, for an AC circuit, the current phasor and a potential difference phasor at $t = 0$ and at $t = 1.0$ s. In each case, assume phasor magnitudes $I = 1.0$ A and $V = 9.0$ V. Give as many details about this circuit as you can. ●●

Figure P32.15



16. Figure P32.16 shows, for a circuit consisting of one element and an AC source, the current through the element as a function of time and the potential difference across the element. Is the element an inductor, a capacitor, or a resistor? ●●

Figure P32.16



17. In a circuit consisting of a nonsinusoidal AC source plus one additional element, the instantaneous current varies as shown in Figure P32.17. Sketch the potential difference across the additional element as a function of time if that element is (*a*) a capacitor and (*b*) an inductor. ●●●

Figure P32.17

18. A friend has built an AC circuit for you to analyze. You know the circuit contains a resistor, but it also contains another element. Because you know the circuit components available to your friend, you know that the unknown element must be a 0.32-F capacitor, a 0.32-mF capacitor, a 6.28-mH inductor, or a 62.8-mH inductor. Figure P32.18 shows curves for the current through the unknown element and the potential difference across it. The maximum current is 1.00 mA, and the maximum potential difference is 1.00 V. Which of the four available elements did your friend use, and how do you know? ●●●

Figure P32.18

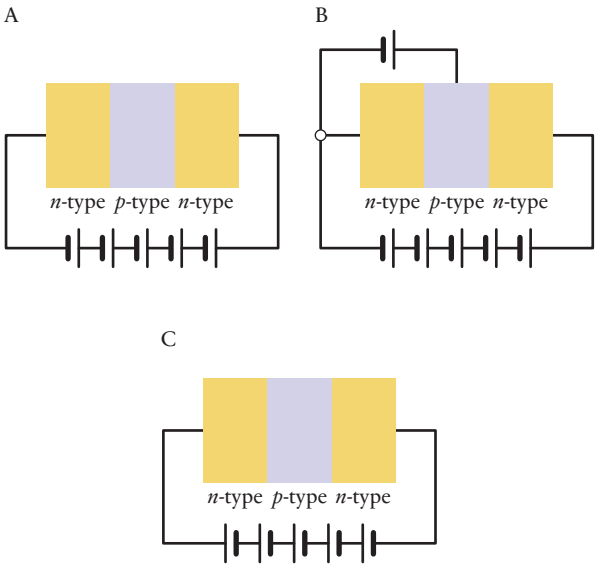
32.3 Semiconductors

19. A sample contains 3.0×10^{22} Si atoms and nothing else. (*a*) How many valence electrons does the sample contain? (*b*) How many of the valence electrons in the sample can conduct electricity? ●

20. Silicon is doped with the following elements. In each case, is the resultant extrinsic semiconductor *n*-type or *p*-type: indium, gallium, phosphorus, boron, arsenic, aluminum, antimony? ●

21. Conduction in a semiconductor can be greatly enhanced by the addition of very small quantities of dopant atoms, even in the parts-per-million range. Explain how the addition of such a tiny percentage of dopant atoms can increase the conduction of a semiconductor by a significant factor. ●

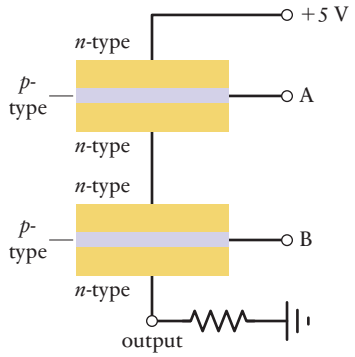
22. Unlike electrons, the holes in a semiconductor do not leave the semiconductor in which they are formed. Yet, holes can be thought of as positive charge carriers. When a hole has traveled to the edge of the semiconductor and reaches an electrical lead, where does it go? ●●



23. You have an intrinsic semiconductor, a *p*-type semiconductor, and an *n*-type semiconductor. The doped samples each contain the same number density of dopant atoms. Which of the three semiconductors do you expect to have (*a*) the greatest ability to carry current when the three are connected to identical batteries, (*b*) the greatest number of electrons, and (*c*) the greatest number of holes entering the battery as they leave the semiconductor? ●●

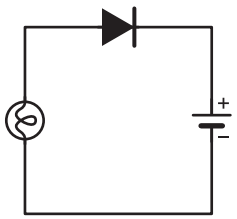
24. You have ordered a 10.00 mm × 10.00 mm × 2.000 mm sheet of pure silicon from a laboratory supply company, but the sheet the company sends has a mass of 465.9480 mg. You know that the company also produces silicon doped with boron, and you wonder if there may have been some contamination. The mass densities are $\rho_{Si} = 2329.6\ \text{kg/m}^3$ and $\rho_B = 2340\ \text{kg/m}^3$, and the atomic weights are B = 10.81 atomic units and Si = 28.085 atomic units. Determine as much information as possible about the contamination of your sheet. If you need pure silicon for its conduction properties, is this sheet likely to meet your needs? ●●●

32.4 Diodes, transistors, and logic gates



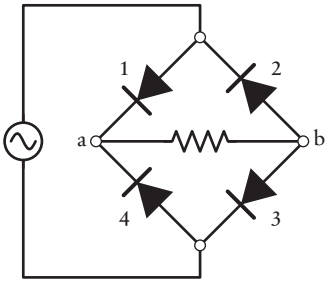
25. Which circuit in Figure P32.25 produces the greatest current in the emitter? •

Figure P32.25



26. The two transistors in Figure P32.26 are connected to each other by wires and also connected to input wires at terminals A and B. The output of this combination depends on the inputs at A and B. In terms of this circuit's reaction to input at A and B, which type of logical operation is performed? •

Figure P32.26



27. Is the light bulb in Figure P32.27 lit? •

Figure P32.27

28. The rectifier shown in Figure P32.28 converts the alternating emf from an AC source to a positive-only potential difference from a to b. Sketch graphs showing (*a*) the source emf as a function of time and (*b*) the potential difference from a to b as a function of time. (*c*) If diode 1 is blown out and acts as an open circuit, what is the output potential difference from a to b? (*d*) What happens to the potential difference from a to b if diode 1 operates normally but diode 2 is blown out? ••

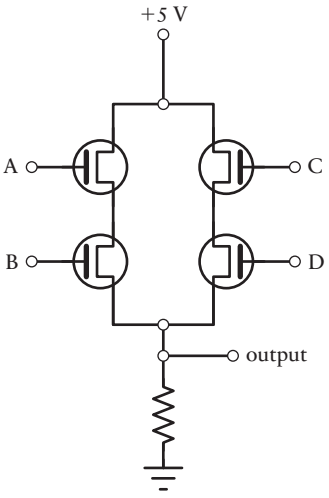


Figure P32.28

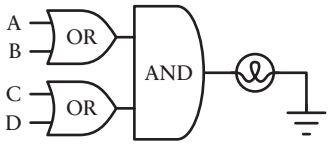
29. The circuit diagram for a rectifier is sometimes drawn with a resistor in the center. Would the rectifier function if this resistor were replaced by a capacitor? ••

30. The logic gate in Figure P32.30 contains four field-effect transistors. Each of the gates A–D of the transistors may be positively biased (Y in the table) or not (N in the table). Depending on the various bias combinations, charge carriers may or may not flow through the circuit. Fill in the output column of the table. ••

Figure P32.30



A	B	C	D	output
Y	Y	Y	Y	
Y	N	Y	Y	
Y	Y	Y	N	
N	N	Y	Y	
N	Y	Y	N	
N	N	N	Y	

31. You have two regions, A and B, of differently doped silicon, with the regions joined together to make a continuous silicon crystal. When the positive terminal of a battery is connected to region A and the negative terminal is connected to region B, no charge carriers flow. When the terminal connections are switched, charge carriers flow. (*a*) When there is a current, in which direction—A to B or B to A—do the positive charge carriers move? (*b*) In which direction do the electrons move? (*c*) Which region is *p*-type and which is *n*-type? (*d*) Which region may contain boron, and which may contain phosphorus? ••

32. Suppose a transistor consists of a very narrow *p*-type material sandwiched between two very wide regions of *n*-type material. (*a*) Is the charge on the *p*-type region positive or negative, and why? (*b*) Is the charge on the *n*-type region positive or negative, and why? ••

33. In Figure P32.33, what combinations of positive bias (input signals) A, B, C, D allow the light bulb to light up? ••

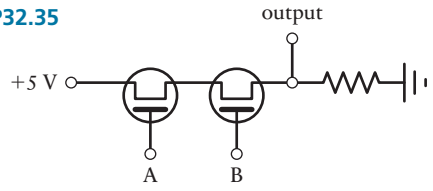


Figure P32.33

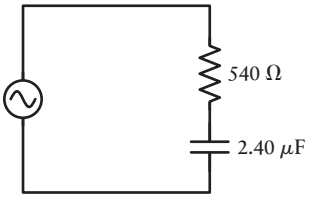
34. If in Figure P32.33 the two gates on the left were both AND and the gate on the right was OR, what combinations of positive bias (input signals) A, B, C, D would allow the light bulb to light up? ••

35. You are using the logic gate of Figure P32.35 to test some transistors and emf sources. The output produced by the logic gate depends on the potential relative to ground at inputs A and B. The only emf sources available to you are AC sources, but using one of them to bias either input A or input B results in an oscillating input potential. Consider how using an AC source affects the potential relative to ground at either A or B. Describe how using an AC source differs from using a DC source, both in general and in the specific function of this circuit. Could any modifications or additions be made to the circuit so that the way it functions with an AC source more closely resembles the way it would function with a DC source? Draw a circuit diagram of any useful modifications. •••

Figure P32.35



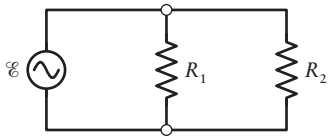
32.5 Reactance

36. In a circuit consisting of a 2 kΩ resistor connected in series with a 50 mH inductor, the amplitude of the emf is $\mathscr{E}_{max} = 20$ V, and a 20-kHz signal is applied. Find impedance, current, phase angle, and potential differences across the resistor and inductor. ••

37. The reactance of a 10-μF capacitor is $X_C = 200\ \Omega$. What is the angular frequency of the current through the capacitor? •

38. For the circuit shown in Figure P32.38, what must the frequency f of the AC source be in order for the amplitude V_C of the potential difference across the capacitor to equal the amplitude V_R of the potential difference across the resistor? •

Figure P32.38

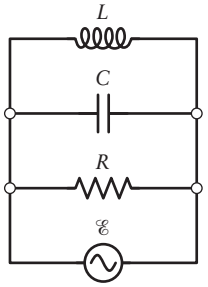


39. A capacitor for which $C = 10$ mF is connected across an AC source. The source emf is given by $\mathscr{E} = \mathscr{E}_{max} \sin \omega t$, with $\mathscr{E}_{max} = 5.0$ V and $\omega = 20\ s^{-1}$. (*a*) What is the amplitude of the current through the capacitor? (*b*) How does the current amplitude change as you increase the source angular frequency? ••

40. An inductor for which $L = 10$ mH is connected to an AC source. The source emf is given by $\mathscr{E} = \mathscr{E}_{max} \sin \omega t$, with $\mathscr{E}_{max} = 5.0$ V and $\omega = 200\ s^{-1}$. (*a*) What is the amplitude of the current through the inductor? (*b*) How does the current amplitude change as you lower the source angular frequency? As you lower the inductance? ••

41. Figure P32.41 shows resistors $R_1 = 10.0\ \Omega$ and $R_2 = 20.0\ \Omega$ connected in parallel to an AC source. (*a*) If the maximum current in the circuit is 12 A, what is the amplitude $\mathscr{E}_{max}$ of the AC source? (*b*) If the source emf peaks at $t = 0$, and the frequency is 60.0 Hz, what is the potential difference across each resistor at $t = 12.5$ ms? ••

Figure P32.41



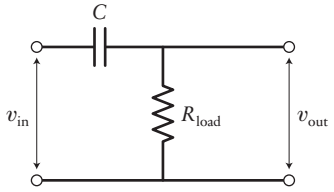
42. You must use a resistor, a capacitor, or an inductor to fill a gap in a circuit. You want to have as much current as possible through this circuit element to ensure that it can be easily detected. Which element should you use if the current through it is (*a*) very high frequency (VHF), (*b*) very low frequency (VLF), (*c*) DC, (*d*) time-varying so that it is sometimes VHF and other times VLF? ••

43. A device is connected to a 60.0-Hz AC source for which the emf is given by $\mathscr{E} = \mathscr{E}_{max} \sin(\omega t)$. If after 5.00 ms the current is 30.9% of its maximum value, is the current leading or lagging the source emf? ••

44. A resistor for which $R = 60.0\ \Omega$ is connected to an AC source. The source emf is given by $\mathscr{E} = \mathscr{E}_{max} \sin(\omega t + \phi_i)$, where $\mathscr{E}_{max} = 5.00$ V, $\omega = 2\pi(30\text{ Hz})$, and $\phi_i = \pi/4$. At what instants is there no current in the circuit? If you replace the resistor with a capacitor for which $C = 200$ mF, at what instants is there no current in the circuit? ••

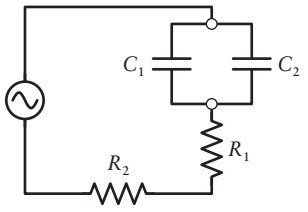
45. In the parallel circuit of Figure P32.45, the current amplitude is the same through the inductor branch, the capacitor branch, and the resistor branch. If $L = 0.36$ mH and $C = 1.0\ \mu$F, what are the source angular frequency and the resistance R? •••

Figure P32.45



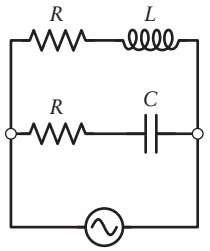
32.6 *RC* and *RLC* series circuits

46. For a given series RLC circuit, draw the variation of X_L, X_C, and impedance with frequency. ••



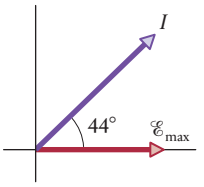
47. For a given series RLC circuit, draw the variation of phase angle with frequency. •
48. For a given series RLC circuit, draw the variation of impedance and current with frequency. •
49. A circuit consists of an AC source wired in series to a 1500-Ω resistor and a 1.5-μF capacitor. For a source emf amplitude $\mathscr{E}_{max} = 800.0$ V, calculate the phase constant ϕ and the amplitudes V_C and V_R if the source frequency is (*a*) 16 Hz and (*b*) 500 Hz. ••
50. For a series RLC circuit, charge at time t is given as $q(t) = Qe^{-Rt/2L}\cos(\omega' t + \phi)$, where Q is the amplitude at time $t = 0$. If $R = 2\ \Omega$, $C = 2.3\ \mu$F and $L = 15$ mH, find the time at which the amplitude of the charge oscillations in the circuit will be 70% of its initial value. ••
51. An AC source with $\mathscr{E}_m = 220$ V AC has a frequency of 50.0 Hz and produces the same maximum current in two series circuits. Each circuit contains a 160-Ω resistor. Circuit 1 contains a 5.6-μF capacitor, and circuit 2 contains an inductor. What is the inductance in circuit 2? ••
52. You need a filter circuit to eliminate a 60-Hz signal and lower frequencies. The load you are trying to drive has a resistance of 50 Ω. You decide to design a low-pass filter that has a cutoff frequency of 200 Hz. If you use the circuit shown in Figure P32.52, what capacitance C should you use? What fraction of any 60-Hz signal potential difference passes through this circuit? ••

Figure P32.52



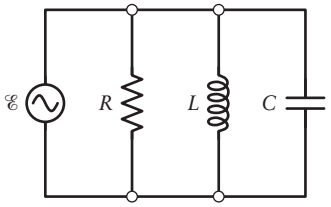
53. (*a*) Construct a phasor diagram for the circuit shown in Figure P32.53. (*b*) What is the phase constant if $C_1 = 1.00\ \mu$F, $C_2 = 3.00\ \mu$F, $R_1 = 200\ \Omega$, $R_2 = 400\ \Omega$, and $\omega = 4000\ \text{s}^{-1}$? ••

Figure P32.53



54. A loudspeaker has a resistance of 8.00 Ω. If you connect it in series with a 10.0-mH inductor, what percentage of the original maximum current are you going to get for a sound that has a pure frequency of 1000 Hz? ••
55. In the circuit shown in Figure P32.55, the current amplitude through the *RL* branch is the same as that through the *RC* branch. If $R = 10.0\ \Omega$ and $C = 50.0\ \mu$F, and the source operates at $\omega = 80.0\ \text{s}^{-1}$, what is the inductance L? ••

Figure P32.55

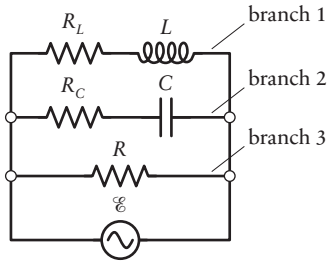


56. In problem 50, how many oscillations are completed within the time at which the amplitude of the charge oscillations in the circuit will be 40% of its initial value? ••
57. A 200-Hz power source in a series *RLC* circuit applies an AC potential difference that has an amplitude of 60 V. The current amplitude is 1.0 A, and the phasor diagram for the circuit is shown in Figure P32.57. What is the resistance of the circuit? ••

Figure P32.57

58. (*a*) What can you say, at all instants, about v_R, v_C, and v_L in the parallel circuit of Figure P32.58? (*b*) Construct a phasor diagram for V_R, V_C, V_L, and $\mathscr{E}$ and a phasor diagram for i_R, i_C, and i_L. (*c*) What is the current in the source? (*d*) Show that the current is a minimum at the frequency $\omega = \sqrt{1/LC}$. •••

Figure P32.58



59. Two AC potential differences $v_1 = V_1\sin(\omega t + \phi_1)$ and $v_2 = V_2\sin(\omega t + \phi_2)$ are added according to

$$v_{sum} = V\sin(\omega t + \phi) = v_1 + v_2$$
$$= V_1\sin(\omega t + \phi_1) + V_2\sin(\omega t + \phi_2),$$

with $\omega = 10.0\ \text{s}^{-1}$, $V_1 = 5.00$ V, and $V_2 = 8.00$ V. At $t = 0$, $v_1(t = 0) = 4.50$ V and $v_2(t = 0) = 3.70$ V. (*a*) Use phasors to determine values for V and ϕ in the expression $v_{sum} = V\sin(\omega t + \phi)$ and a value for $v(t = 0.0500\ \text{s})$. (*b*) Repeat using trigonometry, and then compare your results from the two methods. •••
60. In the circuit shown in Figure P32.60, $\mathscr{E} = \mathscr{E}_{max}\sin\omega t$ and $\omega = 100\ \text{s}^{-1}$. If $R = 20.0\ \Omega$, $R_C = 18.0\ \Omega$, and $R_L = 15.0\ \Omega$, what must the values of L and C be in order for the current amplitude I to be the same in branches 1, 2, and 3? •••

Figure P32.60

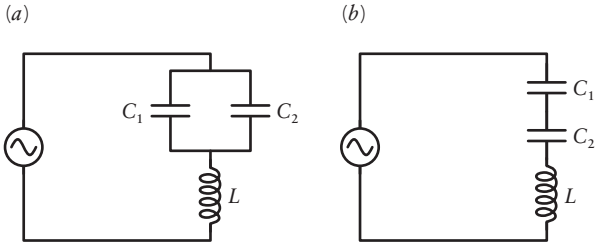
32.7 Resonance

61. An *RLC* circuit consists of a 20-μF capacitor, a 300-Ω resistor, and a 50-mH inductor connected in series with an AC source. What is the resonant angular frequency for this circuit? •

62. A 6.00-mH solenoid is connected in series with a 1.0-μF capacitor and an AC source. The solenoid has internal resistance 3.0 Ω, which can be treated as a series resistor in the circuit. (*a*) What is the resonant angular frequency? (*b*) If the source emf amplitude is $\mathscr{E}_{max} = 15$ V, what is the current amplitude at the resonant angular frequency? •

63. A circuit contains an electromagnet that can be modeled as an inductor of inductance 0.80 H in series with a resistance of 0.50 Ω. If you want to add a capacitor in series with the electromagnet to make the circuit resonate at 380 s^{-1}, what value of *C* must you use? •

64. A series *RLC* circuit is driven by an AC source at resonance. The resistor has a resistance of $R = 10\ \Omega$, and the AC source has an emf amplitude of $\mathscr{E}_{max} = 12$ V. What is the current amplitude? •



65. An *RLC* series circuit initially has resonant angular frequency ω_{0i}. Circuit elements are then changed such that both the capacitive reactance and the inductive reactance double in initial value at every operating frequency. What is the resonant angular frequency ω_{0f} after the changes are made? ••

66. A series RLC circuit consists of $R = 10\ \Omega$, $L = 0.6$ H, and $C = 10\ \mu$F. Determine the impedance at resonant frequency, 10 Hz below resonant frequency, and 10 Hz above resonant frequency. Explain the results. ••

67. An inductor resonates at 2 kHz when placed in series with a 1.80-μF capacitor. When driven at that resonant angular frequency, an AC source for which $\mathscr{E}_{max} = 180.0$ V produces a 0.3-A current in the circuit. What is the inductance? What is the resistance in the circuit? ••

68. In Figure P32.68, $C_1 = 1.00\ \mu$F, $C_2 = 2.00\ \mu$F, and $L = 47.0$ mH. Which circuit has the lower resonant angular frequency, and what is that resonant angular frequency? ••

Figure P32.68

69. An *RLC* series circuit contains an AC source of emf for which $\mathscr{E}_{max} = 30.0$ V, a 5.00-Ω resistor, a 4.00-mH inductor, and an 8.00-μF capacitor. What are (*a*) the resonant angular frequency and (*b*) the current amplitude if it is driven at the resonant angular frequency? (*c*) If a 1.00-kHz, 30.0-V source is used, what is the current amplitude? ••

70. An *RLC* series circuit has a 350-mH inductor and a 25.0-Ω resistor connected to a 50.0-Hz AC power source, and a variable capacitor. (*a*) To what capacitance value must it be set in order to have the circuit be at resonance? (*b*) If the source produces $\mathscr{E}_{rms} = 120$ V, what is the maximum potential difference across the inductor and the capacitor at resonance? ••

71. You want to build an AM radio that uses a series *RLC* circuit for tuning. The circuit consists of a 30.0-Ω resistor, a 15.0-μH inductor, and an adjustable capacitor. At what capacitance should the capacitor be set in order to receive the signal from a station that broadcasts at 870 kHz? How would you make the tuning more selective? ••

72. The resonant angular frequency is ω_0 in identical *RLC* circuits 1 and 2. Because the power delivered by the source at resonance is too high, you reduce the angular frequency of the source of circuit 1 to $\omega_1 = \omega_0/2$. To what value $\omega_2 \neq \omega_1$ must you change the angular frequency of the source of circuit 2 in order to have the power delivered by the source of circuit 1 equal that of circuit 2? •••

32.8 Power in AC circuits

73. An *RLC* circuit consists of a 220-Ω resistor, a 3.3-μF capacitor, and a 3.9-mH inductor. The circuit is connected to a power outlet that has a peak emf of 150 V and oscillates at 200 Hz. What is the average rate at which energy is dissipated in this circuit? •

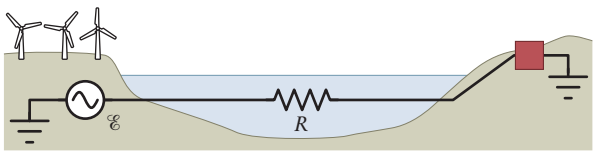
74. A given capacitor of capacitance 3.5 μF is charged to 65 V. The charging battery is then disconnected and a 15-mH inductor is connected in series with this capacitor so that *LC* oscillations occur. Assume that there is no resistance in the circuit, find the maximum current in the inductor. •

75. An AC power line has a current amplitude of 4.00 A and a resistance of 0.500 Ω. At what average rate is energy lost from the line? (Assume a zero phase angle.) •

76. For household electrical outlets in the United States, the root-mean-square value of the source emf is 120 V. (*a*) For a hair dryer rated at 1875 W, what are the root-mean-square current and the current amplitude? Ignore any capacitive and inductive reactance in the hair dryer circuit. (*b*) If an equally powerful hair dryer is to be sold in Germany, where household outlets have $\mathscr{E}_{rms} = 220$ V, what are I_{rms} and I? ••

77. In the first 100.0 ms after the switch on an *RLC* circuit is closed, the resistor dissipates 5.005 J of energy. In the first 200.0 ms, the resistor dissipates 10.03 J of energy. If the circuit contains a 70.0-mH inductor, what is the smallest possible inductive reactance of the circuit? ••

78. For the circuit of Problem 69, what is the average rate at which energy is delivered by the source when the circuit is operated at the resonant frequency? When it is operated at 1.00 kHz? What is the power factor in each case? ••



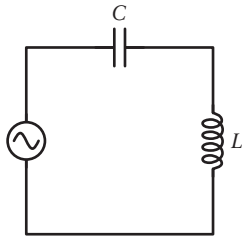
79. (*a*) Corresponding to each step in Figure 32.2 (*a*)-(*b*) [page no.1123], draw bar graphs for stored magnetic and electric energies. (*b*) What should be next time t_2 when, again, $U_E = 0.5\ U_{E,\max}$? ••

80. An AC circuit with a 240-V peak emf has a 30.0-Ω resistor connected in series to a capacitor for which the capacitive reactance is $X_C = 60.0\ \Omega$. (*a*) What is the phase constant? (*b*) What is the average rate at which energy is dissipated in the circuit? (*c*) If the resistance in the circuit is 20.0 Ω, what would the capacitive reactance have to be in order for the power factor to be 0.15? ••

81. At time $t = 0$, an LC oscillator begins to oscillate when the capacitor has its maximum charge. Assume the resistance to be zero in the circuit. If $L = 30$ mH and $C = 2.5\ \mu$F, find the first time at which the electromagnetic energy of the oscillator is shared equally between the corresponding fields of the capacitor and the inductor. ••

82. You need to design a power cable to connect an energy-storage facility located at the ocean shore to a wind turbine farm 2 km offshore (Figure P32.82). The farm can deliver energy at an average rate of 45 MW, and you need to run a single cable to deliver energy at this rate (the turbines and the storage facility share a common ground). The cable has a resistance R, leading to a loss of energy during transmission. Assume that all other loads on the circuit (electrical appliances in all the buildings serviced by this facility) have no capacitive or inductive reactance. Using different transformers at either end, you can change the value of $\mathscr{E}_{\max}$ and I while maintaining the same rate at which electrical energy is delivered to the cable. Should you choose a high or a low value for $\mathscr{E}_{\max}$? •••

Figure P32.82



83. An *RLC* series circuit consists of a 450-Ω resistor, a 3.00-mF capacitor, and a 1.00-H inductor. The circuit is driven by a power source that oscillates at 20.0 Hz and has an $\mathscr{E}_{\text{rms}}$ value of 60.0 V. The power source is switched on at $t = 0$, and at that instant the emf is at its maximum value. Calculate the power supplied at (*a*) $t = 0.0200$ s, (*b*) $t = 0.0375$ s, and (*c*) $t = 0.500$ s. •••

Additional Problems

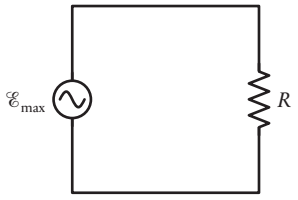
84. Sketch the phasor diagram for v_C, v_L, and the instantaneous current for the circuit shown in Figure P32.84 at an arbitrary instant $t \neq 0$. If the potential difference across the capacitor is a maximum at $t = 0$, what are the initial phases of v_C, v_L, and i? •

Figure P32.84

85. A capacitor is connected to an AC source. Sketch a graph showing how the current amplitude changes as you increase the AC angular frequency. •

86. Can a diode control anything other than the direction of current? ••

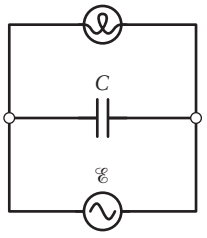
87. (*a*) What are the four possible combinations for input at A and B in an AND logic gate? (See Problem 30 regarding Y/N terminology for input.) What is the output for each combination? (*b*) What are the four possible combinations for input at A and B in an OR logic gate? What is the output for each combination? ••



88. A solenoid can be treated as a series *RL* circuit. If such a cylindrical solenoid driven by a 60-Hz, 120-V AC source has 1200 turns of 2 cm radius wrapped around a 30-cm-long core, and a resistance of 2 Ω, what is the phase constant and the current amplitude? ••

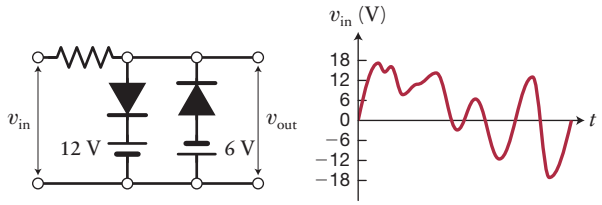
89. Find the potential difference $v_X(t)$, its amplitude V_X, and current $i_X(t)$, its amplitude I_X ($X = R, C, L$), if you are given a (*a*) purely resistive load with resistance $R = 100\ \Omega$, (*b*) purely capacitive load with $C = 20\ \mu$F, and (*c*) purely inductive load with inductor $L = 300$ mH. In all cases, the sinusoidal alternating emf device operates at amplitude $\mathscr{E}_{\max} = 40.0$ V and frequency $f_d = 50.0$ Hz. ••

90. An *RLC* series circuit containing a 30.0-Ω resistor, a 7.5-mH inductor, and a 10-μF capacitor is driven by an AC source operating at 1200 Hz. If the source amplitude is $\mathscr{E}_{\max} = 180.0$ V, determine the amplitude of the current flowing in the circuit. ••



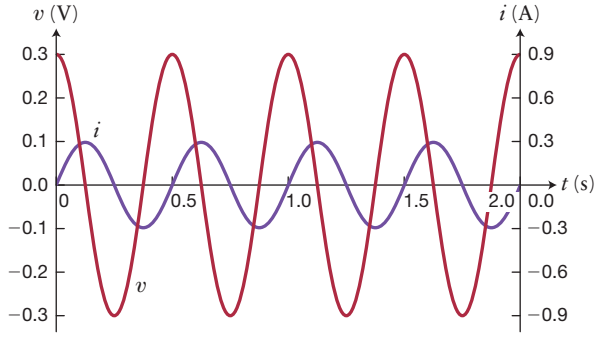
91. In the circuit shown in Figure P32.91, the AC source oscillates at 60 Hz and its emf is given by $\mathscr{E} = \mathscr{E}_{\max} \sin(2\pi ft)$, where $\mathscr{E}_{\max} = 15$ V and $R = 150\ \Omega$. Sketch, as functions of time, the current, the potential difference, and the power to the resistor. ••

Figure P32.91



92. What happens with the light bulb shown in Figure P32.92 as you increase the frequency of the AC source? ••

Figure P32.92



93. A diode *clipper* is a circuit used to eliminate extremes in input potential. If the graph in Figure P32.93 represents input potential as a function of time for the circuit shown, sketch a graph showing the output potential as a function of time. ●●

Figure P32.93

94. Figure P32.94 shows, for an AC circuit, the instantaneous current through a circuit element and the potential difference across the element. What can you determine about the element? ●●●

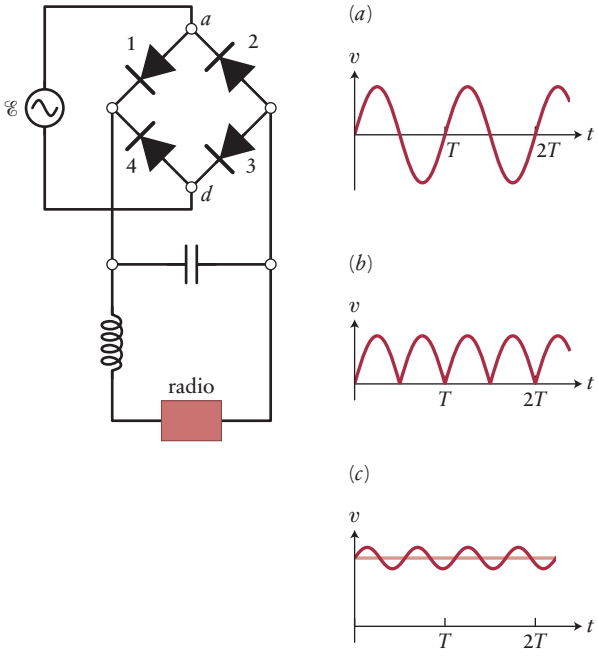


Figure P32.94

95. Your boss has purchased a new AC power source to run a high-voltage, low-current display, but it is not working. While he is fuming, you look at the owner's manual and discover that this power source produces only half the peak potential difference needed to operate the display. Because you are pretty sure you have a transformer on your workbench that will solve the problem, you tell your boss that you can fix it. When you return to your workbench, you are horrified to discover that the other members of your team have scavenged not only the transformer but most of your other supplies as well! Ignoring hookup wire and solder, you have only two identical capacitors and two identical diodes at your disposal. You collapse onto your lab stool and start thinking about how to word your apology to the boss, when suddenly you realize you can solve the problem after all! ●●● CR

96. The circuit in Figure P32.96 represents your planned design for a wall power supply that will run a radio that usually runs on a 9-V battery. The power supply uses a transformer (not shown) to convert the 110-V AC household emf of the wall outlet to a 9-V AC emf. If you do not add any additional components to this circuit, the potential difference over time is as shown in graph *a*, a typical sinusoidally varying $v(t)$ curve. Batteries supply direct current, however, and a radio designed to run on batteries cannot run on alternating current. If you address this problem by adding a rectifier to your circuit, the potential difference over time is as shown in graph *b*. The radio still will not run properly, though, because the 120-Hz cycle would either render the radio dysfunctional or result in an annoying 120-Hz buzz. By adding a large capacitor in parallel with the rectifier, you can smooth out the potential difference as the capacitor charges and discharges over the course of a cycle. Still, there is going to be a residual 120-Hz "wiggle" on top of the DC signal, as shown in graph *c*. You can filter out this wiggle by using an inductor as a low-pass filter. If the radio has an internal resistance of $R = 20.0\ \Omega$, what inductance value do you need in order to reduce the wiggle by a factor of 2? ●●●

Figure P32.96

97. The research laboratory you work in is less than a block away from the transmitting antenna of a radio station that broadcasts at 1100 kHz. You notice that every piece of equipment in the lab has 1100-kHz noise in addition to the signals you want, which are in the range from 2 kHz to 5 kHz. You wonder if there is some sort of simple circuit you could add to the lab equipment that would allow your desired frequencies to pass through without much loss, while reducing the 1100-kHz signal by at least a factor of ten. ●●● CR

33.8 Lensmaker's formula

You can read these words because this page reflects light toward you; your eyes intercept some of the reflected light, and the lenses of your eyes redirect it, forming an image of the page on your retina. Where does the reflected light come from? Our primary source of light during the day is the Sun; our secondary source is the sky's brightness. Indoors and at night, our light sources are flames in candles, white-hot filaments or light-emitting diodes (LEDs) in light bulbs, and glowing gases in fluorescent bulbs. The light from these sources comes from the accelerated motion of electrons as this motion produces electromagnetic waves.

In Chapter 30 we studied the propagating electric and magnetic fields that constitute electromagnetic waves, and we learned that a narrow frequency range of these waves corresponds to what we know as visible light. In this chapter we continue to study light, particularly its propagation and its interactions with materials. We shall not consider the electric and magnetic fields individually, but instead think of the behavior of rays of light. Such behavior, which is called *ray optics*, was understood long before it was known that light is an electromagnetic wave.

33.1 Rays

If you pierce a small hole in a piece of cardboard and then hold the cardboard between a lamp and a screen, the position where the light transmitted through the hole strikes the screen lies on a straight line connecting the lamp and the hole (**Figure 33.1**). This observation suggests that we can think of a light source as made up of many straight beams that spread out in three dimensions from the source. Each beam travels in a straight line until it interacts with an object. That interaction changes the beam's direction of travel.

We represent the propagation of light by drawing **rays:**

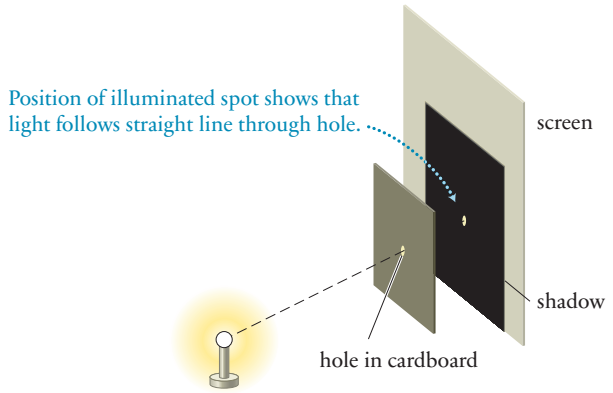
A ray is a line that represents the direction in which light travels. A beam of light with a very small cross-sectional area approximately corresponds to a ray.

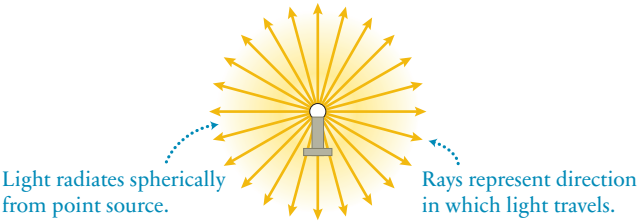
In order to see an object, our eyes form an image by collecting light that comes from the object. If the object is a light source, we see it by the light it emits. We can also see an object that is not a light source because such an object interacts with light that comes from a light source. The light is then redirected toward our eyes by means of this interaction.

When you stand outside on a sunny day, some of the rays from the Sun are blocked by your body while others travel in straight lines to the ground around you. You cast a shadow—a region on the ground that is darker than its surroundings because the Sun's rays that are blocked by your body do not strike this region. (The shadow region is not completely dark because it is still illuminated by light from the sky and by sunlight reflected from nearby objects.)

Figure 33.2 illustrates how rays can be used to represent the directions of light beams emanating from a light source. Just as with field line diagrams, we draw only a few rays to represent all the rays that could possibly be drawn; a ray could be drawn along any line radially outward from the source. Although most sources of light—the Sun, a flame, a light bulb—are extended, when the distance to the source is much greater than the extent of the source, we can treat that source as a *point source* (See Section 17.1). That is, we can treat the source as if all the light were emitted from a single point in space. In the first part of this chapter, we develop a feel for which rays to draw in a given situation.

Figure 33.1 A light beam that is not disturbed travels in a straight line.





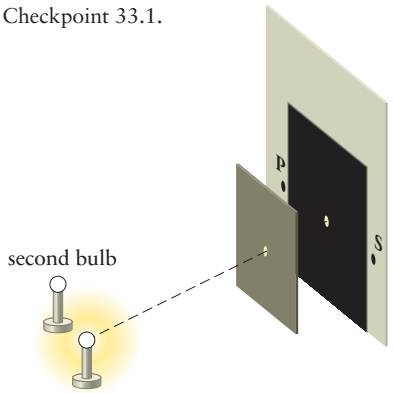


Figure 33.2 Rays emanating from a source of light.

CONCEPTS

33.1 Suppose a second bulb is added to the left of the one in Figure 33.1, as illustrated in **Figure 33.3**. What happens to (*a*) the brightness of the spot created on the screen by the first bulb and (*b*) the brightness at locations close to the vertical edges of the original shadow on the screen (points P, Q, R, and S)?

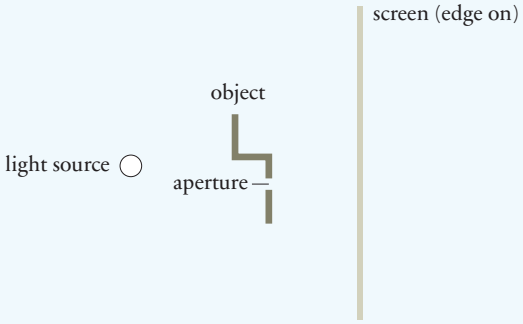

Figure 33.3 Checkpoint 33.1.

EXAMPLE 33.1 Light and shadow

An object that has a small aperture is placed between a light source and a screen, as shown in **Figure 33.4**. Which parts of the screen are in the shadow?

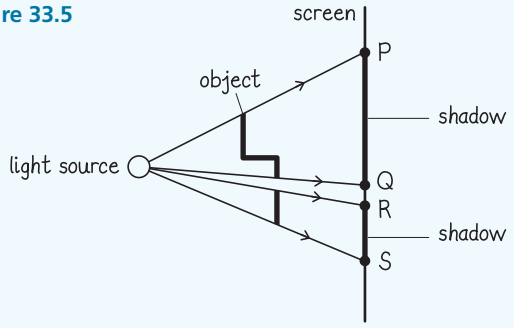

Figure 33.4 Example 33.1.

❶ **GETTING STARTED** The rays emitted by the source radiate outward in all directions following straight paths. The shadow is cast because the object prevents some of the rays from reaching the screen (except for the rays that make it through the aperture).

❷ **DEVISE PLAN** To locate the edges of the shadow, I draw straight lines from the source to the edges of the object (including the edges of the aperture) and extend these rays to the screen (**Figure 33.5**).

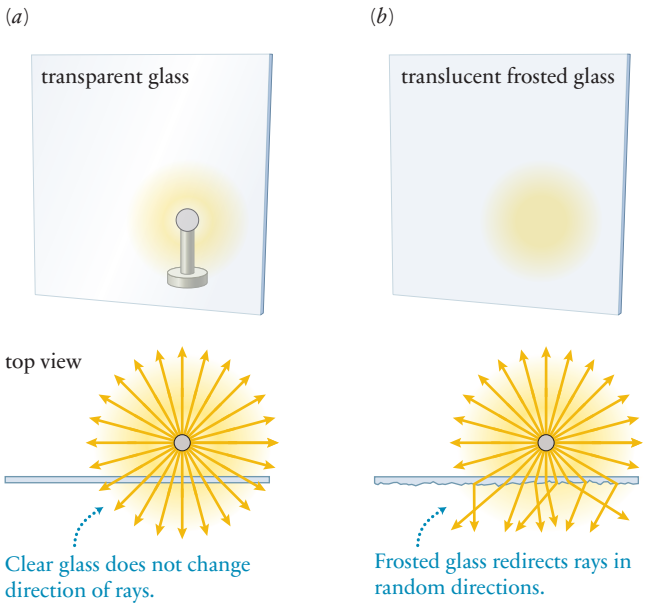
Figure 33.5

❸ **EXECUTE PLAN** The top and bottom edges of the shadow correspond to the highest and lowest screen locations (P and S) reached by light rays that are not blocked by the object. The gap in the shadow between locations Q and R corresponds to light rays that pass through the aperture, which means that this region of the screen is not in shadow. ✔

❹ **EVALUATE RESULT** A shadow that is taller than the object makes sense. Because the light rays from the source emanate in all directions, most of them reach the screen at angles other than 90°. This means that the distance from P to S must be greater than the object height. Indeed, I know from experience that the shadow cast by my hand gets larger as I move my hand closer to a lamp, increasing that angle.

33.2 Hold a piece of paper between your desk lamp (or any other source of light) and your desk or a wall. How does the sharpness of the edges of the shadow change as you move the paper closer to the bulb? Why does this happen?

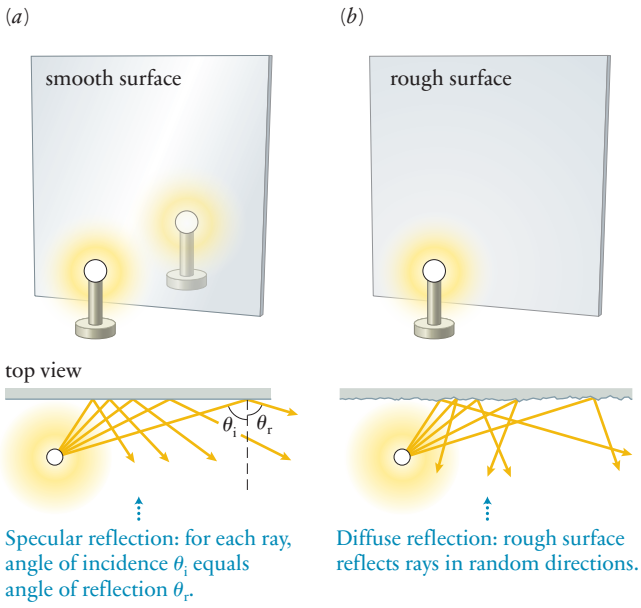
33.2 Absorption, transmission, and reflection



Different materials interact differently with the light that strikes them, which is how you can visually distinguish wood from metal, fabric from skin, and a white piece of paper from a blue one. When light strikes an object, the light can be transmitted, absorbed, or reflected.

Transmitted light passes through a material. Objects that transmit light, such as a piece of glass, are said to be *transparent* (**Figure 33.6a**). In *translucent* materials, such as frosted glass, light rays are *transmitted diffusely*—that is, they are redirected in random directions as they pass through, so that the transmitted light does not come from a definite direction (Figure 33.6*b*). Because translucent materials scatter light in this manner, we cannot see objects clearly through them.

Absorbed light enters a material but never exits again. Objects that absorb most of the light that strikes them, such as a piece of wood, are said to be *opaque*. When light strikes such materials, the energy carried by the light is converted to some other form (usually thermal energy) and the light propagation stops.



Reflected light is any light that is redirected away from the surface of the material (**Figure 33.7**). Smooth surfaces reflect light *specularly*—that is, each ray bounces off the surface in such a way that the angle between it and the normal to the surface doesn't change (Figure 33.7*a*). The angle between the incoming ray and the normal to the surface is called the **angle of incidence** θ_i; the angle between the outgoing ray and the normal is called the **angle of reflection** θ_r.

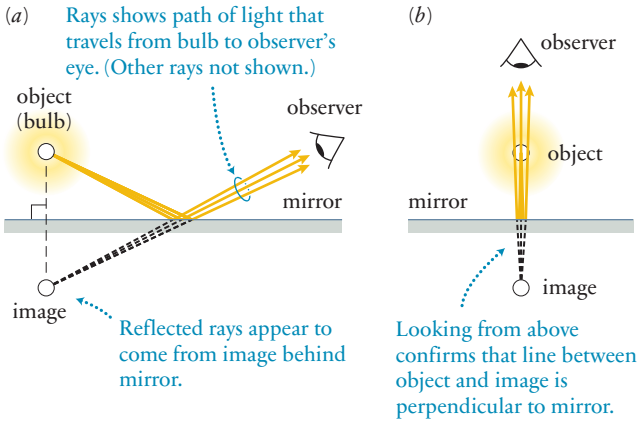
Figure 33.6 We see objects clearly through a sheet of clear glass but diffusely through frosted glass.

CONCEPTS

Figure 33.7 Light reflects specularly from a smooth surface, forming a mirror image. From a rough surface, it reflects diffusely (in random directions), so no image forms.

Empirically we find:

For a ray striking a smooth surface, the angle of reflection is equal to the angle of incidence, and both angles are in the same plane.



This **law of reflection** holds at smooth surfaces for any angle of incidence.

Surfaces that are not smooth reflect light in many directions (Figure 33.7*b*). For such *diffuse reflection*, each ray obeys the law of reflection, but the direction of the surface normal varies over the surface and so the angle of reflection also varies.

How smooth is smooth? If the height and separation of irregularities on the surface are small relative to the wavelength of the incident light, the surface acts like a smooth surface and most light is reflected specularly. For example, paper appears smooth to microwaves, which have wavelengths ranging from millimeters to meters, and therefore microwaves are reflected specularly from paper. Visible light, however, has wavelengths of hundreds of nanometers, and so paper reflects visible light diffusely.

Rays that come from an object and are reflected from a smooth surface form an **image,** an optically formed duplicate of the object (Figure 33.7*a*). **Figure 33.8***a* shows the paths taken by light rays emitted by a light bulb placed in front of a mirror. A diagram like Figure 33.8*a* showing just a few selected rays is called a **ray diagram.** If we trace the reflected rays back to the point at which they appear to intersect, we see that point is behind the mirror. Consequently, the brain interprets the reflected rays as having come from that point, creating the illusion that the light bulb is behind the mirror. The directions of the rays that reach the eyes of the observer are the same as if they had come from an object located behind the mirror.

Figure 33.8 Diagrams showing the paths taken by light rays that are produced by a bulb and reflected by a mirror into an observer's eye. The reflected rays appear to come from behind the mirror, forming an image behind the mirror.

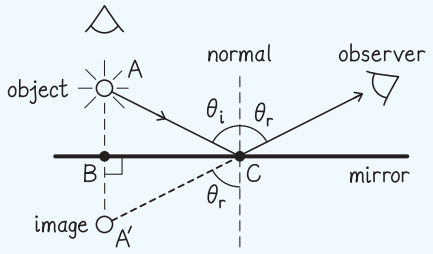
Note that the image is located on the line through the object and perpendicular to the mirror. If we look along that line, the image lies behind the object (Figure 33.8*b*).

Rays that do not actually travel through the point from which they appear to come, like the rays in Figure 33.8*a*, are said to form a *virtual image*. A *real image* is formed when the rays actually do intersect at the location of the image. (Flat mirrors cannot form real images; we'll encounter real images when we discuss lenses in Section 33.4 and curved mirrors in Section 33.7.)

EXAMPLE 33.2 How far behind the mirror?

If the light bulb in Figure 33.8*a* is 1.0 m in front of the mirror, how far behind the mirror is the image?

❶ **GETTING STARTED** The location of the image is the location from which the rays reflected by the mirror appear to come—that is, the point at which they intersect. From Figure 33.8 I know that because the rays intersect directly behind the bulb, a line that passes through the bulb and is normal to the mirror passes through the image.



❷ **DEVISE PLAN** I can obtain the distance of the image behind the mirror by considering one ray that travels from the bulb to the observer and then tracing that ray back through the mirror to its intersection with the line that is perpendicular to the mirror and passes through the bulb.

❸ **EXECUTE PLAN** I begin by drawing a ray that travels from the bulb to the mirror and is reflected to the location of the observer (**Figure 33.9** on the next page). In my drawing, A denotes the bulb location, B denotes the point where the line connecting the bulb and its image intersects the mirror, and C denotes the point at which the ray that is reflected to the observer hits the mirror. According to the law of reflection, $\theta_r = \theta_i$.

(Continued)

CONCEPTS

Figure 33.9

I now extend the reflected ray to behind the mirror (dashed line). I know that the image must lie somewhere along that dashed line and must also lie on the line that passes through the object and is perpendicular to the mirror. The image must therefore lie at the intersection of this line and the dashed ray extension; I denote that intersection point by A′.

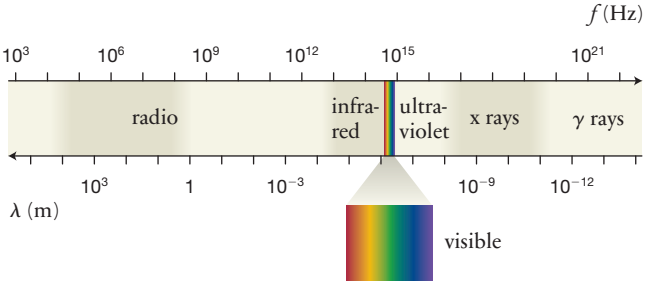
To determine the distance BA′, which is how far behind the mirror the image is, I note that angle A′CB is equal to $90° - \theta_r$ and angle ACB is equal to $90° - \theta_i$. Because $\theta_i = \theta_r$, angles A′CB and ACB are equal. Therefore triangles ABC and A′BC are congruent, and AB = BA′. That is, the image appears at the same distance behind the mirror as the object is in front of it: 1.0 m behind the mirror. ✔

4 EVALUATE RESULT My result makes sense because I know from experience that as I walk toward a mirror, my image also approaches it.

33.3 If the observer in Figure 33.8 moves to a different position, does the location of the image change?

The colors of visible light we see correspond to different frequencies of electromagnetic waves. Red corresponds to the lowest frequency of the visible spectrum. As the frequency increases, the color changes to orange, yellow, green, blue, indigo, and finally violet (the highest frequency of the visible spectrum). The range of visible frequencies is quite small relative to the range of the complete electromagnetic spectrum, as **Figure 33.10** shows. Frequencies lower than the visible correspond to infrared radiation, and higher frequencies to ultraviolet. When a light source produces all the frequencies

Figure 33.10 Visible light makes up only a small part of the electromagnetic spectrum.



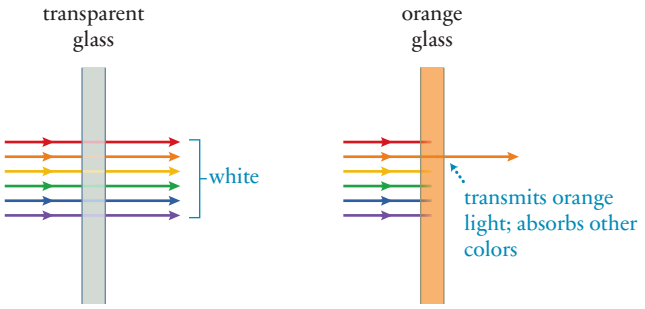


Figure 33.11 All colors of light pass through colorless glass (shown gray for illustration purposes); orange glass transmits orange light and absorbs all colors of light except orange.

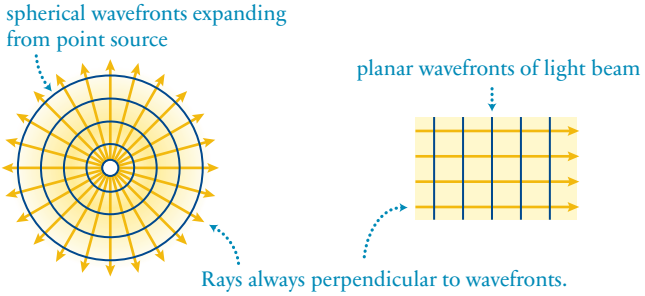

of the visible spectrum at roughly the same intensities, the emitted light appears white.

Different colors of light interact differently with different objects, affecting the color we perceive the object as being. Colorless materials, like a piece of ordinary window glass, transmit all colors of the visible spectrum. A piece of orange glass, on the other hand, transmits only the orange part of the visible spectrum. All other colors are absorbed in the glass (**Figure 33.11**). A red apple absorbs all colors of the visible spectrum except red, which is redirected to our eyes. Grass absorbs all colors except green, which is diffusively reflected at its surface.

Because light is a wave phenomenon, it is sometimes useful to represent the propagation of light with wavefronts, which we introduced in Section 17.1. Wavefronts are drawn perpendicular to the direction of propagation of the wave.* Because light rays point along the direction of propagation of the light, light wavefronts are perpendicular to light rays. **Figure 33.12*a*** shows the spherical wavefronts for light coming from a point source, and Figure 33.12*b* shows the straight-line rays and wavefronts corresponding to a planar electromagnetic wave.

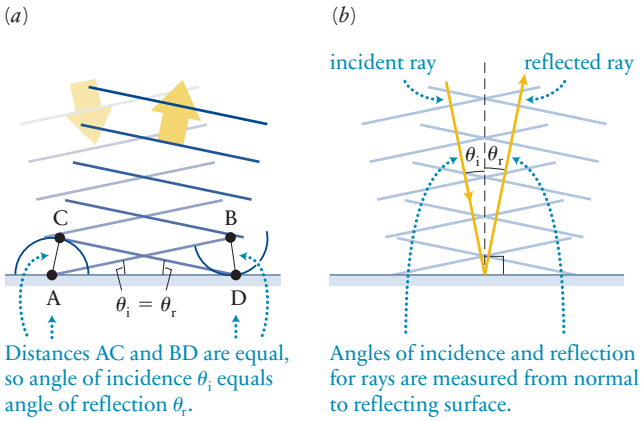

Figure 33.12 A point source of light produces spherical wavefronts; a beam of light contains planar wavefronts.

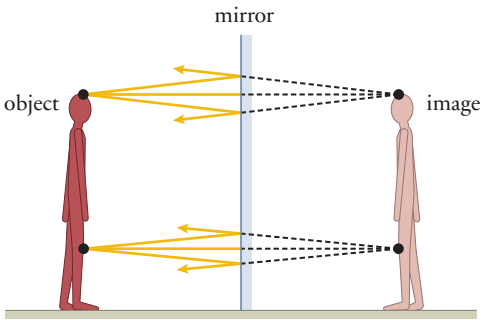
*For mechanical waves, the wavefronts are drawn at the locations of the wave crests, spaced by the wavelength of the wave. Because the wavelength of light is very short, the wavefronts of light cannot be represented to scale.

CONCEPTS

Figure 33.13 (*a*) The reflection of wavefronts from a smooth surface explains the law of reflection. (*b*) The corresponding rays and their angles of incidence θ_i and reflection θ_r.



Note that a planar wave is represented with rays that are parallel to one another because all the wavefronts are parallel to one another.

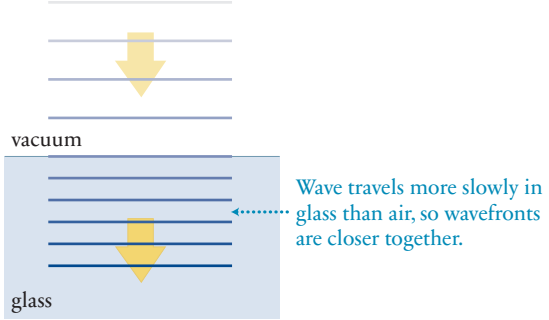
By looking at how wavefronts behave, we can understand the law of reflection. When a light ray strikes a smooth surface at an incidence angle $\theta_i \neq 0$ (**Figure 33.13**), the left end of the first wavefront to reach the surface gets there, at A, before the right end does. In the time interval it takes the right end to reach the surface at D, the left end has traveled back from the surface to C. The distance traveled by the right end toward the surface, BD, is the same as that traveled by the left end away from the surface, AC, so the angles BAD and CDA must be equal. The angle of incidence θ_i equals angle BAD. Likewise, the angle of reflection θ_r equals angle CDA. So $\theta_i = \theta_r$.

So far we have treated the object (and consequently the image) as a single point. **Figure 33.14** shows how images are formed of extended objects. Each point on the object reflects (or emits) light rays, and the reflections of these rays appear to come from a corresponding point on the image. A flat mirror thus produces behind the mirror an exact mirror image of the entire extended object.

Figure 33.14 Paths taken by rays from more than one point on the object, showing how extended images form.

33.4 In order for the person in Figure 33.14 to see a complete image of himself, does the mirror need to be as tall as he is?

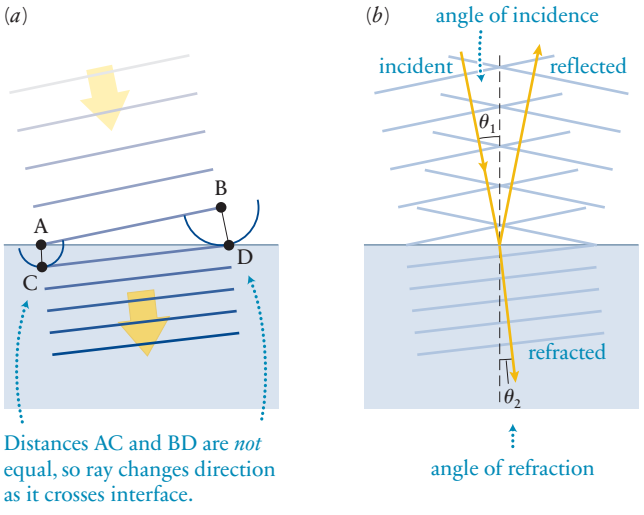
33.3 Refraction and dispersion



As we found in Chapter 30, light propagates with speed $c_0 = 3 \times 10^8$ m/s in vacuum. In air, the speed of light is almost the same as that in vacuum. In a solid or liquid medium, however, light propagates at a speed c that is generally less than c_0. In glass, for example, visible light propagates at two-thirds of the speed of light in vacuum (see Example 30.8).

How does this change in speed affect the propagation of an electromagnetic wave? Recall from Chapter 16 that harmonic waves are characterized by both a wavelength λ and a frequency f and that the product of the wavelength and frequency equals the wave's speed of propagation (Eq. 16.10). The frequency of the wave must remain the same because the oscillation frequency of the electromagnetic field that makes up the wave is determined by the acceleration of charged particles at the wave's source. The acceleration of the source does not alter when the wave travels from one medium to another, and thus the frequency of the traveling wave also cannot change.

33.5 In vacuum, a particular light wave has a wavelength of 400 nm. It then travels into a piece of glass, where its speed decreases to two-thirds of its vacuum speed. What is the distance between the wavefronts in the glass?



As we found in Checkpoint 33.5, when rays of light pass through the interface between vacuum and a transparent material, the wavefronts inside the material are more closely spaced than they are in vacuum, due to the lower speed of the wavefronts. **Figure 33.15** illustrates this effect for wavefronts incident normal to the surface of the material.

Figure 33.15 Wavefronts for a ray traveling from vacuum into transparent glass in a direction normal to the glass surface.

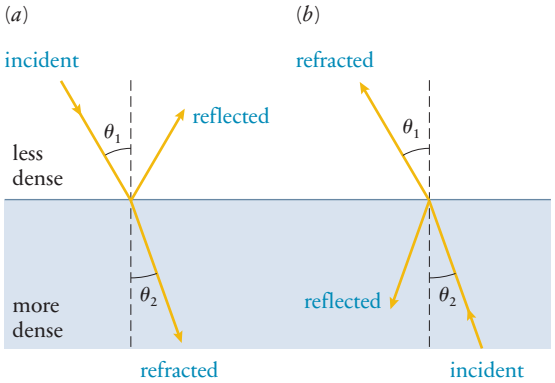
CONCEPTS

Figure 33.16 (*a*) Refraction is explained by the behavior of wavefronts that cross at an angle into a transparent medium in which they travel more slowly. (*b*) Incident, reflected, and refracted rays, showing the angles of incidence θ_1 and refraction θ_2 (measured from the normal to the surface).

When a light ray travels from one material into a second material where light travels more slowly, the ray bends toward the normal to the interface between the materials.

Generally, the speed of light decreases as the mass density of the material increases. Note also that, as shown in Figure 33.16*b*, both reflection and refraction take place at the interface between two media (or between vacuum and a medium).

The amount of bending depends on the angle of incidence and on the relative speeds in the two media. There is no bending for normal incidence (as we saw in Figure 33.15); the bending is less near normal incidence and becomes more pronounced as the angle of incidence increases. In Section 33.5, we'll work out a quantitative expression relating angles θ_1 and θ_2.



33.6 Suppose the ray in Figure 33.16 travels in the opposite direction—that is, from the more dense medium to the less dense medium. If the angle of incidence is now θ_2, how does the angle of refraction compare with θ_1?

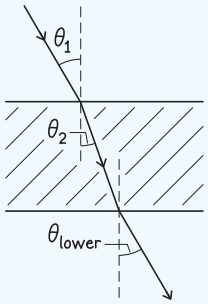
What if the wavefronts strike the transparent material at an angle? In such a case, one end of the wavefront arrives at the surface before the other (**Figure 33.16**). Once the end that reaches the surface first (this happens to be the left end in Figure 33.16) enters the material, it travels at the lower speed while the other end of the wavefront (the right end in our example) continues to travel at the vacuum speed. This means the distance AC traveled by the left end is less than the distance BD traveled by the right end during the same time interval (Figure 33.16*a*). Consequently, the wavefront CD in the material is no longer parallel to the wavefront AB that has not yet entered the material.

The direction of the ray associated with these wavefronts therefore changes on entering the material. As shown in Figure 33.16*b*, the angle of incidence θ_1, between the ray in vacuum and the normal to the interface between the two materials, is greater than the angle θ_2, between the ray in the material and the normal to that interface. This bending of light as it moves from one material into another is referred to as **refraction,** and the angle θ_2 between the refracted ray and the normal to the interface between the materials is called the **angle of refraction.** Whenever light is refracted, the angle between the ray and the normal is always greater in the material in which the light travels faster, so:

Because the relationship between the angles of incidence and refraction is completely determined by the speed of the wavefronts in the two media, the angles do not depend on which is the incident ray and which is the refracted ray. As shown in **Figure 33.17**, θ_1 and θ_2 have the same values whether θ_1 is the angle of incidence (Figure 33.17*a*) or the angle of refraction (Figure 33.17*b*). Keep in mind, however, that the reflected ray is always on the same side of the interface as the incident ray, and so the angle of reflection is *not* the same in Figure 33.17*a* and Figure 33.17*b*.

Figure 33.17 Because refraction is caused by the relative speeds of the wavefronts in two media, the angles of incidence and refraction do not depend on which is the incident ray and which the refracted ray.

CONCEPTS



EXAMPLE 33.3 Crossing a slab

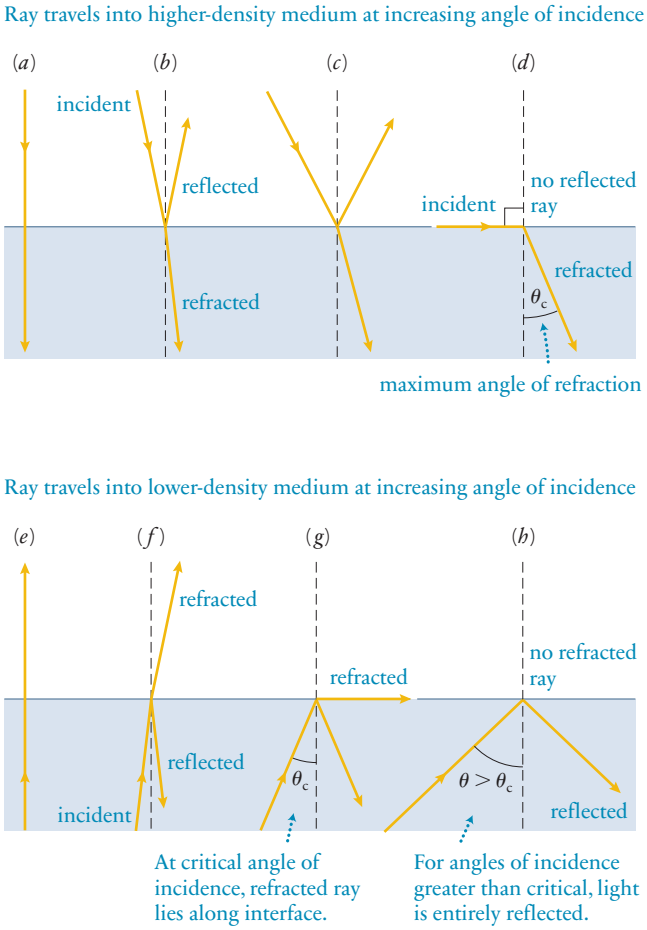
Consider a light ray incident on a parallel-sided slab of glass surrounded by air, as shown in Figure 33.17*a*. The ray travels all the way through the slab and emerges into air on the other side. In what direction does the ray emerge?

❶ **GETTING STARTED** This problem involves two successive encounters of a light ray with interfaces between glass and air. At each interface, the ray is refracted. I need to determine the direction of the ray (its angle to the normal to the slab) after it crosses the lower interface of the slab represented in Figure 33.17*a*.

❷ **DEVISE PLAN** Because I want to know the direction of the emerging ray, I construct an appropriate ray diagram. Figure 33.17*a* shows the direction of the ray inside the slab. I extend the ray through the slab to the lower interface (**Figure 33.18**) and draw the emerging ray, labeling its angle to the normal θ_{lower}. To determine this angle, I need to consider the refraction that occurs at the lower interface.

Figure 33.18

❸ **EXECUTE PLAN** Because the two interfaces are parallel, their normals are also parallel, and so the angle at which the ray is incident on the lower interface is equal to the angle θ_2 at which it is refracted at the upper interface. I saw in Figure 33.17*b* that if the angle between the ray and the normal in the slab is θ_2, it doesn't matter whether the ray in the slab is the incident ray or the refracted ray; either way, the angle between the ray in the air and the normal is θ_1. Therefore $\theta_{\text{lower}} = \theta_1$. ✔



❹ **EVALUATE RESULT** Crossing the lower interface from glass into air, the ray bends away from the normal, as it should because glass is denser than air. With $\theta_{\text{lower}} = \theta_1$, in fact, the ray emerges parallel to the original direction it had before entering the slab. This makes sense because the two air-glass interfaces are parallel. (Note, though, that the ray is shifted sideways by a small distance relative to its original path.)

33.7 When the ray reflected from the bottom surface in Figure 33.18 reemerges from the top surface, how does the angle it makes with the normal compare with θ_1?

What range of refraction angles is possible? To answer this question, let's first consider the case where the ray travels from a low-density medium into a denser medium (**Figures 33.19*a–d***). Because the angle of incidence is always greater than the angle of refraction in this situation, as the angle of incidence approaches 90°, the angle of refraction remains less than 90° (Figure 33.19*d*). The full 90° range of incidence angles gives a range of refraction angles that is less than 90°.

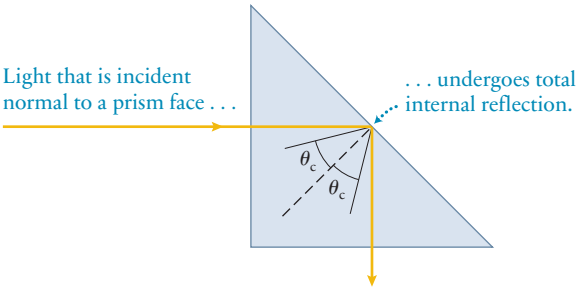
Figure 33.19 The range of possible refraction angles for a ray crossing into a medium of either higher or lower density.

Next consider the case where the ray travels from a high-density medium into a lower-density medium (Figures 34.19*e–g*). The angle of incidence is now less than the angle of refraction. Consequently, as the angle of incidence increases, it reaches a value for which the refracted ray emerges along the interface (Figure 33.19*g*). This angle of incidence is called the **critical angle** θ_c and is equal to the angle of refraction shown in Figure 33.19*d*. For angles of incidence greater than θ_c, the angle of refraction would have to be greater than 90°, which is impossible. Therefore, no light is refracted. Instead, all the light is *reflected* back into the higher-density medium (Figure 33.19*h*), a phenomenon called **total internal reflection.**

Several optical devices make use of total internal reflection to direct light. The glass prism shown in

CONCEPTS

Figure 33.20 A prism can act as a perfect mirror by means of total internal reflection.



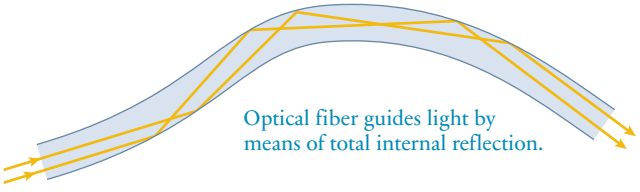


Figure 33.20 reflects light just as a mirror would. A light ray enters the prism's front surface at normal incidence. Because the back surface is slanted relative to the front surface, the angle at which the ray hits the back surface is less than 90°. This back-surface angle of incidence is greater than the critical angle for the glass, however, and so the light is totally reflected from the back surface. Such prisms are actually better mirrors than most regular mirrors; they reflect very close to 100% of the incident light, whereas mirrors are less reflective due to imperfections in the reflecting surface.

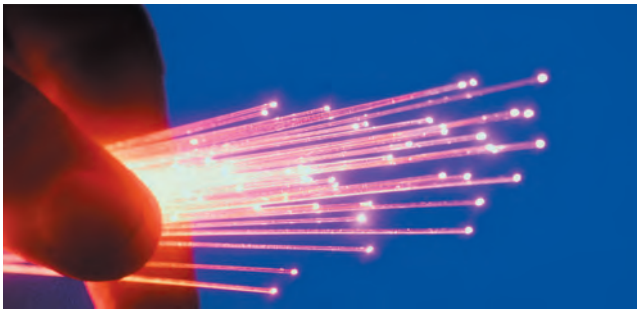
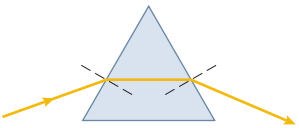
Optical fibers also guide light by means of total internal reflection. An optical fiber is a long, thin fiber made of a transparent material such as glass. If light shines into one end of the fiber at an angle greater than the critical angle, the light travels along the fiber through repeated total internal reflections, and essentially all of the light that entered the fiber emerges at the other end (**Figure 33.21**). Because very little light is lost as the light travels, only a faint glow comes from the rest of the fiber.

CONCEPTS

Figure 33.21 How optical fibers work.





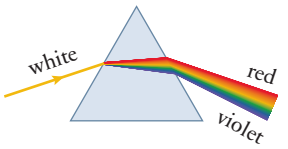


Figure 33.22 The phenomenon of dispersion, which results from the fact that the speed of light in a given medium (and hence the angle of refraction) depends slightly on the frequency of the light.

(*a*) Prism refracts light of single frequency

(*b*) Dispersion: different colors have different angles of refraction

(*c*) Rainbows result from dispersion of sunlight by raindrops

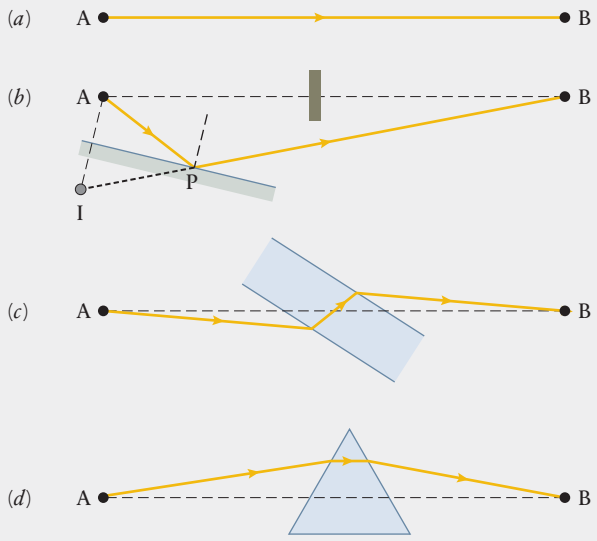
Because the speed of light in any given medium depends slightly on the frequency of the light, the angle of refraction also depends on frequency. This phenomenon is called **dispersion** because it causes rays of different colors to separate—to be *dispersed*—when refracted. Prisms like the one shown in **Figure 33.22** are designed to separate colors by the frequency dependence of the angle of refraction. In most media, high-frequency light travels more slowly than low-frequency light, and so high-frequency light bends more strongly toward the normal. The lowest frequency of visible light is red and the highest is violet, which means violet light bends the most, as the rainbow of Figure 33.22*c* shows.

Both rainbows and the brilliance of gems result from a combination of total internal reflection and dispersion. In a rainbow (Figure 33.22*c*), the combination of total internal reflection and dispersion means that we see different colors coming from water droplets at different viewing angles. Gems are cut with many internal surfaces from which total internal reflection takes place. Because the light is also dispersed, colorless gems such as diamonds shine with many distinct colors.

33.8 Because of dispersion, the critical angle for total internal reflection in a given medium varies with frequency. Is the critical angle for a violet ray greater or less than that for a red ray?

Fermat's principle

Figure 33.23 shows four ways in which a light ray can travel between two locations A and B: directly, reflected from a mirror, refracted through a glass slab, and refracted through a prism.* You could say that in each case the ray reaches B because it is aimed properly from A. However, an entirely different way of looking at the path followed by the light was suggested by the French mathematician Pierre de Fermat (1601–1665) in a formulation today known as **Fermat's principle:**



> **The path taken by a light ray between two locations is the path for which the time interval needed to travel between those locations is a minimum.**

This principle may seem to imply that light always travels in a straight line. However, the *quickest path* between two locations is not necessarily the *shortest distance* when the speed of light differs in different regions.

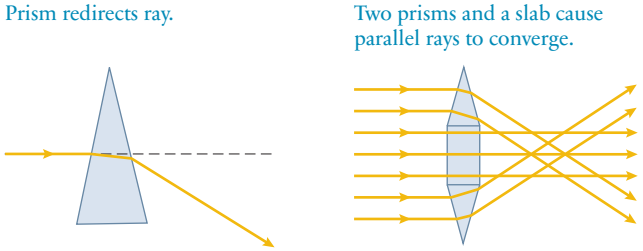
Let's consider the four paths in Figure 33.23 using Fermat's principle. In Figure 33.23*a*, the ray does follow a straight path because the medium in which the ray travels is uniform. As a result, the quickest path is indeed the shortest distance: a straight line from A to B.

In Figure 33.23*b*, the fact that the straight-line path from A to B is blocked means that the ray must reflect somewhere off the mirror in order to travel from A to B. The path shown, which satisfies the law of reflection, is the shortest distance from A to B involving reflection from the mirror. Because the distance from A to the reflection location P equals the distance between the image location I and P, the straight line IB is equal in length to the path traveled by the ray from A to B. Moving the reflection location to either side of P, so that the angle of incidence does not equal the angle of reflection, increases the length of the path. Thus, Fermat's principle implies the law of reflection.

Figure 33.23 Ray diagrams illustrating the *quickest path* for a light ray traveling from A to B for four situations.

When the ray must travel through some air and some glass, as in Figures 33.22*c* and *d*, the quickest path is not a straight line because the ray's speed in the glass is only two-thirds of its speed in air. To minimize the time interval needed to travel from A to B, the ray bends on entering and exiting the glass. Such a bent path reduces the distance traveled through the glass without increasing the distance traveled in air so much that it offsets the amount of time saved. In Example 33.7, we shall see that calculating the bending angles with Fermat's principle gives the same result as with ray optics.

*Note that what distinguishes a glass slab from a glass prism is the way I use the terms: In a slab, the two opposite surfaces are parallel to each other; in a prism, they are not.



33.4 Forming images

As shown in **Figure 33.24**, by combining two prisms and a glass slab we can create a device that steers parallel light rays toward each other. The rays through the center of the device pass straight through, those through the top prism are refracted downward, and those through the bottom prism are refracted upward.

To bring all parallel incident rays to a single point, a structure called a **lens** is used. A lens is designed with curved surfaces so that the refraction of incident rays increases gradually as we move away from the center. To accomplish this, lenses are typically made with spherical surfaces, which are easy to manufacture.

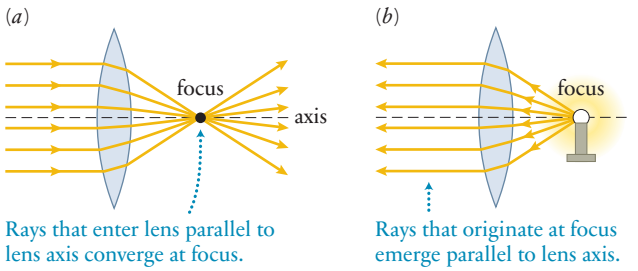


Figure 33.25*a* on the next page is a cross section of a lens with *convex* spherical surfaces, where a *convex surface* is defined as one that curves like the outside of a sphere. Rays parallel to the lens *axis*—a line perpendicular to the lens through its center—converge through such a lens onto a single point called either the **focus** or the **focal point.** A lens with convex surfaces is therefore called a *converging lens*. The distance from the center of the lens to the focus is called the **focal length** *f*.

Figure 33.24 A device that redirects parallel light rays toward each other.

CONCEPTS

Figure 33.25 Converging lens with convex spherical surfaces.

What if we place a light source at the focus of a lens, as in Figure 33.25*b*? As we saw in the preceding section, the path followed by a light ray is unaffected by reversing the direction of propagation of the ray, as long as the ray is not absorbed by the medium. So, if we place a light source at the focus of a lens, a beam of parallel rays emerges on the other side of the lens.

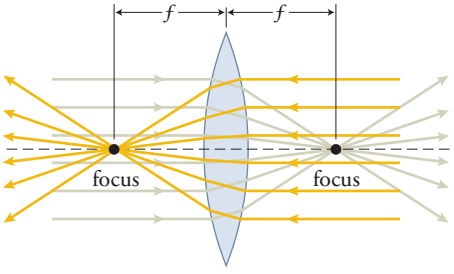
33.9 Sketch the wavefronts corresponding to all the rays in Figure 33.25*a*, both the parallel ones on the left and the refracted ones on the right.

We can reverse the direction of the rays through the lens of Figure 33.25, so that parallel rays enter from the right (**Figure 33.26**). The rays converge again at a focus that is the same distance f from the center of the lens. Thus, every lens has two foci, one on either side of the lens at the same distance f from it.

If we tilt the parallel rays a bit relative to the lens axis (**Figure 33.27**), the rays still converge at a distance f from the center, but the focus is no longer on the axis. Provided the parallel rays make only a small angle with the lens axis, they all converge at a point on a plane—called the *focal plane*—that is perpendicular to the axis a distance f from the lens. Rays that run near the lens axis—either parallel to it or at a small angle—are said to be *paraxial*.

Now that we know how parallel rays and rays that emanate from the focus of a lens are refracted by the lens, we can determine where images are formed. The image of a point on an object is formed where all the light rays emanating from that point converge. (These light rays then diverge from the location of the image; when they enter the eye, the brain interprets them as having come from the location of the image.)

Figure 33.26 A lens has two equivalent foci, one on each side, at equal distances from the center of the lens.



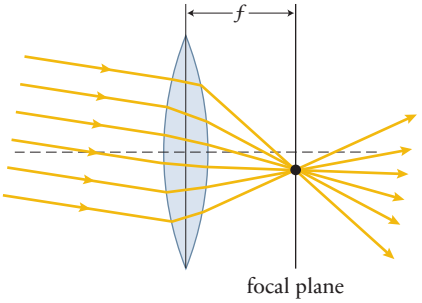


Figure 33.27 If the rays strike the lens at an angle, they no longer converge on the focus, but they still converge on a focal plane at the focal distance f.

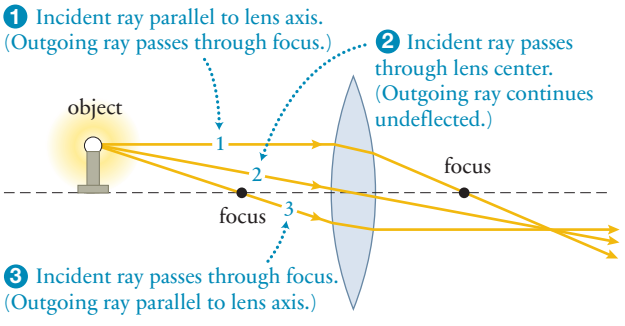
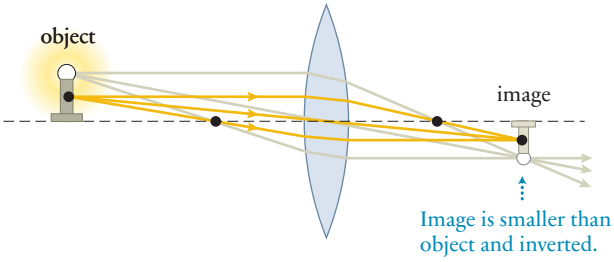
An image of the entire object is made up of the images of all the individual points on the object.



To determine where the rays emanating from a point on an object converge, we don't need to draw all the rays. Instead, we draw three special ones, called **principal rays,** and see where they converge:

1. a ray that travels parallel to the lens axis before entering the lens,
2. a ray that passes through the center of the lens, and
3. a ray that passes through the focus that is on the same side of the lens as the object.



These three principal rays are shown in **Figure 33.28*a*** for the case where the object lies beyond the focus of the lens. We already know how rays 1 and 3 travel. Ray 1

Figure 33.28 The three principal rays for a spherical lens can be used to determine the location, size, and orientation of the image for a given object.

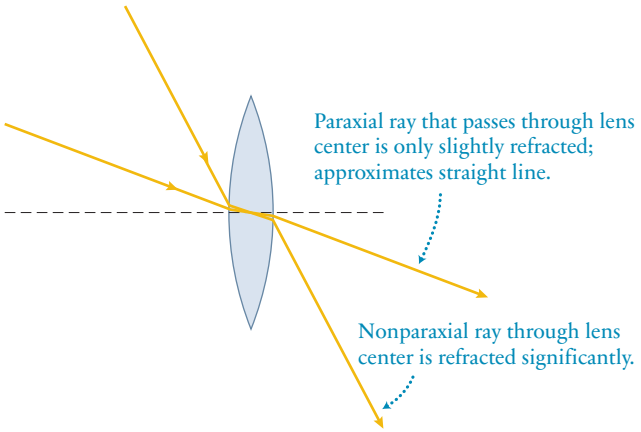
(*a*) The three principal rays

(*b*) Using principal rays to determine location and orientation of image

CONCEPTS

PROCEDURE: Simplified ray diagrams for lenses

To determine the location and orientation of an image formed by a lens, follow this procedure:



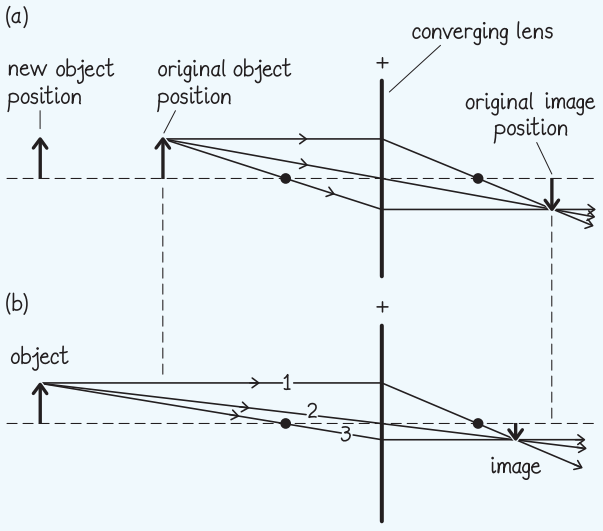
1. Draw a horizontal line representing the lens axis (the line perpendicular to the lens through its center). In the center of the diagram, draw a vertical line representing the lens. Put a + above the line to represent a converging lens or a − to represent a diverging lens.
2. Put two dots on the axis on either side of the lens to represent the foci of the lens. The dots should be equidistant from the lens.
3. Represent the object by drawing an upward-pointing arrow from the axis at the appropriate relative distance from the lens. For example, if the distance from the object to the lens is twice the focal length of the lens, put the arrow twice as far from the lens as the dot you drew in step 2. The top of the arrow should be at about half the height of the lens.
4. From the top of the arrow representing the object draw two or three of the three *principal rays* listed in the Procedure box "Principal rays for lenses" on page 1177.
5. The top of the image is at the point where the rays *that exit the lens* intersect (if they diverge, trace them backward to determine the point of intersection). If the intersection is on the opposite side of the lens from the object, the image is real; if it is on the same side, the image is virtual. Draw an arrow pointing from the axis to the intersection to represent the image (use a dashed arrow for a virtual image).

In general it is sufficient to draw two principal rays, but depending on the situation, some rays may be easier to draw than others. You can also use a third ray to verify that it, too, goes through the intersection. (If it doesn't, you have made a mistake.)

passes through the focus on the other side of the lens, and ray 3 emerges from the lens parallel to the axis. As for ray 2, as long as it is paraxial, it passes straight through with negligible refraction (**Figure 33.29**). (Nonparaxial rays are shifted significantly; our treatment of lenses in this chapter is restricted to images formed by paraxial rays.) Ray 2 can therefore be drawn as traveling in a straight line through the center of the lens.

To determine the location and orientation of the image of an extended object, we work out the locations of the images of several points on the object. Figure 33.28*b* shows where the rays converge for two points on the object, and the extended image that can be inferred from these points. The image is smaller than the object and inverted. See the Procedure box "Simplified ray diagrams for lenses" above for a general description of how to draw simplified ray diagrams for lenses.

Figure 33.29 Paraxial and nonparaxial rays. For a paraxial ray or a lens that is not too thick, the refraction is so slight that we can consider this ray to be one uninterrupted straight line.



33.10 Do you need to draw all three principal rays to determine the location of an image?

EXAMPLE 33.4 Where is the image?

Consider the light bulb that is the object in Figure 33.28. If you move the bulb to the left, does the image shift left, shift right, or stay in the same place?

❶ **GETTING STARTED** Using the procedure for drawing simplified ray diagrams, I represent the lens, object, and image of Figure 33.28, and draw the bulb at its new position (**Figure 33.30*a***).

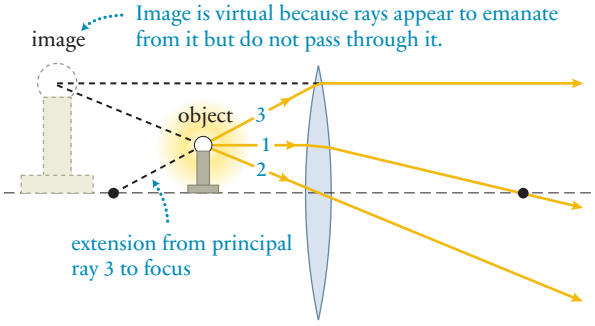
Figure 33.30

(Continued)

CONCEPTS

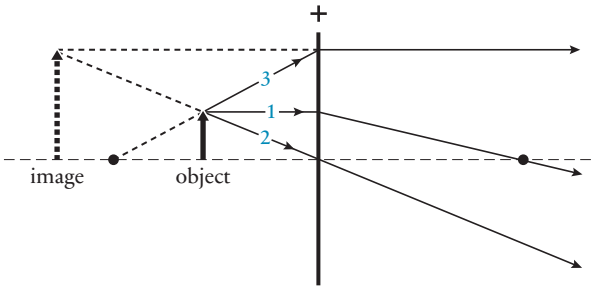
2 DEVISE PLAN I can determine which way the image shifts by drawing the principal rays for the light bulb in its new position.

3 EXECUTE PLAN With the rays drawn (Figure 33.30*b*), I see that the image shifts left. ✔



4 EVALUATE RESULT As I move the light bulb to the left, principal ray 1 remains the same, but principal ray 2 makes less of an angle with the lens axis than before. Consequently, the location at which these two rays intersect is closer to the lens than before, shifting the image to the left, as I concluded from the diagram.

Notice in Figure 33.30 that the image gets smaller as the object moves farther away from the lens. Conversely, moving the object closer to the lens makes the image larger. Indeed, one of the most common uses of lenses is to enlarge images. If the object is placed at the focus, no image forms because the rays all emerge from the lens parallel to each other—in other words, the rays do not converge.



Consider placing an object *between* the lens and its focus, as in **Figure 33.31**. In this configuration, principal ray 3 does not pass through the focus. Instead, it lies on the line that joins the focus to the point of interest on the object.

Figure 33.31 (*a*) When an object is located between the lens and the focus, the image is virtual and enlarged. (*b*) In a simplified ray diagram, the object and image are replaced with solid and dashed arrows, respectively, and the lens is replaced by a vertical line. (The + indicates a converging lens.)

(*a*) Ray diagram for an object located between the focus and the lens

(*b*) Simplified version of ray diagram

The image formed in the configuration of Figure 33.28 (object beyond focus) is real because the rays really do converge at the point where the image is formed. In contrast, the image in Figure 33.31 is virtual because the rays do not actually converge at the point where the image is formed. (The extensions of these rays do cross the image point, however, and so an observer interprets the rays emerging from the lens as having traveled along straight lines from the location of the image, as indicated in Figure 33.31*a*.)

An important difference between real and virtual images is that if a screen is placed at the location of a real image, the image can be seen on the screen. Placing a screen at the location of a virtual image does not display the image because the light rays do not actually pass through the image location.

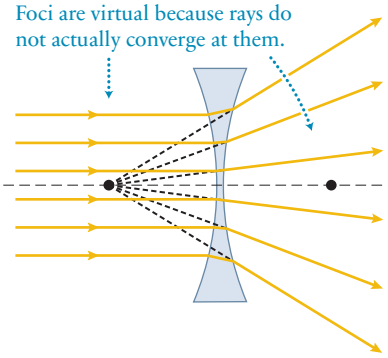


Figure 33.31*a* shows that, for this configuration of object and lens (object between focus and lens), the image is larger than the object and upright (unlike the image in Figure 33.28, which is inverted). A magnifying glass is designed to produce an enlarged, upright image of an object, which means that magnifying glasses are made with converging lenses and are held close to the object of interest (so that the object is between the lens and the focus).

33.11 As the object in Figure 33.31 is moved closer to the lens, does the size of the image increase, decrease, or stay the same?

Just as with electric circuits, it is convenient to use a simplified notation for ray diagrams. Figure 33.31*b* shows such a simplified version of the ray diagram of Figure 33.31*a*. Note that objects and real images are denoted by solid arrows and virtual images are denoted by dashed arrows.

Lenses can also be made with concave spherical surfaces rather than convex ones, where a *concave surface* is one that curves like the inside of a sphere. Such a lens is called a *diverging lens*, and **Figure 33.32** shows why: A series of parallel rays entering the lens are no longer parallel when they emerge. If we follow the path of the emerging rays back to the left side of the lens, we see that the

Figure 33.32 A diverging lens.

CONCEPTS

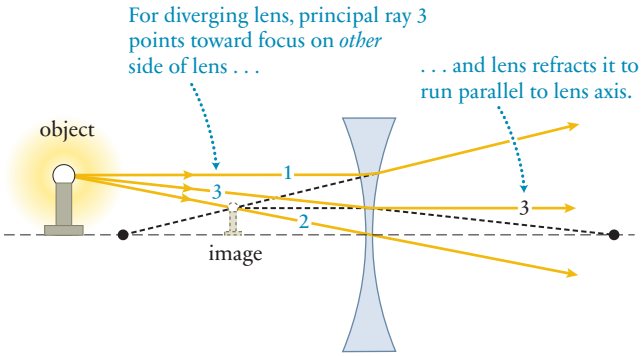
PROCEDURE: Principal rays for lenses

The propagations of principal rays for converging and diverging lenses are very similar. The description below holds for rays that travel from left to right.

Converging lens

1. A ray that travels parallel to the lens axis before entering the lens goes through the right focus after exiting the lens.
2. A ray that passes through the center of the lens continues undeflected.
3. A ray that passes through the left focus travels parallel to the lens axis after exiting the lens. If the object is between the focus and the lens, this ray doesn't pass through the focus but lies on the line from the focus to the point where the ray originates.

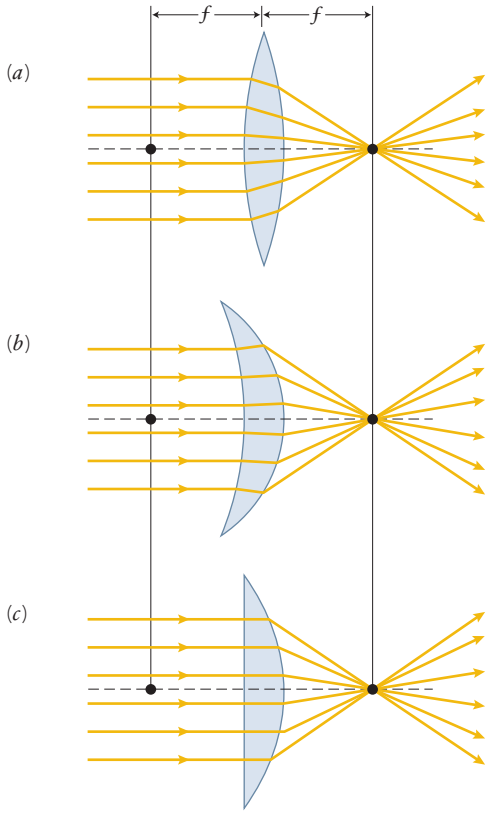
Diverging lens



1. A ray that travels parallel to the lens axis before entering the lens continues along the line from the left focus to the point where the ray enters the lens.
2. A ray that passes through the center of the lens continues undeflected.
3. A ray that travels toward the right focus travels parallel to the lens axis after exiting the lens.

diverging rays appear to all come from the same location on the left side. This location corresponds to the focus of a converging lens, but in a diverging lens it is a *virtual focus* rather than a real focus because the rays never actually travel through this location. (Just as for converging lenses, there is an equivalent focus on the other side of the lens.)

Figure 33.33 shows a ray diagram for a diverging lens. The same principal rays are drawn, but now ray 3 does not pass through the focus on the same side of the lens as the object. Instead, for diverging lenses ray 3 is drawn on the line that runs from the point where the ray originates to the focus on the other side of the lens; once refracted by the lens, this ray travels parallel to the lens axis. The general procedure for drawing ray diagrams for diverging lenses is still the same as the one for converging lenses (see the Procedure box "Simplified ray diagrams for lenses" on page 1175), but the drawing of principal rays is a little bit different (see the Procedure box "Principal rays for lenses" above).

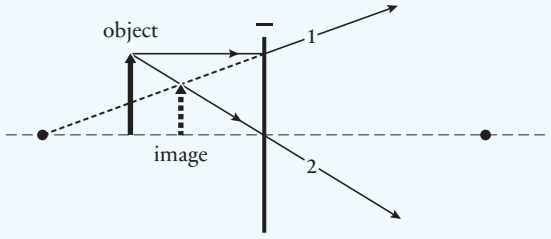


The lenses we have considered so far all have identical curved surfaces on each side. Many lenses have different surfaces, however. For example, it is possible to construct a converging lens with a certain focal length with two identical curved surfaces, two differently curved surfaces, or even a flat and a curved surface (**Figure 33.34**), as long as the lens is thicker at its center than at the edges. Regardless of the *radii of curvature* (that is, the radii of the spheres that best fit the surfaces), the lens has two foci, one on either side of the lens at the same distance f from it.

Figure 33.33 Ray diagram for an object outside the focus of a diverging lens.

33.12 Is the image in Figure 33.33 real or virtual?

Figure 33.34 These lenses are all converging because each is thicker at the center than at the edges.



CONCEPTS

EXAMPLE 33.5 Demagnifying glass

Suppose the object in Figure 33.33 is placed between the focus and the lens. (*a*) Is the image real or virtual? (*b*) Is it larger than, smaller than, or the same size as the object?

❶ **GETTING STARTED** To sketch the situation (**Figure 33.35**), I represent the diverging lens as a vertical line with a minus sign above it, and draw the horizontal lens axis. I add the focal points at equal distances from the lens along its axis. Finally, I add a solid arrow, representing the object, between the left focal point and the lens.

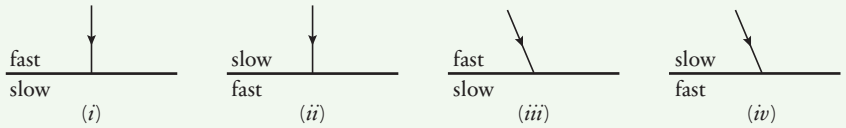
Figure 33.35

❷ **DEVISE PLAN** To locate the image and determine its size and whether it is real or virtual, I can draw the principal rays.

❸ **EXECUTE PLAN** (*a*) I add to my diagram the principal rays coming from the tip of my object arrow. All I need is rays 1 and 2; I do not need ray 3 because the intersection of ray 2 and the dashed extension of ray 1 unambiguously determines the location of the tip of the image arrow. The dashed extension I had to draw for ray 1 tells me that the rays do not actually intersect at this location; they only appear to intersect here. Therefore the image is virtual. ✔

(*b*) My diagram tells me that the image is smaller than the object. ✔

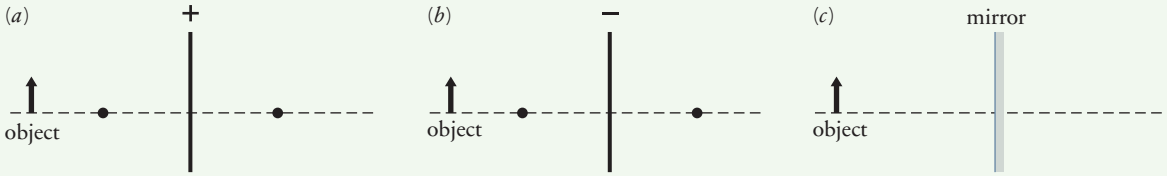
❹ **EVALUATE RESULT** Because a diverging lens spreads rays out rather than bringing them together, it makes sense that a virtual image will form. I also know from experience that in contrast to a converging lens, which magnifies images, diverging lenses create smaller images, as I found.



33.13 (*a*) Draw the third principal ray in Figure 33.35. Is there any position for the object in Figure 33.35 for which (*b*) the image is larger than the object and (*c*) the image is real?

CONCEPTS

Self-quiz



1. Why do you get a clear reflection from the surface of a lake on a calm day but little or no reflection from the surface on a windy day?
2. (*a*) As light travels from one medium into another, as shown in **Figure 33.36** ("fast" and "slow" refer to the wave speed in each medium), what happens to the wavelength of the light? (*b*) Draw the reflected and refracted rays at each surface.

Figure 33.36

3. What is the difference between a real image and a virtual image?
4. In each situation in **Figure 33.37**, draw the three rays emanating from the top of the object and reflecting or refracting from the optical element shown. Show the image, and state whether it is real or virtual.

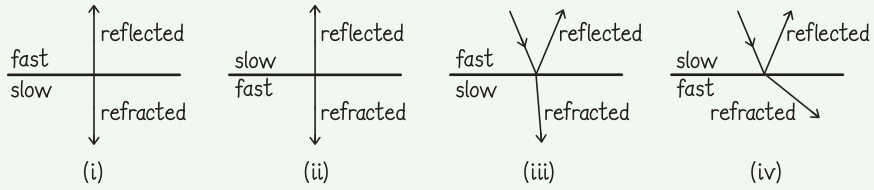


Figure 33.37

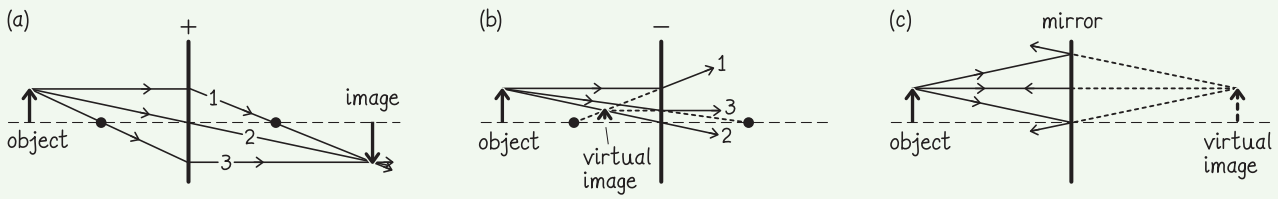
Answers



1. On a calm day, the lake surface is smooth, and specular reflection is like that of a mirror. On a windy day, the surface is rough, which makes the reflection diffuse and prevents the formation of an image.
2. (*a*) The wavelength decreases when the wave travels more slowly in the second medium (*i* and *iii*) and increases when the wave travels faster in the second medium (*ii* and *iv*). (*b*) See **Figure 33.38**.

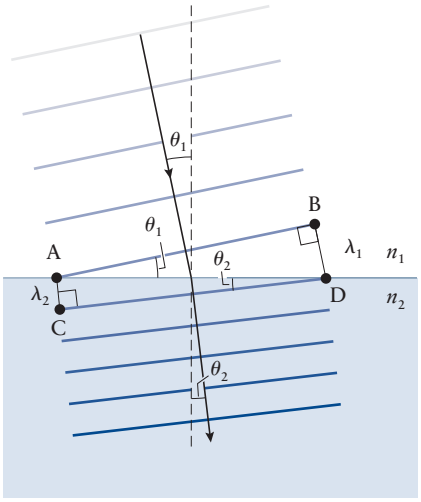
Figure 33.38

3. Real image: All rays actually pass through the location of the image, and the image can be seen on a screen placed at the image location. Virtual image: All rays do not pass through the location of the image (only the extensions of the rays do), and the image cannot be seen on a screen placed at the image location.
4. See **Figure 33.39**. For the lenses, the three principal rays can be used to locate the image; for the mirror, any rays and the law of reflection can be used to locate the image. The images are (*a*) real, (*b*) virtual, (*c*) virtual.

Figure 33.39

33.5 Snel's law

In the first part of this chapter, we saw that light refracts when it travels from one medium into another because the speed of light depends on the medium. The speed of light in a medium is specified by the **index of refraction:**



$$n \equiv \frac{c_0}{c}, \tag{33.1}$$

where c is the speed of light in the medium and c_0 is the speed of light in vacuum. (By definition, $n_{\text{vacuum}} = 1$; in air $n_{\text{air}} \approx 1$.) If a light wave of frequency f travels from one medium into another, the frequency doesn't change because the source determines the frequency (see also Checkpoint 16.10). The wavelength, however, does change; it is greater in the medium in which wave speed is greater.

The wavelength λ of the light is related to the wave speed and frequency, in the same manner that these quantities are related for harmonic waves (Eq. 16.10). In vacuum, for example,

$$\lambda = \frac{c_0}{f} \quad \text{(vacuum)}. \tag{33.2}$$

Figure 33.40 Relationship between angle of incidence θ_1 and angle of refraction θ_2.

In a medium in which a wave has speed c_1, the wavelength λ_1 is given by

$$\lambda_1 = \frac{c_1}{f} = \frac{c_0/n_1}{f} = \frac{1}{n_1}\lambda, \tag{33.3}$$

where λ is the wavelength of the wave in vacuum and n_1 is the index of refraction of the medium. Thus, the wavelength decreases as the index of refraction increases. As discussed in Section 33.3, the amount of refraction a light wave undergoes varies somewhat with wavelength (see Figure 33.22) because different wavelengths of light travel at different speeds. Therefore the index of refraction depends on the wavelength. **Table 33.1** lists the indices of refraction for some common transparent materials at a wavelength of 589 nm.

Let us now work out the quantitative relationship between the angle of incidence and the angle of refraction. **Figure 33.40** shows wavefronts and one ray for a beam of light incident on the interface between medium 1 and medium 2 at angle θ_1 from the normal. The angle of refraction is θ_2. Using right triangles ABD and ACD, we can express angles θ_1 and θ_2 in terms of the wavelengths λ_1 and λ_2:

$$\sin\theta_1 = \frac{\text{BD}}{\text{AD}} = \frac{\lambda_1}{\text{AD}} \tag{33.4}$$

and

$$\sin\theta_2 = \frac{\text{AC}}{\text{AD}} = \frac{\lambda_2}{\text{AD}}. \tag{33.5}$$

Table 33.1 Indices of refraction for common transparent materials

Material	n (for λ = 589 nm)
Air (at standard temperature and pressure)	1.00029
Liquid water	1.33
Sugar solution (30%)	1.38
Sugar solution (80%)	1.49
Microscope cover slip glass	1.52
Sodium chloride (table salt)	1.54
Flint glass	1.65
Diamond	2.42

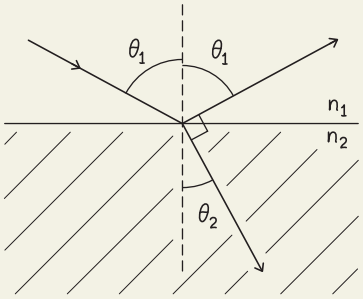
QUANTITATIVE TOOLS

Combining these equations to eliminate AD and substituting $\lambda_1 = \lambda/n_1$ (Eq. 33.3), we get

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{\lambda_1}{\lambda_2} = \frac{\lambda/n_1}{\lambda/n_2} = \frac{n_2}{n_1}, \tag{33.6}$$

which can be written as

$$n_1 \sin\theta_1 = n_2 \sin\theta_2. \tag{33.7}$$



This relationship between the indices of refraction and the angles of incidence and refraction is called **Snel's law,** after the Dutch astronomer and mathematician Willebrord Snel van Royen (1580–1626). (In English, his name is often spelled as "Snell" instead.)

EXAMPLE 33.6 Bending 90°

A ray traveling through a medium for which the index of refraction is n_1 is incident on a medium for which the index of refraction is n_2. At what angle of incidence θ_1, expressed in terms of n_1 and n_2, must the ray strike the interface between the two media for the reflected and transmitted rays to be at right angles to each other?

❶ **GETTING STARTED** This problem involves both reflection and refraction at an interface between two media. To visualize the problem, I draw the incident, reflected, and refracted rays and indicate that the reflected and refracted rays are 90° apart (**Figure 33.41**).

Figure 33.41

❷ **DEVISE PLAN** Snel's law (Eq. 33.7), the law of reflection, and the indices of refraction determine the paths taken by the reflected and refracted rays. Therefore I need to use those relationships to obtain an expression that tells me the value of θ_1 that produces reflected and refracted rays oriented 90° to each other. To obtain θ_1 in terms of n_1 and n_2, I need to eliminate θ_2 from Eq. 33.7. To do so, I use the fact that the angles on the right side of the normal to the interface must add to 180°. Thus, with reflected and refracted rays forming a 90° angle, I can say $180° = \theta_1 + 90° + \theta_2$. Solving this expression for θ_2 gives $\theta_2 = 90° - \theta_1$, which I can substitute into Eq. 33.7.

❸ **EXECUTE PLAN** Substituting $\theta_2 = 90° - \theta_1$ into Eq. 33.7, I get

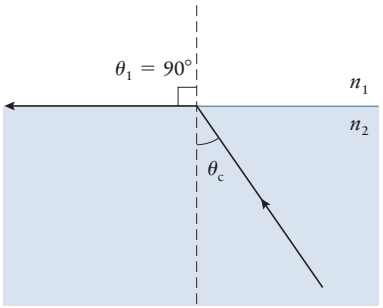
$$n_1 \sin\theta_1 = n_2 \sin(90° - \theta_1) = n_2 \cos\theta_1,$$

and isolating the terms that contain θ_1 gives

$$\frac{\sin\theta_1}{\cos\theta_1} = \tan\theta_1 = \frac{n_2}{n_1}$$

$$\theta_1 = \tan^{-1}\left(\frac{n_2}{n_1}\right). \checkmark$$

❹ **EVALUATE RESULT** My result says that θ_1 increases as n_2 increases. This makes sense because as n_2 increases, the refracted ray bends more, meaning that θ_2 becomes smaller. To keep the reflected and refracted rays perpendicular to each other, the angle of reflection must increase, and so θ_1 must also increase.



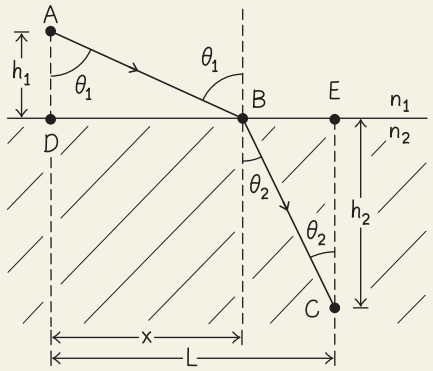
Earlier in this chapter, we found that for rays traveling from a denser medium to a less dense medium, we can define a critical angle of incidence θ_c such that the angle of refraction θ_1 is equal to 90° (**Figure 33.42**); beyond this critical angle θ_c, total internal reflection occurs. We can calculate the critical angle θ_c for an interface between two media with indices of refraction n_1 and n_2 ($n_2 > n_1$) by applying Snel's law (Eq. 33.7) and setting $\theta_1 = 90°$:

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{1}{\sin\theta_c} = \frac{n_2}{n_1}. \tag{33.8}$$

Solving for θ_c gives

$$\theta_c = \sin^{-1}\left(\frac{n_1}{n_2}\right). \tag{33.9}$$

Figure 33.42 Critical angle for a ray traveling from a denser medium (n_2) to a less dense medium ($n_1 < n_2$).



EXAMPLE 33.7 Fermat's principle

For a light ray that crosses the interface between medium 1 having index of refraction n_1 and medium 2 having index of refraction n_2, what relationship between θ_1 and θ_2 follows from Fermat's principle (page 1173)?

❶ **GETTING STARTED** I begin with a sketch of both media and a ray traveling from an arbitrary point A in the n_1 medium to an arbitrary point C in the n_2 medium (**Figure 33.43**). Fermat's principle states that the path the ray takes from A to C is the path for which the time interval needed for the motion is a minimum. Therefore this ray must cross the interface at a point B that makes the time interval a minimum.

Figure 33.43

An alternative way to express this problem is: Given the locations of A and C, where must B lie so as to minimize the time interval needed to travel from A to C?

❷ **DEVISE PLAN** I add two more location labels to my drawing: D directly below A and lying on the interface, and E directly above C and lying on the interface. Doing so gives me two right-angle triangles that permit me to express the angles in terms of the distance traveled. I write h_1 for the distance AD and h_2 for the distance EC. I can think of the distance from D to B as unknown—I'll call it x—and the distance from D to E, which I'll call L, is fixed by the locations of A and C. My goal is to determine the value of x for which the travel time from A to C is minimized. Once I obtain x, I hope to obtain a relationship between θ_1 and θ_2.

❸ **EXECUTE PLAN** I begin by expressing the time interval Δt_{AC} the ray needs to travel from A to C in terms of the distances shown in Figure 33.43 and the speed of light in the two media:

$$\Delta t_{AC} = \Delta t_{AB} + \Delta t_{BC} = \frac{AB}{c_1} + \frac{BC}{c_2} = \frac{AB}{c_0/n_1} + \frac{BC}{c_0/n_2}. \quad (1)$$

Next I express AB and BC in terms of h_1, h_2, L, and x:

$$AB = \sqrt{h_1^2 + x^2}$$

$$BC = \sqrt{h_2^2 + (L-x)^2}.$$

Substituting these two expressions into Eq. 1 gives me

$$\Delta t_{AC} = \frac{\sqrt{h_1^2 + x^2}}{c_0/n_1} + \frac{\sqrt{h_2^2 + (L-x)^2}}{c_0/n_2}.$$

Except for x, all quantities in this expression are constants.

The path for which the time interval Δt_{AC} is a minimum—as it must be from Fermat's principle—is the path for which the derivative of Δt_{AC} with respect to x is zero:

$$\frac{d}{dx}(\Delta t_{AC}) = \frac{xn_1}{c_0\sqrt{h_1^2 + x^2}} - \frac{(L-x)n_2}{c_0\sqrt{h_2^2 + (L-x)^2}} = 0. \quad (2)$$

Solving this equation for x would tell me where the light ray crosses the interface, but I do not have values for L and x. However, the right triangles ADB and BEC in Figure 33.43 allow me to express these distances in terms of θ_1 and θ_2:

$$\sin\theta_1 = \frac{x}{\sqrt{h_1^2 + x^2}} \quad \text{and} \quad \sin\theta_2 = \frac{L-x}{\sqrt{h_2^2 + (L-x)^2}}. \quad (3)$$

I can now use these expressions to rewrite Eq. 2 in terms of θ_1 and θ_2. From Eq. 2 I obtain

$$\frac{xn_1}{c_0\sqrt{h_1^2 + x^2}} = \frac{(L-x)n_2}{c_0\sqrt{h_2^2 + (L-x)^2}}.$$

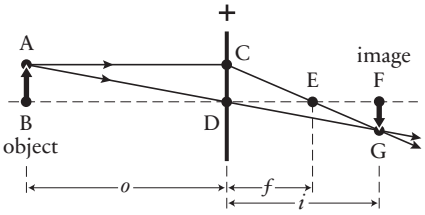
Canceling the c_0 factors that appear on both sides and substituting from Eq. 3, I get

$$n_1 \sin\theta_1 = n_2 \sin\theta_2. \checkmark$$

❹ **EVALUATE RESULT** My result is identical to Snel's law—which I derived by considering the effect of changing speed on the propagation of wavefronts. So Fermat's principle yields the same result as Snel's law, which I know to be correct.

Fermat's principle applies to all of ray optics, not only to refraction. As discussed in the box "Fermat's principle" on page 1173, the law of reflection also follows from this principle.

33.14 We found in Example 33.3 that a light ray is refracted twice when it passes completely through a slab of transparent material (see Figure 33.18). The result of these two refractions is that the exiting ray is shifted sideways relative to the entering ray. Let the slab be in air with an index of refraction $n_1 = 1$. (*a*) Derive an expression for the distance (perpendicular to the ray) over which the ray is shifted sideways for an angle of incidence θ_1, slab thickness d, and slab index of refraction n_2. (*b*) Calculate the value of the shift for $\theta_1 = 30°$, $n_2 = 1.5$, and $d = 0.010$ m.



QUANTITATIVE TOOLS

33.6 Thin lenses and optical instruments

In the first part of this chapter, we found that converging lenses form images of objects by focusing the light rays emanating from those objects. Let us now work out quantitatively the location and size of such images. We shall restrict our discussion to lenses that are thin enough that we can ignore the type of effects shown in Figure 33.29. Such lenses are called *thin lenses*.

A simplified ray diagram of the image formed by a converging lens is shown in **Figure 33.44**. The focal length f of the lens is DE, the distance o from the lens to the object (also called the *object distance*) is BD, and the distance i from the lens to the image (also called the *image distance*) is DF. The height of the object is AB, and the height of the image is FG. Let us denote the height of the object by h_o and the height of the image by h_i. We choose the values of h_o and h_i to be positive for upright objects and images and negative for inverted objects and images. We want to obtain a relationship between h_i and h_o, which will tell us how large the image is relative to the object. We also want a relationship among f, i, and o, which will tell us how the positions of the object and the image are related.

Figure 33.44 Simplified ray diagram for the formation of an image by a converging lens.

We begin by noting that triangles ABD and DFG are similar, which means

$$\frac{\text{AB}}{\text{DB}} = \frac{\text{FG}}{\text{DF}}. \tag{33.10}$$

Because the image is inverted, $h_i = -\text{FG}$, we can rewrite Eq. 33.10 as

$$\frac{h_o}{o} = \frac{-h_i}{i}. \tag{33.11}$$

Rearranging this expression gives

$$-\frac{h_o}{h_i} = \frac{o}{i}. \tag{33.12}$$

In this case, the absolute value of the ratio of the object height to the image height equals the ratio of the object distance to the image distance.

Triangles CDE and EFG are also similar, which means

$$\frac{\text{DE}}{\text{CD}} = \frac{\text{EF}}{\text{FG}}, \tag{33.13}$$

which can be written as

$$\frac{f}{h_o} = \frac{i-f}{-h_i}. \tag{33.14}$$

Using Eq. 33.12 to rewrite Eq. 33.14 in terms of f, o, and i gives us

$$\frac{f}{o} = \frac{i-f}{i} = 1 - \frac{f}{i}. \tag{33.15}$$

Dividing by f and rearranging terms yield

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i}. \tag{33.16}$$

This result is known as the **lens equation.**

It can be shown that Eq. 33.16 is generally true for either real or virtual images formed by either converging or diverging lenses, as long as we choose the signs of f, i, and o properly. For a converging lens, f is positive and o is positive if the object is in front of the lens. (This is always true for a single lens and for the first lens in a lens combination. For situations involving multiple lenses, however, it is possible that the object imaged by a secondary lens is on the opposite side of the lens from the side where the rays enter it—that is, the object is "behind the lens." In that case o is negative.) If the image is on the same side of the lens as the emerging light, the image is real and i is positive; if the image is on the opposite side of the lens from the emerging light, the image is virtual and i is negative.

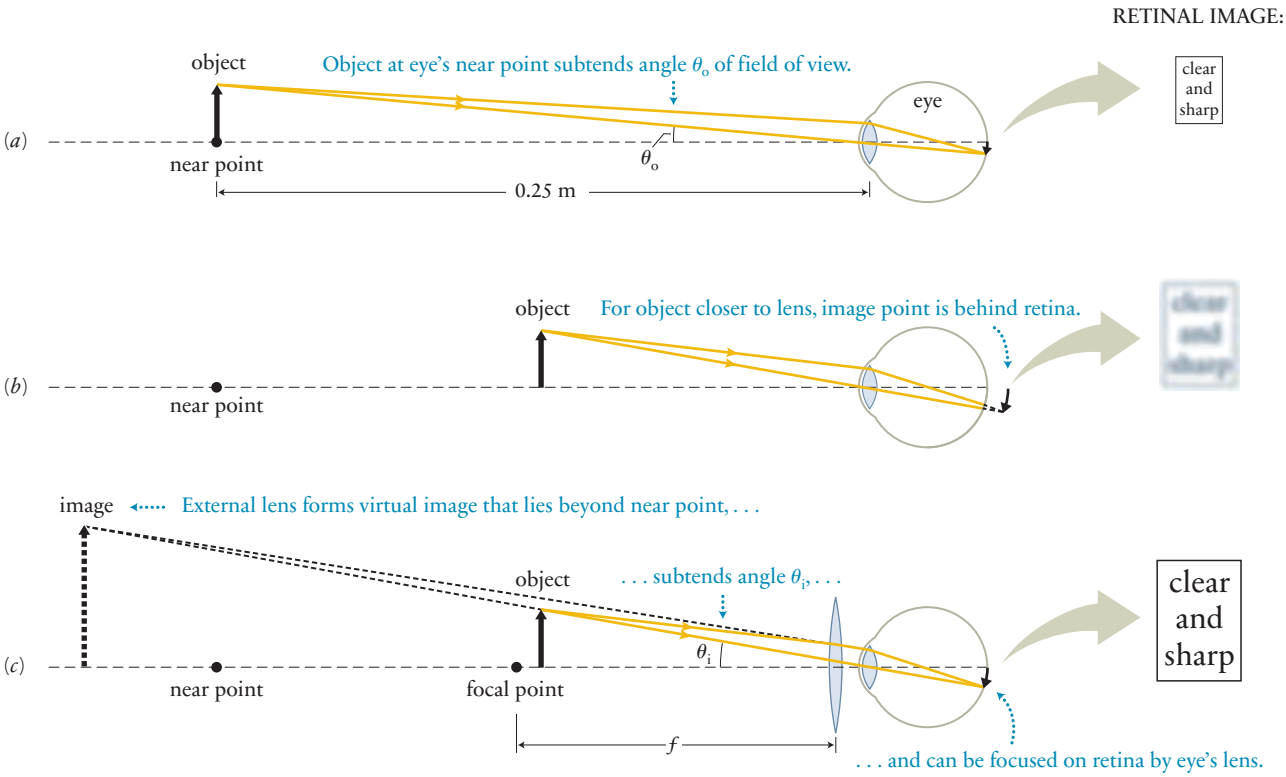
For a diverging lens (a lens with concave surfaces), the focal length f is negative because the focus is virtual rather than real—that is, parallel rays appear to come from the same side of the lens where the light source is rather than converging on the other side of the lens. The same sign convention applies to o as for converging lenses. A single diverging lens always produces a virtual image (see Example 33.5), so i is always negative for such lenses.

The sign conventions for f, i, and o are similar for images formed by spherical mirrors, which are discussed in the next section. **Table 33.2** summarizes these sign conventions.

The **magnification** of the image is defined as the ratio of the signed image height to the object height. Using Eq. 33.12, we get

$$M \equiv \frac{h_i}{h_o} = -\frac{i}{o}. \tag{33.17}$$

We define M this way so that the magnification of upright images is positive and that of inverted images is negative. Examining Figures 33.30, 33.31, and 33.33, we can see that for a single lens, when the image distance and object distance are both positive, as in Figure 33.30, we obtain an inverted image, whereas when the image distance is negative, as in Figures 33.31 and 33.33, we obtain an upright image.



33.15 If the diverging lens in Figure 33.33 has a focal length of 80 mm and the object is located 100 mm from the lens, (*a*) what is the image distance and (*b*) how tall is the image relative to the object?

Table 33.2 Sign conventions for f, i, and o (positive = real; negative = virtual)

Sign	Lens	Mirror
$f > 0$	converging lens	converging mirror
$f < 0$	diverging lens	diverging mirror
$o > 0$	object in front[b] of lens	object in front of mirror
$o < 0$[a]	object behind lens	object behind mirror
$i > 0$	image behind lens	image in front of mirror
$i < 0$	image in front of lens	image behind mirror
$h_i > 0$	image upright	image upright
$h_i < 0$	image inverted	image inverted
$\|M\| > 1$	image larger than object	image larger than object
$\|M\| < 1$	image smaller than object	image smaller than object

[a]Encountered only with lens or mirror combinations.
[b]For both lenses and mirrors, "in front" means on the side where the rays originate; "behind" refers to the opposite side.

Figure 33.45 An eye cannot focus on an object that is closer than its near point (which represents the limit of the biological lens's ability to change curvature). However, an external converging lens (such as a magnifying lens) makes it possible to see objects that are closer than the near point. It also enlarges them.

The human eye focuses incoming light rays, forming an image on the retina of the eye (**Figure 33.45*a***). One part of the eye is its lens, but unlike the lenses we have examined so far, the focal length of the eye's lens is variable, which allows us to see objects clearly over a wide range of distances. When the muscle around the lens is fully relaxed, the lens flattens out and the retina lies in the focal plane of the lens. Thus, light rays from distant objects focus onto the retina.

To the unaided eye, the largest (and thus most detailed) image of an object is observed when we bring the object as close as possible to the eye. However, there is a limit to how much the eye's lens can adjust. The *near point* is the closest object distance at which the eye can focus on the object comfortably. Typically, for an adult, the near point is about 0.25 m from the eye. An object positioned at the near point appears clear and sharp to the observer, as shown in Figure 33.45*a*. With age the distance between the near point and the eye tends to increase, and when an object is brought closer than the near point, the plane where the image is formed lies behind the retina and the image "seen" by the retina is blurry (Figure 33.45*b*). This situation can be corrected by an external lens that works in combination with your eye's lens to focus the image on the retina (Figure 33.45*c*).

An external converging lens properly placed between the object and the eye, as in Figure 33.45*c*, magnifies the object. To maximize the size of the image, the object is held near the focus of the external lens, and the lens is held as close as possible to the eye. The image formed by the external lens then serves as the object for the eye's lens. The image formed by the external lens is virtual and subtends an angle θ_i that is greater than the angle θ_o subtended by the object in Figure 33.45*a*, permitting the viewer to see finer

details. The image is also outside the near point; if the object is placed exactly at the focus of the external lens, the image is at infinity and can be viewed comfortably. We can define the *angular magnification* produced by the lens as

$$M_\theta \equiv \left|\frac{\theta_i}{\theta_o}\right|. \tag{33.18}$$

For small angles and an object placed close to the focus of the external lens, as in Figure 33.45*c*, the angle θ_i subtended by the image can be expressed in terms of the object height h_o and the focal length f of the lens:

$$\theta_i \approx \tan\theta_i \approx \frac{h_o}{f} \quad \text{(object close to focus, small } \theta_i\text{)}. \tag{33.19}$$

For small angles and an object placed at the eye's near point, as in Figure 33.45*a*, the angle subtended by the object is approximately

$$\theta_o \approx \tan\theta_o = \frac{h_o}{0.25\ \text{m}} \quad \text{(object close to near point, small } \theta_o\text{)}. \tag{33.20}$$

Substituting Eqs. 33.19 and 33.20 into Eq. 33.18 gives an angular magnification of

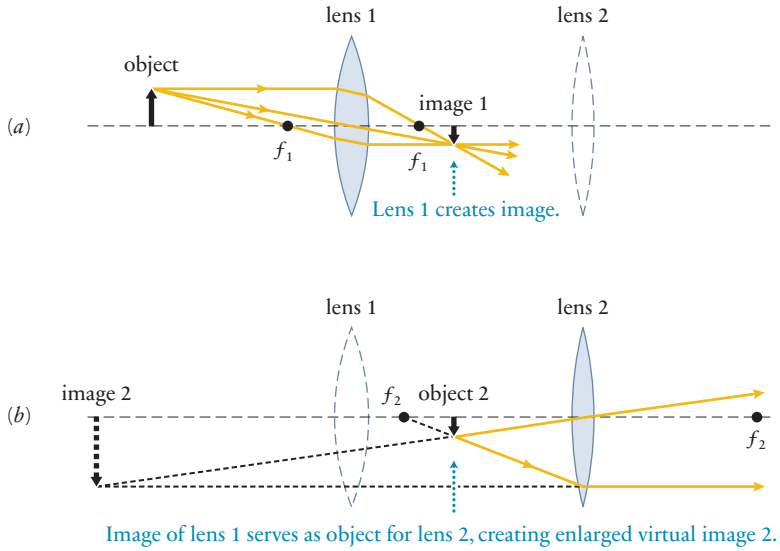
$$M_\theta \approx \frac{0.25\ \text{m}}{f}. \tag{33.21}$$

This expression gives what is called either the *small-angle approximation* or the *paraxial approximation* to the angular magnification because it is obtained with the small-angle approximations of Eqs. 33.19 and 33.20. These approximations are good to within 1% for angles of 10° or less.

Lenses placed near the eye (in the form of eyeglasses) are used to correct vision for far-sighted or near-sighted eyes. The strength of eyeglass lenses (and of magnifying lenses, too) is commonly symbolized by d and measured in *diopters*:

$$d \equiv \frac{1\ \text{m}}{f}. \tag{33.22}$$

The *lens strength* d, like the lens focal length f, is positive for converging lenses and negative for diverging lenses. For example, a +4-diopter lens is a converging lens with a focal length of 0.25 m. Diverging lenses are typically used to correct nearsightedness, with lens strengths ranging from −0.5 to −4 diopters.



33.16 A single-lens magnifying glass used to examine photographic slides produces eightfold angular magnification. (*a*) What is the lens strength in diopters? (*b*) What is the focal length of the lens?

Many optical instruments combine two or more lenses to increase magnification. To trace rays through a combination of lenses, use the following procedure: The image formed by the first lens serves as the object for the second lens, the image formed by the second lens serves as the object for the third lens, and so on. **Figure 33.46** shows a ray diagram constructed in two steps for a combination of two lenses. Figure 33.46*a* shows the object, image, and rays for lens 1, and Figure 33.46*b* shows these elements for lens 2. Note that the rays from object 2 (which is the image formed by lens 1) are *not* the continuation of those used to locate image 1.

QUANTITATIVE TOOLS

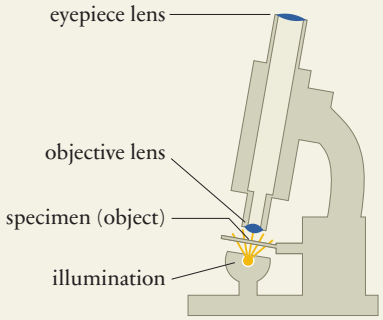


Figure 33.46 Two-step process for tracing rays through a combination of two lenses. When lenses are combined, the image of each lens serves as an object for the next lens.

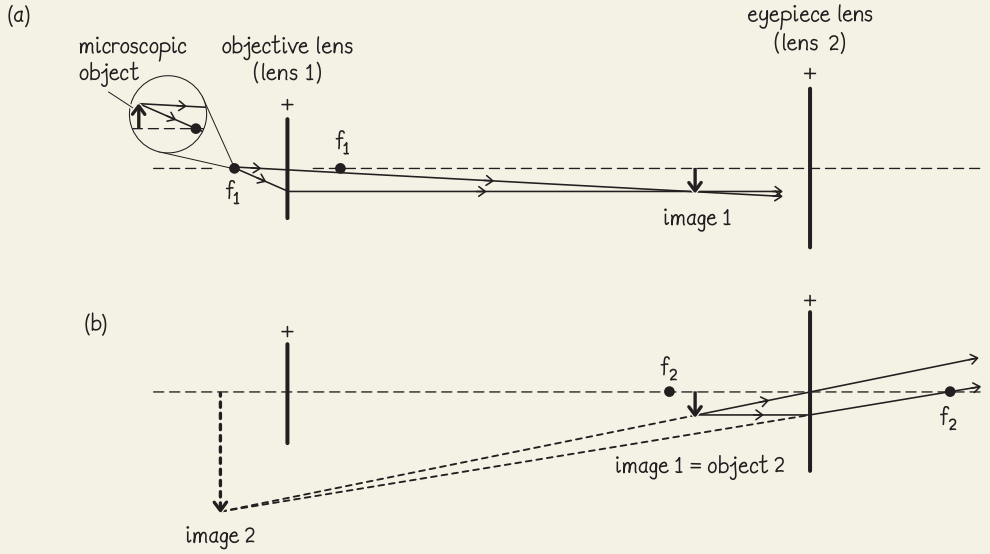
EXAMPLE 33.8 Compound microscope

A compound microscope consists of two converging lenses, the *objective lens* and the *eyepiece lens*, positioned on a common optical axis (**Figure 33.47**). The objective lens is positioned to form a real, highly magnified image 1 of the sample being examined, and the eyepiece lens is positioned to form a virtual, further magnified image 2 of image 1. It is image 2 that the user sees. A knob on the microscope allows the user to move the objective lens upward and downward to change both the sample-objective lens distance and the distance between the two lenses. (*a*) How must the sample and the two lenses be positioned relative to one another so that the user sees a highly magnified, virtual image of the sample? (*b*) What is the overall magnification produced by the microscope?

Figure 33.47 Example 33.8.



❶ **GETTING STARTED** I begin by examining Figure 33.46, which shows how, in a combination of two lenses 1 and 2, the image formed by lens 1 serves as the object for lens 2. The objective lens in a compound microscope corresponds to lens 1 in Figure 33.46, and the eyepiece lens corresponds to lens 2. Thus to keep things simple I refer to the objective lens as 1 and the eyepiece lens as 2.

❷ **DEVISE PLAN** To determine the relative positioning of the two lenses relative to each other, I must examine ray diagrams for various lens-sample distances and determine for which arrangement I get the greatest magnification. To determine the magnification M_1 of image 1, I can use the lens equation (Eq. 33.16) together with the relationship among magnification, image distance, and object distance (Eq. 33.17). The focal length of the lenses is fixed by their construction, and in operating a microscope, the observer can adjust the distance between the sample and the objective lens, so I can express this magnification in terms of f_1 and o_1. To determine the magnification of image 2, I recognize that lens 2 is used as a magnifying glass, so I can use Eq. 33.21, which gives the angular magnification $M_{\theta 2}$ produced by a simple magnifier. The overall magnification produced by the microscope is the product $M_1 M_{\theta 2}$.

❸ **EXECUTE PLAN** (*a*) In Figure 33.46, lens 1 produces an image that is smaller than the object. I am told that the image formed by lens 1 in a microscope is larger than the sample, and so I must choose a different sample position, one that yields an image 1 larger than the sample. I am also told that this image is real. Placing the sample just outside the focal point of lens 1 gives me an image 1 that is larger than the sample. My choices are to increase or decrease the sample-lens 1 distance. Drawing a ray diagram for each possibility, I see that moving the sample farther and farther from lens 1 makes the image smaller and smaller. Therefore I should position the sample closer to lens 1 than in Figure 33.46*a*. Should I choose a position inside or outside the lens focus? I know

(Continued)

Figure 33.48

from the problem statement that this image is real, and I know from Figure 33.31 that an object inside the focus of a converging lens produces a virtual image. Thus my best choice is to adjust the sample-lens 1 distance so that the sample is just outside the lens focus (**Figure 33.48a**).

I am told that image 2 is virtual and larger than image 1. I know from Figure 33.31 that a converging lens produces a virtual, magnified image when the object is inside the lens focus. I again draw ray diagrams for various positions inside the focus and see that the greatest magnification is obtained when I adjust the distance from lens 1 to lens 2 to make image 1 fall just inside the focal point of lens 2, as shown in Figure 33.48*b*. ✔

(*b*) To determine M_1, I use the lens equation to write i_1 in terms of f_1 and o_1:

$$i_1 = \frac{1}{\left(\frac{1}{f_1} - \frac{1}{o_1}\right)}.$$

I substitute this expression into Eq. 33.17:

$$M_1 = -\frac{i_1}{o_1} = -\frac{1}{o_1} \times \frac{1}{\left(\frac{1}{f_1} - \frac{1}{o_1}\right)} = -\frac{1}{\frac{o_1}{f_1} - 1},$$

which tells me that the magnification M_1 produced by lens 1 is determined by the ratio o_1/f_1. Because I have made o_1 slightly larger than f_1 in order to produce a real image 1, the denominator is positive and therefore M_1 is negative.

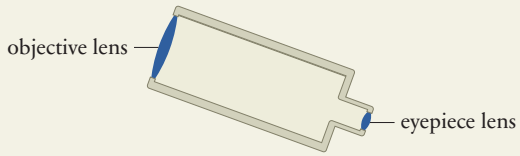
The angular magnification produced by lens 2 is approximately

$$M_{\theta 2} = \frac{0.25\ \text{m}}{f_2}.$$

The overall magnification produced by the microscope is thus

$$M = M_1 M_{\theta 2} = \frac{-0.25\ \text{m}}{f_2\left(\frac{o_1}{f_1} - 1\right)}. \checkmark$$

4 EVALUATE RESULT Figure 33.48*a* indicates that image 1 is inverted, making M_1 negative and giving me confidence in my expression for M_1. Figure 33.48*b* tells me that image 2 is upright relative to its object, and so $M_{\theta 2}$ is positive, which agrees with my result. Because image 2 is inverted relative to the sample, the overall magnification is negative, as my result shows.



QUANTITATIVE TOOLS

33.17 (*a*) Consider replacing the objective lens in Fig. 33.48*a* with one that has a greater focal length, and moving the sample in order to keep it just outside the focal point of the lens. Does the image formed by the objective lens move closer to the objective lens, stay in the same place, or move farther from the objective lens? (*b*) In practice it is desirable for a microscope to be fairly compact. To keep the microscope compact, should the focal length of the objective lens be chosen to be short or long, or does it matter?

EXAMPLE 33.9 Refracting telescope

A refracting telescope, like a compound microscope, contains two converging lenses, the objective lens and the eyepiece lens, positioned on a common optical axis (**Figure 33.49**). However, a telescope is designed to view large, very distant objects, whereas a microscope is used to view very small objects that are placed very close to the objective lens. Consequently, the arrangement of lenses in a telescope is different from the arrangement in a microscope. The telescope's objective lens is positioned to form a real image of very distant objects, and the eyepiece lens is positioned to form a virtual image of the image produced by the objective lens, to be viewed by an observer. (*a*) How should the lenses be arranged to accomplish this? (*b*) What is the overall magnification produced by the telescope?

Figure 33.49 Example 33.9.

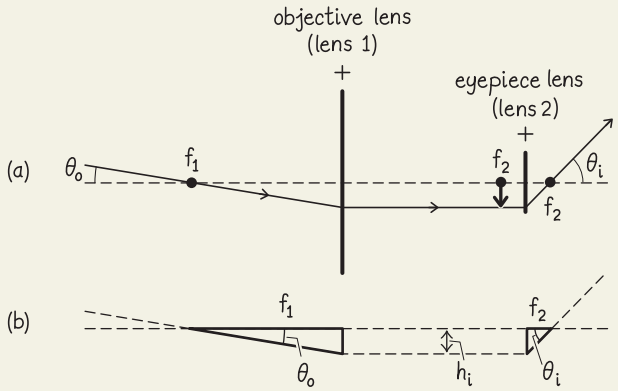
❶ **GETTING STARTED** I begin by examining Figure 33.46 and then construct a similar ray diagram with the object at a very great distance from the lenses. As in Example 33.8, I use lens 1 to refer to the objective lens and lens 2 to refer to the eyepiece lens. Because the object is very far away, light rays from it enter lens 1 as parallel rays. These rays form an image 1 in the focal plane of lens 1 (**Figure 33.50*a***). Because I know the location of image 1, I need to draw only one principal ray. As in the microscope, lens 2 is used as a simple magnifier to view image 1.

❷ **DEVISE PLAN** Because the original object is very distant and the final image is viewed by the observer's eye, I can calculate the angular magnification of this image. Although I could calculate the angular magnification produced by each lens and multiply them together, in this case it is simpler to determine the overall angular magnification because the angles θ_o and θ_i the object and image 2 subtend at the observer's eye are both very small. I can determine the overall angular magnification by taking the ratio of these angles while using the small-angle approximation.

❸ **EXECUTE PLAN** (*a*) In order for lens 2 to produce a magnified, virtual image of image 1, image 1 should be positioned just inside the focal plane of lens 2. If lens 2 is placed such that the image is at the focal plane of lens 2 (Figure 33.50*b*), lens 2 forms an infinitely distant, virtual image that can be viewed comfortably by the observer's relaxed eye. As my diagram shows, the lenses are then arranged such that their foci coincide. ✔

(*b*) **Figure 33.51*a*** shows the ray that passes through the foci of the lenses, labeled with the angles θ_o (subtended by the object) and θ_i (subtended by the image). Figure 33.51*b* shows the triangles I use to relate each of these angles to the height h_i of image 1 and the focal lengths of the lenses. The angular magnification is the ratio θ_o/θ_i. I can approximate

Figure 33.51



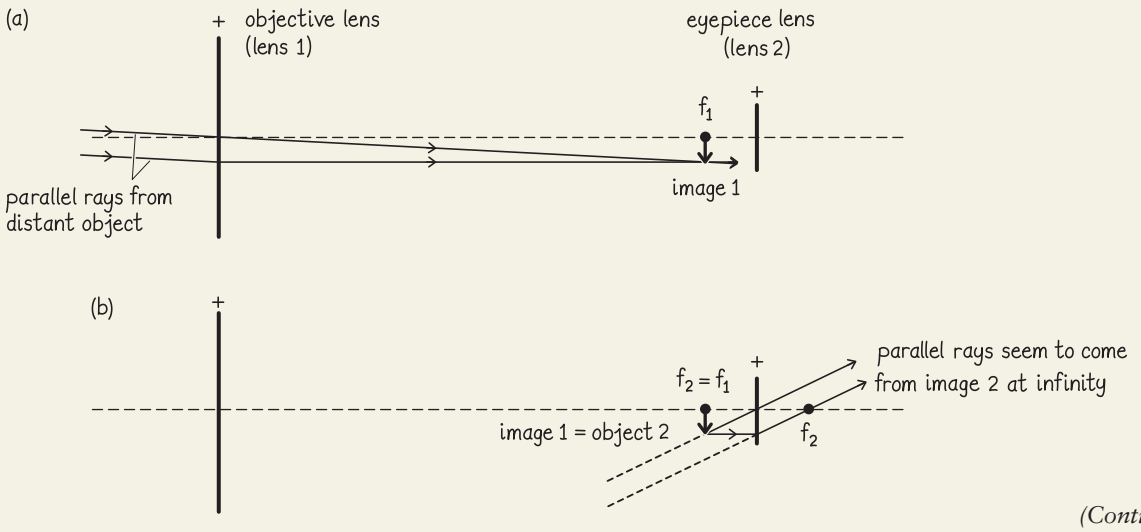


Figure 33.50

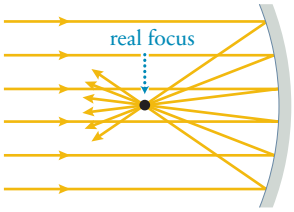
(Continued)

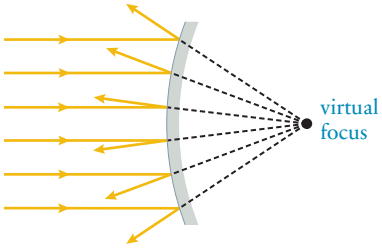
these angles by their tangents; substitute for the tangents of the angles in terms of h_i, f_1, and f_2; and simplify:

$$M_\theta = \left|\frac{\theta_i}{\theta_o}\right| \approx \left|\frac{\tan\theta_i}{\tan\theta_o}\right| = \frac{|h_i/f_2|}{|h_i/f_1|} = \left|\frac{f_1}{f_2}\right|. \checkmark$$



❹ **EVALUATE RESULT** Figure 33.50 indicates that image 1 is inverted and that image 2 is upright relative to image 1, which means that image 2 is inverted relative to the distant object. This makes sense because the incoming ray in Figure 33.51 is angled downward but the outgoing ray is angled upward.

33.18 A telescope with a magnification of 22× has an eyepiece lens for which the focal length f_2 is 40.0 mm. (*a*) What is the focal length f_1 of the objective lens? (*b*) What is the length of the telescope?



33.7 Spherical mirrors

Figure 33.52 Spherical mirrors focus parallel rays just like lenses do.

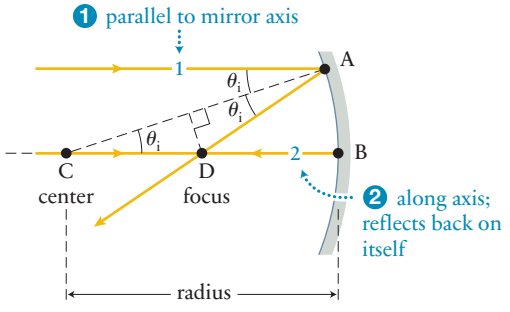
(*a*) Concave spherical mirror

(*b*) Convex spherical mirror

Just like lenses, spherical mirrors focus parallel rays (**Figure 33.52**). A concave mirror focuses rays to a point in front of the mirror, corresponding to a real focus; a diverging mirror makes rays diverge so that they appear to come from a point behind the mirror, corresponding to a virtual focus. Thus, just as with lenses, we can have both converging and diverging spherical mirrors. Unlike lenses, however, spherical mirrors have only a single focus.

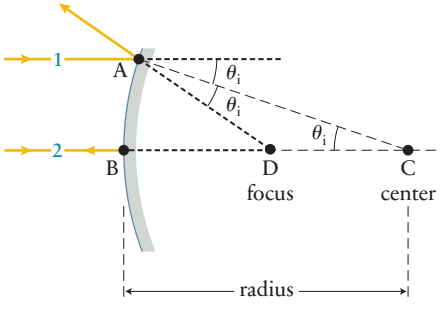
To obtain the location of the focus of a converging mirror, we examine the reflection of the two rays shown in **Figure 33.53*a***. Ray 1 comes in parallel to the axis of the mirror, striking the mirror at A, and ray 2 comes in along the axis of the mirror. The focus of the mirror is at D, where the two reflected rays cross, and the center of the sphere on which the surface of the mirror lies is at C. Line CA is therefore a radius of the sphere and perpendicular to the mirror surface. We denote the length of the radius by R. This distance is called the *radius of curvature*.

Ray 2 strikes the mirror at normal incidence and so is reflected back along the axis. Ray 1 is reflected through the focus at D. Consequently, the distances CD and AD in Figure 33.53*a* are equal. Dividing triangle ACD into two congruent right triangles by drawing a line perpendicular to the base from D, we see that $CD = (R/2)/\cos\theta_i$. For small θ, $\cos\theta \approx 1$, and so $CD = R/2$ and $BD = R - CD = R/2$, independent of θ. Therefore, the focus, which is located at D because that is where the two reflected rays cross, lies halfway between the mirror and the center of the sphere, making the focal length



$$f = \frac{R}{2}. \tag{33.23}$$

As Figure 33.53*b* shows, the geometry and hence the position of the focus are exactly the same for diverging mirrors except that here the focus lies behind the mirror.



To determine the location of images formed by mirrors, we follow the same ray-tracing procedure we used for lenses. The three principal rays

Figure 33.53 The two principal rays used to determine the focus of a spherical mirror.

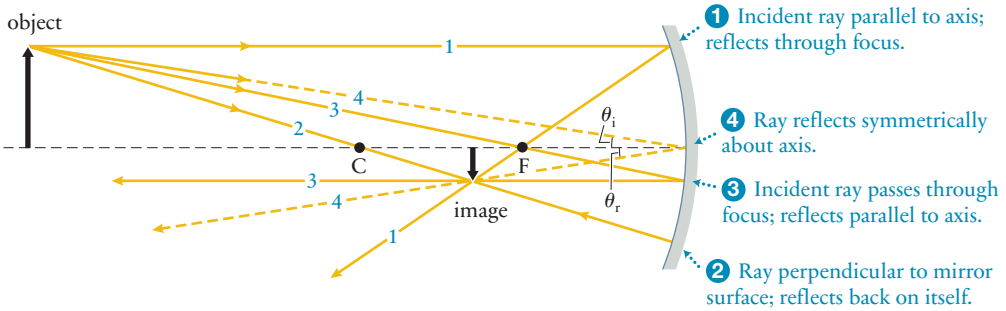
(*a*) Concave spherical mirror

(*b*) Convex spherical mirror

QUANTITATIVE TOOLS

PROCEDURE: Ray diagrams for spherical mirrors

Ray diagrams for spherical mirrors are very similar to those for lenses. This procedure is for rays traveling from the left to the right.



1. Draw a horizontal line representing the mirror axis. In the center of the diagram, draw a circular arc representing the mirror. A converging mirror curves toward the left; a diverging mirror curves toward the right.
2. Put a dot on the axis at the center of the circular arc and label it C. Add another dot on the axis, halfway between C and the mirror. This point is the focus. Label it f.
3. Represent the object by drawing an upward-pointing arrow from the axis at the appropriate relative distance to the left of the mirror. For example, if the distance from the object to a converging mirror is one-third the radius of curvature of the mirror, put the arrow a bit to the right of the focus. The top of the arrow should be at about half the height of the mirror.
4. From the top of the arrow representing the object draw two or three of the following three so-called *principal rays* listed in the Procedure box "Principal rays for spherical mirrors" on the next page.
5. The top of the image is at the point where the rays that are reflected by the mirror intersect. If the intersection is on the left side of the lens, the image is real; if it is on the right side, the image is virtual. Draw an arrow pointing from the axis to the intersection to represent the image (use a dashed arrow for a virtual image).

emanating from a given point on the object are analogous: ray 1 approaching the mirror parallel to the mirror axis, ray 2 passing through the center C of the mirror, and ray 3 passing through the focus on its way to the mirror. Now, however, "center" refers to *the center of the sphere on which the mirror surface lies* rather than the center of the lens. **Figure 33.54** shows a ray diagram for an image formed by a converging mirror. Ray 1 is reflected through the focus, ray 2 strikes the mirror at normal incidence and thus reflects back on itself, and ray 3 is reflected parallel to the mirror axis. As Figure 33.54 shows, there is a fourth ray that can easily be drawn: A ray that hits the mirror on the axis is reflected back symmetrically about the axis. The procedures for drawing ray diagrams and principal rays for spherical mirrors are given in the Procedure boxes on this page and the next.

Object distance, image distance, and focal length are measured from the surface of the mirror, and the relationship among o, i, and f is the same as that for lenses:

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i}. \tag{33.24}$$

Figure 33.54 Principal ray diagram for an object outside the focus of a concave spherical mirror. The image is real, inverted, and smaller than the object.

Just as for lenses, the focal length f for any spherical mirror is positive for a real focus and negative for a virtual focus, and o is positive when the object is in front of the mirror and negative when it is behind the mirror (that can happen only when the object is an image formed by another mirror or a lens). Similarly, i is positive for a real image and negative for a virtual image.

PROCEDURE: Principal rays for spherical mirrors

This description holds for rays that travel from left to right.

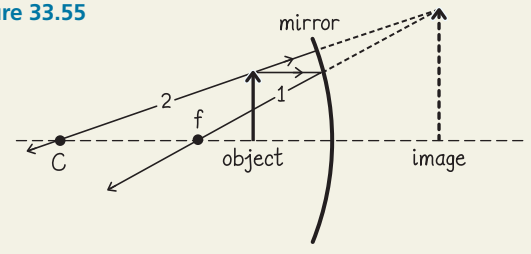
Converging mirror

1. A ray that travels parallel to the mirror axis before reaching the mirror goes through the focus after being reflected.
2. A ray that passes through the center of the sphere on which the mirror surface lies is reflected back onto itself. If the object is between the center and the mirror, this ray doesn't pass through the center but lies on the line from the center to the point at which the ray originates.
3. A ray that passes through the focus is reflected parallel to the axis. If the object is between the focus and the mirror, this ray doesn't pass through the focus but lies on the line from the focus to the point at which the ray originates.

Diverging mirror

1. A ray that travels parallel to the mirror axis before reaching the mirror is reflected along the line that goes through the focus and the point where the ray strikes the surface.
2. A ray that passes through the center of the sphere on which the mirror surface lies is reflected back onto itself.
3. A ray whose extension passes through the focus is reflected parallel to the axis.

For both converging and diverging mirrors, a ray that hits the mirror on the axis is reflected back symmetrically about the axis.



With mirrors, however, a real image is located on the same side of the mirror as the object and a virtual image is located on the opposite side—the opposite of what happens with lenses. These sign conventions are summarized in Table 33.2. Finally, the relationship between object and image distances and heights for lenses (Eq. 33.12) also applies to mirrors, so that equation can be used to determine the size of the images formed by mirrors.

EXAMPLE 33.10 Funny mirror

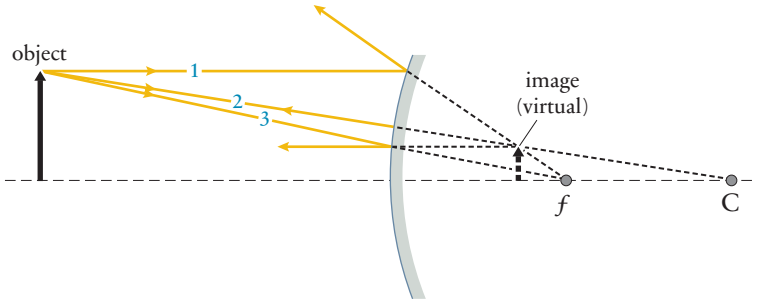
An object is placed 0.30 m in front of a converging mirror for which the radius of curvature is 1.0 m. (*a*) On which side of the mirror is the image? Is the image real or virtual? (*b*) If the object is 50 mm tall, what is the height of the image?

❶ **GETTING STARTED** To visualize the situation, I draw the mirror and its axis, and indicate its center of curvature C and its focal point *f* halfway between the mirror surface and C. I represent the object as a solid arrow (Figure 33.55).

Figure 33.55

❷ **DEVISE PLAN** To locate the image and identify whether it is real or virtual, I can draw the principal rays. I can use Eq. 33.12 to obtain the image height from the object height and the image and object distances. I can determine the image distance from the focal length and the object distance using Eq. 33.24.

❸ **EXECUTE PLAN** (*a*) As Figure 33.55 shows, I need to draw only two principal rays because the intersection of two rays unambiguously determines the position of the image. I draw ray 1 parallel to the mirror axis and reflecting through the focus. Because the object is between the mirror and the center of curvature, I draw ray 2 along the line defined by C and the tip of the object. Ray 2 does not pass through C until after it is reflected from the mirror, however, and I indicate this by adding an arrowhead pointing toward the mirror on the part of the ray to the right of the object and an arrowhead pointing away from the mirror on the part to the left of the object. My diagram shows that the rays do not actually meet but appear to come from a point behind the mirror. Therefore the image is behind the mirror and virtual. ✔



(*b*) I begin by determining the image distance *i*. The focal length of the mirror is half the radius of curvature, $f = 0.50$ m. Substituting this value and $o = 0.30$ m into Eq. 33.24 and solving for *i* give me $i = -0.75$ m. The negative sign indicates that the image is virtual and therefore behind the mirror; this is consistent with my result from part *a*. I then solve Eq. 33.12 for h_i (the signed image height) and substitute the values from this problem:

$$h_i = \frac{-i\,h_o}{o} = \frac{-(-0.75\text{ m})(0.050\text{ m})}{(0.30\text{ m})} = 0.13\text{ m}. \checkmark$$

❹ **EVALUATE RESULT** My ray diagram (Figure 33.55) indicates that the image is enlarged and upright, so h_i should be positive and greater than h_o. This agrees with my result.

QUANTITATIVE TOOLS

Figure 33.56 Ray diagram for an image formed by a convex spherical mirror (object distance greater than focal length). The image is virtual, upright, and smaller than the object.

Example 33.10 shows that placing an object inside the focus of a converging mirror produces an upright, virtual image. Compare this with the situation in Figure 33.54, where a real, inverted image is formed for an object placed outside the mirror's focus. The same occurs with a converging lens: Placing the object inside the focus produces an upright, virtual image (Figure 33.31), while placing the object outside the focus produces a real, inverted image (Figure 33.30).

Diverging mirrors, like diverging lenses, always form virtual images when used alone because the light rays must diverge from the mirror surface. **Figure 33.56** shows a ray diagram for an image formed by a diverging mirror. The image is much smaller than the object, which allows a relatively large scene to be captured on a small mirror surface, and is upright. For these reasons, wide-angle rear-view mirrors on the passenger side of cars and trucks and wide-angle surveillance mirrors are typically convex. (A converging mirror also produces small images of distant objects, but the images are inverted, as Figure 33.54 shows.)

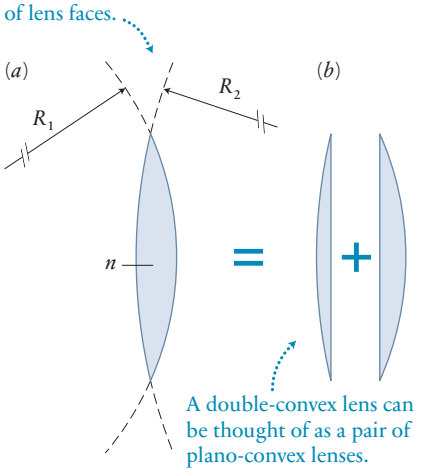
33.19 An object is placed 1.0 m in front of a diverging mirror for which the radius of curvature is 1.0 m. (*a*) Where is the image located relative to the mirror? Is the image real or virtual? (*b*) If the object is 0.30 m tall, what is the height of the image?

33.8 Lensmaker's formula

The focal length of a lens is determined by the refractive index n of the material of which the lens is made and by the radii of curvature R_1 and R_2 of its two surfaces (**Figure 33.57*a***). In this section we work out the relationship among f, R_1, R_2, and n. In this analysis, we can think of a double-convex lens as two plano-convex lenses placed with the two flat surfaces facing each other (Figure 33.57*b*). Remember that both foci of a thin lens are the same distance f from the center of the lens. Because this is true, we can interchange the two surfaces of a thin lens without changing its focal length.

We begin by determining the focal lengths of the two plano-convex lenses in Figure 33.57*b*. **Figure 33.58** on the next page shows a ray diagram for light that passes through the right lens only. To calculate the focal length f_1 of this lens, consider a ray incident from the left that comes in parallel to the axis at a distance h above the axis. Because the ray is normal to the planar surface of the lens, it is not refracted at that surface. After passing through the lens, it strikes the curved surface at an angle θ_i measured from the normal to the curved surface and is refracted as it leaves the lens. The refracted ray emerges at an angle θ_r measured from the normal to the curved surface and crosses the lens axis a distance f_1 from the lens. Therefore the angle that the emerging ray makes with the lens axis is $\theta_r - \theta_i$.

Figure 33.57 Analysis of a double-convex lens.



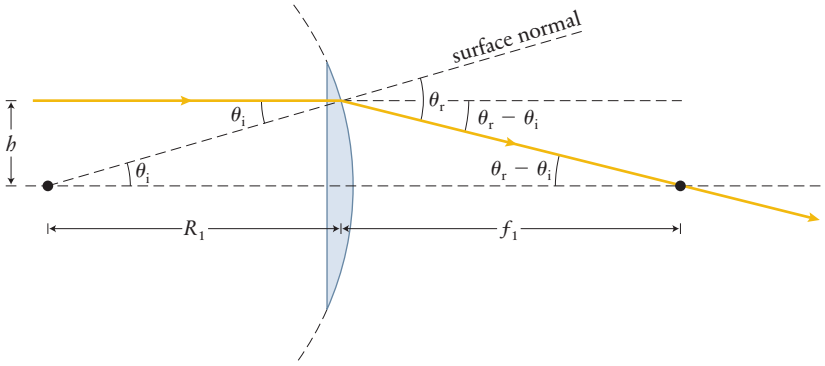


Figure 33.58 Ray diagram for light passing through the right-hand plano-convex lens of Figure 33.57*b*.

Applying Snel's law (Eq. 33.7) to this situation gives

$$n \sin \theta_i = \sin \theta_r. \tag{33.25}$$

(We do not need to show an n on the right because the medium is air and $n_{air} = 1$.) For paraxial rays, we can approximate the sines of the angles in Eq. 33.25 by the angles

$$n\theta_i = \theta_r \quad \text{(small angles)}. \tag{33.26}$$

Using this relationship, we can express the angle between the emerging ray and the lens axis as

$$\theta_r - \theta_i = n\theta_i - \theta_i = (n-1)\theta_i. \tag{33.27}$$

For small angles, the angles are approximately equal to their tangents, which means this relationship can be expressed as

$$\theta_r - \theta_i = (n-1)\theta_i \approx \frac{h}{f_1} \tag{33.28}$$

and

$$\theta_i \approx \frac{h}{R_1}. \tag{33.29}$$

Substituting Eq. 33.29 into Eq. 33.28 and dividing both sides by h, we get

$$\frac{1}{f_1} = \frac{n-1}{R_1}. \tag{33.30}$$

We can follow the same procedure for the left lens in Figure 33.57*b*, using R_2 as our radius of curvature and a ray that originates at the left focus of that lens. The result analogous to Eq. 33.30 is

$$\frac{1}{f_2} = \frac{n-1}{R_2}. \tag{33.31}$$

Now let us determine the focal length of the lens combination by working out the lens equation (Eq. 33.16) for the combination, just as we did for the microscope and telescope in Section 33.6. Consider both the object and light source to be on the left side of the lens combination in Figure 33.57. First, the light from the object strikes the left lens from the left and forms an

image someplace to the right of the right lens. The lens equation that relates the location of this object and image, in terms of the focal length f_2 calculated in Eq. 33.31, is

$$\frac{1}{o_2}+\frac{1}{i_2}=\frac{1}{f_2}=\frac{n-1}{R_2}. \tag{33.32}$$

The image formed by the left lens now serves as the (virtual) object for the right lens. Consequently, $o_1 = -i_2$. (The object for the right lens is virtual, and therefore the object distance o_1 is negative because the object is located on the right side of the lens and the illumination comes from the left side of the lens.) The lens equation for the right lens is thus

$$-\frac{1}{i_2}+\frac{1}{i_1}=\frac{1}{f_1}=\frac{n-1}{R_1}, \tag{33.33}$$

where the rightmost equality comes from Eq. 33.30.

Adding Eqs. 33.32 and 33.33 yields

$$\frac{1}{o_2}+\frac{1}{i_1}=(n-1)\left(\frac{1}{R_1}+\frac{1}{R_2}\right). \tag{33.34}$$

The lens equation for the lens as a whole is simply

$$\frac{1}{o}+\frac{1}{i}=\frac{1}{f}, \tag{33.35}$$

where f, o, and i are the focal length, object distance, and image distance of the lens combination, respectively. The object of the left lens is the actual object, and the image formed by the right lens is the final image, which means that in Eq. 33.35 $o = o_2$ and $i = i_1$. Comparing Eqs. 33.34 and 33.35 gives us the **lensmaker's formula** for the focal length of our lens combination:

$$\frac{1}{f}=(n-1)\left(\frac{1}{R_1}+\frac{1}{R_2}\right). \tag{33.36}$$

Our derivation was for a double-convex lens, but it can be shown that the lensmaker's formula applies to any thin lens, not just a double-convex lens. The radii of curvature are positive for convex surfaces, negative for concave surfaces, and infinity for planar surfaces. For a double-convex lens, f is positive. For a double-concave lens, f is negative (because $n > 1$ for any material used for lenses).

33.20 How should the lensmaker's formula be modified if a lens for which the index of refraction is n_1 is submerged in a medium for which the index of refraction is n_2?

Chapter Summary

Rays (Sections 33.1, 33.2, 33.3, 33.5)

Concepts A **ray** is a line that represents the direction in which light travels.

For **reflected light,** the **angle of incidence** θ_i is the angle between the incident ray and the normal to the reflecting surface, and the **angle of reflection** θ_r is the angle between the reflected ray and the normal to the surface. The **law of reflection** says that when a ray strikes a smooth surface, $\theta_r = \theta_i$ and the two angles are in the same plane.

Refraction is the bending of light when it travels from one medium to another. The **angle of refraction** is the angle between the refracted ray and the normal to the surface at the interface between the materials.

Light passing from a high-density medium into a lower-density medium is bent away from the normal to the surface at the interface between the media. The **critical angle** θ_c is the angle of incidence for which the angle of refraction is 90°, which means the refracted rays emerge along the interface. If the angle of incidence is greater than θ_c, the light is all reflected back into the denser medium (**total internal reflection**).

An **image** is formed when light rays emanating from an object either intersect or appear to intersect at some location in space. The image is *real* when the rays actually do intersect at the location of the image and *virtual* when the rays do not pass through the location of the image.

Dispersion is the spatial separation of waves of different wavelengths in a light ray. When caused by refraction, the separation occurs because the speed at which each wave in the ray moves through a medium depends on the frequency of the wave.

Fermat's principle states that the path taken by a light ray between any two locations is the path for which the time interval needed for the ray to travel between those locations is a minimum.

Quantitative Tools The **index of refraction** n of a medium is

$$n \equiv \frac{c_0}{c}, \tag{33.1}$$

where c_0 is the speed of light in vacuum and c is the speed of light in the medium.

If light has wavelength λ in vacuum, its wavelength λ_1 in a medium having index of refraction n_1 is

$$\lambda_1 = \frac{\lambda}{n_1}. \tag{33.3}$$

Snel's law: When light passes from a medium having index of refraction n_1 into a medium having index of refraction n_2, the angles and indices satisfy the relationship

$$n_1 \sin\theta_1 = n_2 \sin\theta_2, \tag{33.7}$$

where θ_1 is the angle of incidence and θ_2 is the angle of refraction.

For light traveling from a high-density medium having index of refraction n_2 to a lower-density medium having index of refraction $n_1 < n_2$, the **critical angle** is

$$\theta_c = \sin^{-1}\left(\frac{n_1}{n_2}\right). \tag{33.9}$$

Forming images using thin lenses (Sections 33.4, 33.5, 33.6, 33.8)

Concepts A **lens** is an optical element that redirects light rays by refraction such that they form images. The *axis* of a lens is a line that passes through the lens center and is perpendicular to the lens surface. Rays that run close to the lens axis are called *paraxial* rays. They can be either parallel to the lens axis or at a small angle to it.

Quantitative Tools The **lens equation** is

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i}, \tag{33.16}$$

where f is the **focal length** of the thin lens, o is the *object distance*, and i is the *image distance*. The sign possibilities for f, o, and i are given in Table 33.2.

Rays that are parallel to and close to the axis of a thin *converging* (*convex*) lens converge to a point called the **focal point** (or **focus**) of the lens. For a thin *diverging* (*concave*) lens, rays entering the lens from the left parallel to and close to the axis diverge as though they came from a single point to the left of the lens, called the **focal point.**

The **focal length** of a lens is the distance from the focal point to the center of the lens.

To determine the location and orientation of an image formed by a lens, make a ray diagram using the **principal rays.** See the accompanying Procedure boxes.

The **magnification** of a lens is

$$M \equiv \frac{h'}{h} = -\frac{i}{o}, \tag{33.17}$$

where h' is the image height and h is the object height. The image is upright if M is positive and inverted if M is negative.

Lensmaker's formula: The focal length of a lens made of material of index of refraction n, having radii of curvature R_1 and R_2, and surrounded by air is given by

$$\frac{1}{f} = (n-1)\left(\frac{1}{R_1} + \frac{1}{R_2}\right). \tag{33.36}$$

The radii are positive for convex surfaces, negative for concave surfaces, and infinity for planar surfaces.

Table 33.2 Sign conventions for f, i, and o (positive = real; negative = virtual)

Sign	Lens	Mirror
$f > 0$	converging lens	converging mirror
$f < 0$	diverging lens	diverging mirror
$o > 0$	object in front[b] of lens	object in front of mirror
$o < 0$[a]	object behind lens	object behind mirror
$i > 0$	image behind lens	image in front of mirror
$i < 0$	image in front of lens	image behind mirror
$h_i > 0$	image upright	image upright
$h_i < 0$	image inverted	image inverted
$\|M\| > 1$	image larger than object	image larger than object
$\|M\| < 1$	image smaller than object	image smaller than object

[a]Encountered only with lens or mirror combinations.
[b]For both lenses and mirrors, *in front* means *on the side where the rays originate; behind* refers to the opposite side.

Optical instruments (Section 33.6)

Concepts The lens of the eye forms an image on the retina. The *near point* is the closest object distance at which the eye can focus comfortably, about 0.25 m from the eye for an adult.

A compound microscope uses two converging lenses to form its image. The image formed by the first lens (the *objective* lens) serves as the object for the second lens (the *eyepiece* lens).

A refracting telescope uses two converging lenses to form its image. They are positioned so that the objective lens forms a real image of a distant object and the eyepiece lens forms, at infinity, a virtual image of this real image.

Quantitative Tools The **angular magnification** M_θ of a lens is

$$M_\theta = \left|\frac{\theta_i}{\theta_o}\right|, \tag{33.18}$$

where θ_i is the angle subtended by the image and θ_o is the angle subtended by the object.

For small angles, the angular magnification of a converging lens placed between an object and the eye is

$$M_\theta \approx \frac{0.25\ \text{m}}{f}. \tag{33.21}$$

The *strength* d of a lens measured in diopters is

$$d \equiv \frac{1\ \text{m}}{f}. \tag{33.22}$$

The magnification M of a compound microscope is

$$M = M_1 M_{\theta 2} = \frac{-0.25\ \text{m}}{f_2\left(\frac{o_1}{f_1} - 1\right)},$$

where M_1 is the magnification of the objective lens, $M_{\theta 2}$ is the angular magnification of the eyepiece lens, o_1 is the distance from the object to the objective lens, f_1 is the focal length of the objective lens, and f_2 is the focal length of the eyepiece lens.

The angular magnification M_θ of a refracting telescope is

$$M_\theta = \left|\frac{\theta_i}{\theta_o}\right| \approx \left|\frac{f_1}{f_2}\right|,$$

where f_1 is the focal length of the objective lens and f_2 is the focal length of the eyepiece lens.

Mirrors (Sections 33.2, 33.7)

Concepts A flat mirror forms a virtual image of an object. The image is just as far behind the mirror as the object is in front of the mirror.

A *concave* spherical mirror focuses incident rays that are parallel to and close to the axis of the mirror to a point in front of the mirror (the **focal point**), corresponding to a real focus. A *convex* spherical mirror disperses the parallel incident rays such that they appear to come from a point behind the mirror (the **focal point**), corresponding to a virtual focus.

To determine the location and orientation of an image formed by a mirror, make a ray diagram showing the three **principal rays.** See the accompanying Procedure boxes.

Quantitative Tools The focal length of a spherical mirror is one-half its *radius of curvature*:

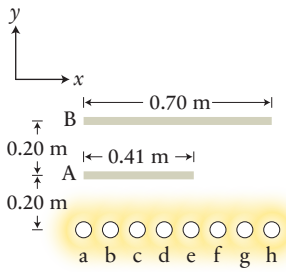
$$f = \frac{R}{2}. \tag{33.23}$$

For a spherical mirror, the relationship of focal length f, object distance o, and image distance i is given by the lens equation:

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i}. \tag{33.24}$$

The sign possibilities for f, o, and i are given in Table 33.2.

Questions and Problems



For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy,* •• = *intermediate,* ••• = *hard;* CR = *context-rich problem.*

33.1 Rays

1. Figure P33.1 shows eight point sources of light, a–h, and two detectors, A and B. The point sources are evenly spaced, with 0.10 m between adjacent sources, and detector A shields part of detector B from the point sources. If no light is reflected from any nearby objects, how many of the point sources illuminate any part of (*a*) detector A and (*b*) detector B? •

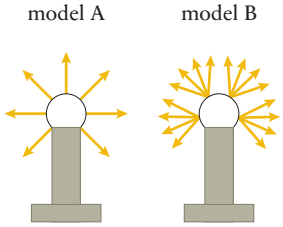


Figure P33.1

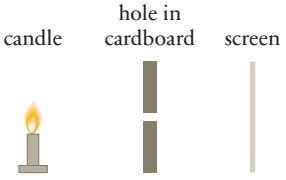
2. A point source is fixed 1.0 m away from a large screen. Call the line normal to the screen surface and passing through the center of the point source the z axis. When a sheet of cardboard in which a square hole 0.040 m on a side has been cut is placed between the point source and the screen, 0.50 m from the point source with the hole centered on the z axis, a bright square shows up on the screen. If, instead, a second sheet of cardboard with a similar square hole is placed between the point source and screen, 0.25 m from the point source with the hole centered on the z axis, the bright square it casts on the screen is identical to the bright square from the first sheet. What are the dimensions of the hole in this sheet? •



3. A thin, flat object in which a square hole 30.0 mm on a side has been cut is illuminated with a point source. Light that passes through the hole strikes a screen 300 mm behind the object. Call the direction normal to the screen the z direction. The point source is shifted away from the center of the hole by 150 mm in the positive x direction. The point source is centered on the hole in the y direction and is 300 mm in front of the object in the z direction. What are (*a*) the dimensions of the bright region on the screen and (*b*) the x and y coordinates of the perimeter of the bright region? ●●
4. Sunlight that reaches Earth is blocked by Earth from traveling any farther, so that the region on the side of Earth facing away from the Sun is in shadow. The portion of this region in complete shadow is the *umbra*, and the portion in partial shadow is the *penumbra*. The Sun's radius is 7.0×10^5 km, Earth's radius is 6.4×10^3 km, and the Sun–Earth distance is 1.5×10^8 km. (*a*) What is the shape of the umbra? Of the penumbra? (*b*) Consider an observer in space on the side of Earth facing away from the Sun—that is, in the shadow region. Does this observer see the Sun when he is in the umbra? When he is in the penumbra? ●●
5. Two models of light emitted from a light bulb are illustrated in Figure P33.5. (*a*) Describe the difference in the behavior of light in each model. (*b*) Describe an experiment that can determine which model of light is more accurate. ●●

Figure P33.5

6. An aquarium light bulb has a long, straight glowing filament surrounded by a tubular, clear glass bulb. This lighted bulb, with its filament oriented vertically, is placed 1.0 m from a screen in an otherwise dark room. A thin sheet of cardboard is placed halfway between the filament and the screen so that no light can reach the screen. If a small hole, shaped like an equilateral triangle, is cut through the center of the cardboard sheet, describe the pattern of light that appears on the screen. ●●●
7. A burning candle is placed in front of a screen, and a sheet of cardboard with a small round hole in it is inserted between the candle and the screen as shown in Figure P33.7. Describe the pattern of light that appears on the screen. ●●●

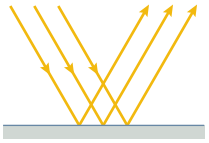


Figure P33.7

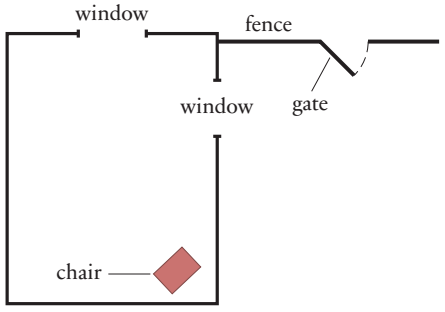
33.2 Absorption, transmission, and reflection



8. Figure P33.8 shows light rays reflected from a smooth surface. Draw three wavefronts along the rays that have not yet struck the surface and three wavefronts along the reflected rays. ●

Figure P33.8

9. For the room shown in Figure P33.9, draw a diagram that shows where a mirror should be mounted so that a person sitting in the chair has a full view of the gate in the fence outside. ●

Figure P33.9

10. A classmate exclaims about the professor's bright blue shirt, "Wow, that shirt has a lot of blue in it!" Evaluate your classmate's statement. ●
11. A flat mirror oriented perpendicular to the y axis of a Cartesian coordinate system extends along the x axis from $x = 0$ to $x = 4.0$ m. An object is located in the xy plane at the point (1.0 m, 2.0 m). With your eye in the xy plane in the range $y < 0$ and x equal to any value, you cannot see the image of this object in the mirror. For what range of x and y in the xy plane can you see the image in the mirror? ●●
12. The bottom edge of a wall-mounted mirror aligns with your waist, and the top edge aligns with a point somewhere above your head. Draw a diagram that illustrates, when you stand in front of this mirror, the portion of your whole body that you can see in the image. ●●
13. The minimum height of a wall mirror in which you can view your entire body is half your height, with the distance from the floor to the bottom of the mirror equal to half the distance between your eyes and feet. This relationship between mirror height/position and object height does not hold for objects that are far behind you, however. How large (height, width, or both) a reflecting surface is needed in order for you to see the

entire image of a large distant object—a tree, say? (Hint: What quantity is different when you view your own image as opposed to when you view the image of a distant object?) ●●

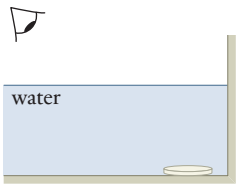
14. Standing 1.0 m away from a large mirror, you see an image of a flashlight in the mirror. If the image appears to be 2.0 m behind the mirror, 1.0 m vertically above your eyes, and 3.0 m to your right (your actual right, not your reflection's right), what is the flashlight's location relative to you? ●●

15. A classmate believes that the image you see in a mirror is on the mirror surface rather than behind the mirror. What is something you can do to convince your classmate he is incorrect? ●●

16. A woman holds a mirror stationary and perfectly vertical as a boy runs toward it at a speed of 1.0 m/s. (*a*) In her reference frame, what does the woman observe for the speed at which the boy and his reflection move toward the mirror? (*b*) In the reference frame of the boy, what does he observe for the speed at which the woman and his reflection move toward him? ●●

17. Consider this statement: Think of the reflection of the Moon on a cloudless night: Look in the ocean, you see a large moon. Look in a pond; the same moon is there. In a puddle, in a teacup—everywhere, diminished somewhat in size, but all the features are there. (*a*) What physical attribute (referred to only indirectly in the statement) is it that differs in size for the ocean, pond, puddle, and cup? (*b*) What other quantity or quantities determine this attribute? Draw a diagram showing how the image of the Moon forms and relating all the quantities you've identified to one another. ●●●

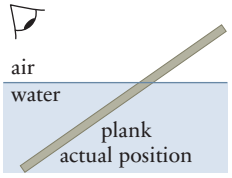
18. You want to see how your new belt buckle matches your new hat. Your eyes are 110 mm below the top of the hat and 800 mm above the buckle. You walk up to your mirror and notice that the mirror is exactly large enough and exactly in the right position for you to see both the top of the hat and the buckle. (*a*) What is the position of the top edge of the mirror relative to your eyes? (*b*) How tall is the mirror? ●●●



33.3 Refraction and dispersion

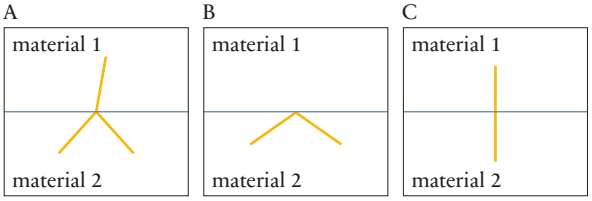
19. The light bulb in a bathroom ceiling is directly over a toy boat floating in a bathtub filled with water to a depth x. How does the shadow the boat casts on the bottom of the tub compare with the shadow it casts when the water is drained out and the boat is held the same distance x above the tub bottom? Treat the bulb as a point source. ●

20. While scuba diving, you have injured yourself and must signal the boat on the surface for help. You have five laser pointers, each emitting light of a different color: red, orange, yellow, green, and blue. When you shine the yellow light up toward the boat, the beam makes such a small angle with the surface that all the light is reflected back into the water. (*a*) If you are not able to move closer to the boat, which color or colors of light might you try? (*b*) Are these other lights likely to be successful in penetrating the surface at that point? ●



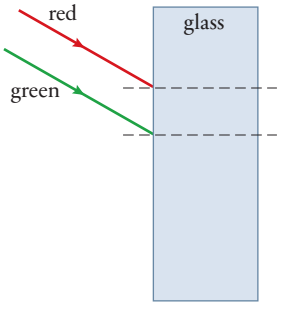
21. The observer in Figure P33.21 is looking at a coin near the edge of a pool filled with water. To this observer, does the water appear to be shallower or deeper than it really is? ●

Figure P33.21



22. In Figure P33.22, a straight plank of lumber enters a pool of water at an angle. What does the plank look like to the observer? ●●

Figure P33.22

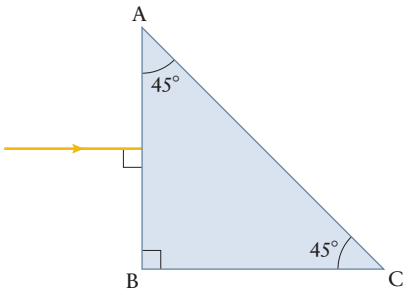


23. Figure P33.23 depicts incident and all reflected or refracted light rays in three cases, A, B, and C. For each case, state (*a*) in which material, 1 or 2, the light travels faster and (*b*) in which material, 1 or 2, the ray originates. ●●

Figure P33.23

24. Parallel red and green laser rays are incident on a glass slab as shown in Figure P33.24. Sketch the rays as they pass through the slab and after they have entered the air to the right of the slab. Are the rays parallel after they exit the slab? Is the distance between the rays after they exit the slab equal to the distance between them before they entered? ●●

Figure P33.24



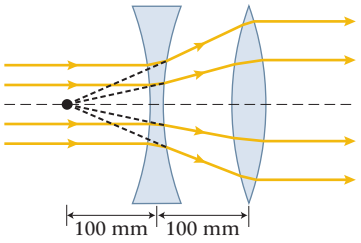
25. A thick layer of transparent oil floats on top of water. Sketch what happens to a ray of light coming in at a 30° angle away from the normal to the surface. ●●

26. Suppose a small flashlight bulb is on the bottom of the bathtub of Problem 19, directly under the toy boat. When this bulb is lit and the ceiling light is turned off, how does the size of the shadow cast by the boat on the ceiling change when the water in the tub is replaced by a liquid in which the speed of light is (*a*) faster than the speed of light in water and (*b*) slower than the speed of light in water? ●●

27. Suppose the prism in Figure P33.27 is immersed in a liquid in which the speed of light is lower than the speed of light in glass. Describe what happens to the light shown entering at normal incidence. ••

Figure P33.27

28. Driving down a long straight highway, you see a reflection of the sky in the road ahead. It disappears before you get to it but reappears down the road continually. Because there is nothing different about the road from one location to another, explain what is happening in terms of refraction. ••
29. White light passing through a prism is dispersed into its constituent colors. Describe how this rainbow of colors can be changed back to white light. •••
30. A glass cylinder is placed inside a large beaker, and corn oil is poured into the combination until the beaker is full. If the glass cylinder is now invisible inside the oil, what must you conclude about how light interacts with the oil and the glass? •••



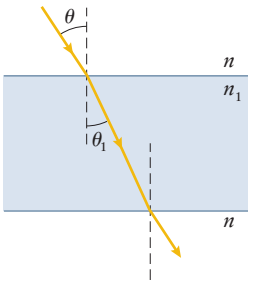
33.4 Forming images

31. (*a*) Draw a simplified ray diagram showing the three principal rays for an object located outside the focal length of a converging lens. (*b*) Is the image real or virtual? (*c*) Is it upright or inverted? (*d*) What happens to the image as the object is moved farther from the lens? •
32. (*a*) Draw a simplified ray diagram showing the three principal rays for an object located outside the focal length of a diverging lens. (*b*) Is the image real or virtual? (*c*) Is it upright or inverted? (*d*) What happens to the image as the object is moved farther from the lens? •
33. The lens in a magnifying glass is a converging lens, but parallel light rays that pass through a converging lens must converge to a point. This being true, how can a magnifying glass form an image that is larger than the object? Why isn't the image reduced to a point? •
34. A lens has a radius of curvature of magnitude R on its left surface and a radius of curvature of magnitude $2R$ on its right surface. Parallel rays entering the lens from the left are focused to a point 100 mm to the right of the right surface. At what distance from the lens is the point at which parallel rays entering from the right are focused? •
35. Looking at an object through a thin lens, you see a virtual image. Which side of the lens is the image on, or does it appear to be inside the lens? What property of this image tells you whether the lens is converging or diverging? ••
36. (*a*) Draw a simplified ray diagram showing the three principal rays for an object located inside the focal length of a diverging lens. (*b*) Is the image real or virtual? (*c*) Is it upright or inverted? (*d*) What happens to the image as the object is moved toward the focal point? ••
37. (*a*) Draw a simplified ray diagram showing the three principal rays for an object located inside the focal length of a converging lens, closer to the lens than to the focal point. (*b*) Is the image real or virtual? (*c*) Is it upright or inverted? (*d*) What happens to the image as the object is moved closer to the focal point? ••
38. An object 20 mm tall is placed 70 mm to the left of a converging lens that has a focal length of 100 mm. (*a*) Draw a scale diagram showing the three principal rays, and use them to locate the image. Is the image (*b*) real or virtual, (*c*) inverted or upright, (*d*) larger or smaller than the object? ••
39. An object is placed 80 mm to the left of a diverging lens for which the focus is 100 mm from the lens. (*a*) Draw a scale diagram showing the three principal rays, and use them to locate the image. Is the image (*b*) real or virtual, (*c*) inverted or upright, (*d*) larger or smaller than the object? ••
40. Complete the table below for a converging lens. ••

		Image		
Object Location	**Image Location**	**Real or virtual?**	**Upright or inverted?**	**Larger or smaller than the object?**
Between lens and focus	Between positive infinity and lens (same side)	Virtual	Upright	Larger
At focus				
Between focus and twice the focal length				
At twice the focal length				
Beyond twice the focal length				
At infinity				

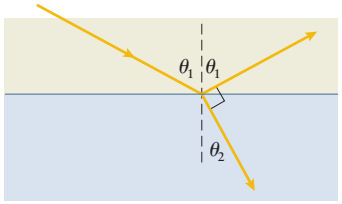
41. Figure P33.41 shows light passing first through a diverging lens and then through a converging lens placed 100 mm to the right of the diverging lens. The rays emerge from the converging lens parallel to one another. Calculate the distance from each lens to its focus. ••

Figure P33.41



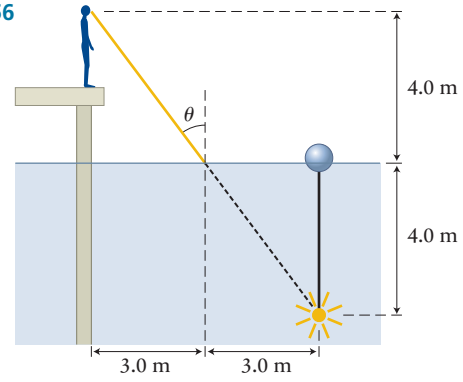
42. Two identical converging lenses of focal length 100 mm are placed 400 mm apart, and an object 40 mm tall is placed 230 mm to the left of the left lens. (*a*) Draw a scale diagram showing the three principal rays for the left lens, and use them to locate the image formed by this lens. (*b*) Draw the principal rays for the right lens, and use them to locate the image formed by this lens. Is the image formed by the right lens (*c*) real or virtual, (*d*) inverted or upright, (*e*) larger or smaller than the object? •••

33.5 Snel's law



43. Light is traveling at a speed of 1.82×10^8 m/s through a certain material. Determine what material it is likely traveling through. •
44. What is the index of refraction of a material in which the speed of light is 20% less than the speed of light in vacuum? •
45. A red laser light has a wavelength of 700 nm in air. What are the frequency and wavelength of this light in flint glass (index of refraction $n = 1.65$)? •
46. A light ray traveling through medium 1 with index of refraction $n_1 = 1.70$ reaches the interface between medium 1 and medium 2 with index of refraction $n_2 = 1.50$. (*a*) At what minimum angle with respect to the normal must the ray be incident on the interface in order to be totally internally reflected? (*b*) How would the situation change if the ray were traveling in medium 2 when it reached the interface? •
47. A light ray travels up from the bottom of a tank containing oil (index of refraction $n = 1.48$). If the oil surface is smooth, at what minimum angle from the normal to that surface would the light ray have to strike the surface in order to reflect back into the tank and not escape? •
48. You shine a laser pointer at an angle of 30° from the normal onto the surface of a thick block of glass for which the index of refraction is $n = 1.5$. (*a*) What is the angle of refraction of the laser beam? (*b*) Draw a diagram showing the normal, the surface of the block, and the incident and refracted wavefronts and rays. (*c*) How would the angles in parts *a* and *b* change if the incident angle were 45°? ••
49. In vacuum, the wavelength of the red light in your laser pointer is 680 nm. Standing at the shore of a calm pond, you shine the laser beam onto the water surface at an angle of 45° from the normal to the surface. If the index of refraction for the water is $n = 1.333$, how do each of the following properties of the light change as the light enters the water: (*a*) wavelength, (*b*) frequency, (*c*) speed, and (*d*) direction of propagation? (*e*) If you shine the beam onto the surface along the normal, do any of your answers change and, if so, how? ••
50. A light ray is incident on a layer of oil floating on water. The index of refraction of oil is greater than that of water, which is greater than that of air. Call the angle of incidence in air θ_a, the angle of refraction in oil θ_o, and the angle of refraction in water θ_w. (*a*) Draw a diagram showing all three layers and all angles. (*b*) Show that $n_a \sin\theta_a = n_w \sin\theta_w$. (*c*) The result in part *b* implies that in calculating the final direction (θ_w) of a light ray passing from medium 1 into medium 2 and then into medium 3, all having different n values, we can ignore the presence of medium 2. Can you also ignore medium 2 if what you are calculating is the *location* where the ray strikes the bottom of the container of water? ••
51. The index of refraction in flint glass is 1.66 for blue light and 1.61 for red light, with the values for other colors between these limits. A ray of white light traveling from left to right through a slab of flint glass undergoes dispersion as it exits the slab and enters the air. If the exiting ray strikes the right surface of the slab at an angle of 30.0° from the normal to the surface, what is the angle of refraction (*a*) for the blue light and (*b*) for the red light? (*c*) A flat opaque screen is placed in the path of the refracted rays such that the red ray strikes perpendicular to the screen. If the distance along the refracted red ray from slab to screen is 0.50 m, what is the distance between the point of red light and the point of blue light in the rainbow produced on the screen? (Use the small-angle approximation.) ••
52. What is the critical angle for total internal reflection for an optical fiber cable surrounded by air if the index of refraction is (*a*) 1.4 and (*b*) 1.8? (*c*) Which fiber could have a sharper bend (smaller radius of curvature) and still be capable of total internal reflection? ••
53. Show that the ray exiting the block in Figure P33.53 is parallel to the ray entering the block. ••

Figure P33.53



54. Green laser light for which the wavelength in air is 550 nm strikes a flint glass ($n_{glass} = 1.65$) at an angle of 50.0° from the normal to the air-flint glass interface. Calculate (*a*) the wavelength and frequency of the light inside the flit glass and (*b*) the angle of refraction. ••
55. A light ray travels through medium 1, index of refraction $n_1 = 1.5$, into medium 2, index of refraction $n_2 = 2.4$ (Figure P33.55). At what angle with respect to the normal to the interface between the media does the light need to strike the interface so that the reflected and the refracted rays are at right angles to each other? ••

Figure P33.55

56. A researcher stands at the end of a lakeside pier, 4.0 m above the water surface and 6.0 m away from a buoy floating on the lake (Figure P33.56). A rope hangs from the bottom of the buoy down into the water, with a light attached to its end. When the researcher looks at the light from a position at which his line of sight intersects the water surface exactly halfway between the pier and the buoy, the light appears to be 4.0 m below the water surface. How far under the surface is the light? ●●

Figure P33.56

57. Figure P33.57 depicts a light ray entering an optical fiber from air and being transmitted through the fiber by total internal reflection. (*a*) If the index of refraction of the fiber is n, what is the maximum value of θ, the angle the entering ray makes with the normal to the flat end of the fiber, for which total internal reflection occurs? (*b*) When n is greater than a certain value n_0, the light ray can enter the fiber at any angle θ between 0 and 90° and total internal reflection still occurs inside the fiber. What is n_0? ●●●

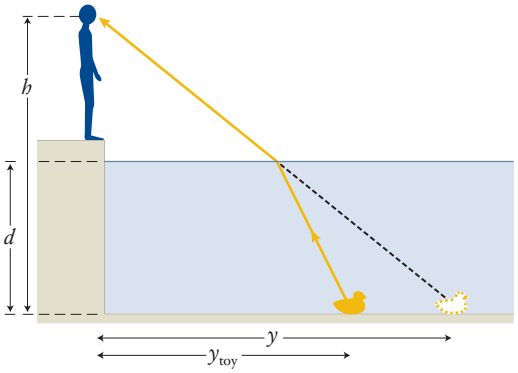


Figure P33.57

58. A ray traveling through a large vat filled with medium 1, index of refraction $n_1 = 1.3$, is incident on a flat layer (thickness $d = 20$ mm) of medium 2, index of refraction $n_2 = 2.4$. If the light enters medium 2 at an angle $\theta_1 = 30°$ with respect to the normal to the interface between the media, how far is it shifted from its original path once it exits medium 2? ●●●

59. A child's toy sits on the bottom of a swimming pool in which the water ($n = 1.33$) depth is $d = 2.0$ m (Figure P33.59). To a child standing at the pool edge and a distance $h = 3.6$ m above the pool bottom, the toy appears to be a horizontal distance $y = 4.8$ m away from the sidewall. At what horizontal distance from the sidewall is the toy located? ●●●

Figure P33.59

60. What is the lens strength of a diverging lens that has a focal length of magnitude 200 mm? ●

61. Mathematically, why can't a single diverging lens produce a real image? ●

62. What is the focal length of eyeglasses that have a lens strength of +2.5 diopters? ●

63. Using a converging lens that has focal length $f = 200$ mm, how far behind the lens do you expect to see a sharp image of an object located 1.00 m in front of the lens? ●

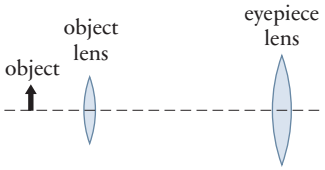
64. A cheap cell phone camera uses a single lens to form an image on a sensor that is 10 mm high and 5.8 mm behind the lens. How far do you need to be away from the Eiffel Tower (height 324 m) to get its whole length in a photograph? Ignore the tilting that occurs as you take the photo from the ground. ●

65. The objective lens in a telescope that produces a 50-fold angular magnification has a focal length of 3.0 m. What is the focal length of the eyepiece lens? ●

66. An object is placed 800 mm away from a thin converging lens that has a focal length of 500 mm. What are (*a*) the image distance and (*b*) the magnification? (*c*) Draw a simplified ray diagram for this case. ●●

67. An object is placed 150 mm away from a converging thin lens that has a focal length of 400 mm. What are (*a*) the image distance and (*b*) the magnification? (*c*) Draw a simplified ray diagram for this case. ●●

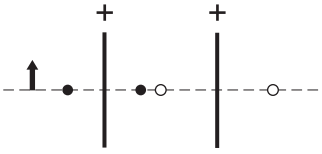
68. An object is placed 500 mm away from a diverging thin lens for which the focal length is −200 mm. What are (*a*) the image distance and (*b*) the magnification of the image? ●●



69. An object is placed 200 mm from a diverging thin lens that has a focal length of −500 mm. What are (*a*) the image distance and (*b*) the magnification? (*c*) Draw a simplified ray diagram for this case. ●●

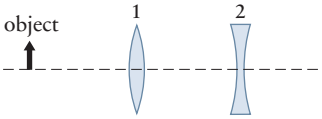
70. A bug is 30 mm away from a lens. As you look through the lens, the bug appears to be just at your near point (0.250 m in front of your eyes). If the actual distance between your eyes and the bug is 130 mm, what is the lens focal length? ●●

71. A woman is not able to focus on objects that are closer to her eyes than 400 mm unless she wears eyeglasses. Her glasses enable her to clearly see objects at the near point of an average human (and no closer). What is the strength of the lenses in her glasses? ●●



72. Two converging lenses are placed facing each other and 600 mm apart, with lens 1 to the left of lens 2. An object is placed 400 mm to the left of lens 1, which has a focal length of 150 mm. (*a*) If the focal length of lens 2 is 200 mm, where is the image located? (*b*) What is the overall magnification of the image? (*c*) Is the image upright or inverted? ••
73. An astronomical telescope of angular magnification M_θ consists of an objective lens and an eyepiece lens separated by a distance d, such that the focal points of the lenses coincide inside the telescope. In terms of M_θ and d, what are (*a*) the focal length of the objective lens and (*b*) the focal length of the eyepiece lens? ••
74. A schematic diagram of a refractive microscope is shown in Figure P33.74. The focal length of the objective lens is 25 mm, that of the eyepiece lens is 63 mm, and the two lenses are 200 mm apart. If the object is 30 mm away from the objective lens, what are (*a*) the distance between the eyepiece lens and the image produced by that lens and (*b*) the overall magnification of this image? ••

Figure P33.74



75. Two converging lenses, 1 and 2, are positioned facing each other, with lens 1 on the left. The focal length of lens 1 is 100 mm, that of lens 2 is 180 mm, and the two lenses are 150 mm apart. If an object is 50 mm to the left of lens 1, (*a*) at what distance from lens 2 should a screen be placed if the object's image is to be focused on the screen? (*b*) What is the overall magnification of the image? (*c*) Is the image upright or inverted? ••
76. Two lenses with focal lengths $f_1 = 200$ mm and $f_2 = 300$ mm are placed facing each other a distance $d = 1.5$ m apart, with lens 1 to the left of lens 2. What is the location of the image formed of an object placed 250 mm to the left of lens 1? ••
77. The focal points of the two converging lenses shown in Figure P33.77 are denoted by solid dots for the left lens and open dots for the right lens. Describe the final image. ••

Figure P33.77

78. In Figure P33.78, a converging lens 1, of focal length 100 mm, and a diverging lens 2, of focal length –80.0 mm, are 160 mm apart. If the object is 180 mm away from lens 1, what are (*a*) the distance between lens 2 and the image produced by that lens and (*b*) the overall magnification of this image? •••

Figure P33.78

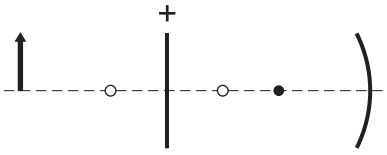
79. Problem 42 describes a setup of two identical converging lenses spaced 400 mm apart. Each lens has a focal length of 100 mm, and a 40-mm-tall object stands 230 mm to the left of the left lens. (*a*) Use an analytical approach to determine the position of the final image. Based on your calculation, is the final image (*b*) inverted or upright and (*c*) real or virtual? (*d*) Calculate the overall magnification. •••
80. You need to design a magnification system that provides a magnification of 3.00 and creates a real, upright image located 300 mm from the surface of the final lens in the system. The only lenses you have to work with are two converging lenses, each having a focal length of 100 mm. How should you place them with respect to the object, as well as with respect to each other, so as to achieve your goals? •••
81. You are trying to look at a geosynchronous communications satellite that is 5.500 m long. A typical human eye can resolve objects that are 0.1000 mm wide when the objects are at the person's near point, and the same angular size applies to objects farther away than the near point. Suppose the telescope you are using is 1.000 m long from one lens to the other. Describe what must be true of the lenses in order for you to be able to look at the satellite. Assume the satellite is exactly resolvable when viewed through your telescope. Is your result reasonable? What modifications could you make to the telescope in order to make it easier to see the satellite? •••

33.7 Spherical mirrors

82. Sunlight reflected off a mirror you are holding is focused at a point 100 mm in front of the mirror. What is the radius of curvature of the mirror? •
83. A spherical mirror with radius of curvature $R = 200$ mm is used to form an image of an object placed a distance $d = 150$ mm in front of the mirror. Where does the image appear? •
84. A bathroom shaving mirror has radius of curvature $R = 400$ mm. Describe the image of your face formed when you stand (*a*) a distance $d_{close} = 100$ mm from the mirror and (*b*) a distance $d_{far} = 1.20$ m from the mirror. •
85. Passenger-side car mirrors often carry the warning "Objects in mirror are closer than they appear." If the mirror on your car has radius of curvature $R = -800$ mm and the car behind you and one lane to the right is a distance $o = 20.0$ m away, how far away does it appear? •
86. An object is placed 60 mm in front of a converging spherical mirror for which the radius of curvature is 200 mm. What are (*a*) the image distance and (*b*) the magnification of the image? (*c*) Is the image real or virtual? (*d*) Is it upright or inverted? (*e*) Draw a ray diagram illustrating this situation and including the three principal rays. ••
87. A converging mirror that has a radius of curvature of 70.0 mm forms an image of an object that is 20.0 mm tall and 150 mm in front of the mirror. (*a*) What is the image height? (*b*) Is the image real or virtual? (*c*) Is it upright or inverted? (*d*) Draw a ray diagram illustrating this situation and including the principal rays. ••
88. You stand 0.50 m in front of a diverging mirror for which the radius of curvature is −3.5 m. (*a*) Is your image real or virtual? (*b*) Is it upright or inverted? (*c*) How far away from the mirror surface is it located? (*d*) What is its magnification? ••

89. When you look at yourself in a converging mirror, you appear to be one-fourth your actual size. If you are standing 1.0 m in front of the mirror, what is the mirror's radius of curvature? ••

90. You wish to use a converging mirror to form an image that is N times larger than the object. In terms of N and R, the radius of curvature of the mirror, at what distance o from the mirror should you place the object? ••



91. A spherical mirror produces a real image of your face that is twice as large as your face. If your face is 750 mm from the mirror, what is the radius of curvature of the mirror? ••

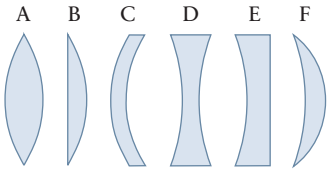
92. A converging mirror has a focal length of 200 mm. Calculate the image distance and magnification for an object located (*a*) halfway between the focal point and the mirror, (*b*) at the focal point, (*c*) halfway between the focal point and the center of curvature, (*d*) at the center of curvature, (*e*) a distance f beyond the center of curvature, and (*f*) at infinity. ••

93. Repeat Problem 92 for a diverging mirror. Comment on any similarities or differences with the two types of mirrors. ••

94. A security mirror in a shop is designed to give a wide-angle view, but as a result the images it forms are much smaller than their objects. If you want an image that appears 10.0 m behind the mirror to have a magnification of 10.0%, what radius of curvature must the mirror have? ••

Figure P33.95

95. The optical system of Figure P33.95 consists of a converging lens and a converging mirror. The focal points of the lens are marked by open dots and the center of curvature of the mirror by a solid dot. Draw a simplified ray diagram, and describe the final image. •••



96. The kind of image a spherical mirror produces for a real object depends on where the object is located relative to the focal point of the mirror. There are three types of spherical mirrors—converging, diverging, and flat—if you consider a flat mirror as being one portion of a curved surface for which the radius of curvature is infinitely large. For a real object placed in front of each type of mirror, characterize the image as real or virtual; upright or inverted; in front of or behind the mirror; and enlarged, shrunken, or the same size as the object. •••

97. You position an object in front of a spherical mirror for which the magnitude of the radius of curvature is R_1. The image formed is real, inverted, and twice as large as the object. You then replace this spherical mirror with one that has a radius of curvature of magnitude R_2 (keeping the object distance unchanged). The image formed by this mirror is virtual, upright, and twice as large as the object. Calculate a value for the ratio R_2/R_1. •••

33.8 Lensmaker's formula

98. All the lenses in Figure P33.98 are surrounded by air. Which of the lenses are converging, and which are diverging? •

Figure P33.98

99. You have a thin lens that is convex on both surfaces. The material of which the lens is made has index of refraction $n = 1.40$, and the radii of curvature are $|R_1| = 300$ mm and $|R_2| = 500$ mm. What is the lens focal length in air? •

100. To correct the vision of a near-sighted patient, an optician needs to make a pair of eyeglasses using –3.0-diopter lenses. The lenses are plano-concave, and the front surface (that is, the surface farthest from the eye) is the flat surface. If the glass used for the lenses has an index of refraction of 1.5, what radius of curvature must the remaining surface have? •

101. A plano-convex lens has a focal length of 150 mm, and the material out of which the lens is made has an index of refraction of 1.5. What is the radius of curvature of the convex surface? •

102. The radius of curvature of one surface of a glass lens ($n = 1.45$) is 1.50 m. If sunlight is focused at a point 0.300 m away from the lens, what is the radius of curvature of the other surface? ••

103. The two surfaces of a double convex, thin lens made of plastic each have an absolute value of radius of curvature of 1.8 mm. If the focal length of the lens is 4.5 mm, what is the index of refraction of the plastic? ••

104. A lens has an index of refraction of 1.50. Its left side curves outward with an absolute value of radius of curvature of 0.15 m, and its right side curves inward with an absolute value of radius of curvature of 0.25 m. What is its focal length if you look through it (*a*) from the left side and (*b*) from the right side? ••

105. A thin lens is made of material that has an index of refraction of 1.50. When an object 10 mm tall is placed 500 mm away from the lens, an upright image 21.5 mm tall is formed. One surface of the lens is concave, with an absolute value of radius of curvature of 350 mm. What is the radius of curvature of the other surface? ••

106. A lens made of glass for which the index of refraction is 1.55 has a focal length of 0.500 m in air. What is its focal length when this lens is submerged in water? ••

107. The convex surface of a plano-convex lens has an absolute value of radius of curvature of 40 mm. The index of refraction for the glass of which the lens is made is 1.5. (*a*) What is the focal length of the lens? (*b*) You take some measurements and determine that the 40-mm radius of curvature is correct but the focal length is 100 mm instead of the value calculated in part *a*. What must the index of refraction for the glass be? ••

108. A thin lens of focal length f_A is made of a material for which the index of refraction is $n_A = 1.1$. If you make a lens B that is identical to lens A in every way except that the index of refraction of the material used to make B is $n_B = 2n_A$, how does the focal length f_B for this lens compare with f_A? ••

109. The thin lens in air of Figure P33.109 is drawn showing $|R_1| < |R_2|$. (*a*) Is this lens converging or diverging? (*b*) If the lens were drawn showing $|R_1| = |R_2|$, would it be converging or diverging? (*c*) If it were drawn showing $|R_1| > |R_2|$, would it be converging or diverging? ●●

Figure P33.109

110. The two surfaces of a lens made of an unknown material have the same magnitude of radius of curvature $|R|$. When an object is placed a distance R away from the lens, the image formed is real and twice as large as the object. What is the index of refraction of the material of which the lens is made? ●●●

Additional Problems

111. When you shine a laser-beam pointer at a wall, why do you see a dot on the wall but not the beam running from pointer to wall (in the absence of dust or mist)? ●

112. A man spearfishing from a dock sees a fish in the water. In order to hit the fish, should he aim the speargun above, below, or directly at the image he sees? ●

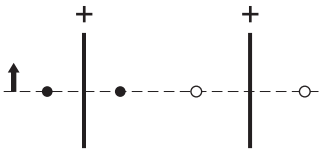
113. Traveling through an optical cable for which the index of refraction is 1.6, how long does it take a light signal to travel from New York to Los Angeles, a distance of 4.0×10^3 km? ●

114. In about the years 214–212 BC, the Greek philosopher and scientist Archimedes is said to have repelled a Roman attack with a "death-ray" converging mirror, using sunlight to set the approaching fleet on fire. Assume an early morning attack from the east, with the Sun directly behind the ships. If the approaching fleet is 100 m away from the mirror, what would the mirror's radius of curvature have to be in order to achieve the maximum effect? ●

115. What is an application of a converging lens for these situations: (*a*) object is at twice the focal length, (*b*) object is at the focal length, and (*c*) object is at infinity? ●●

116. An object that is 50 mm tall is placed 75 mm in front of a converging thin lens. If the image is inverted and 100 mm tall, what are (*a*) the distance of the image from the lens and (*b*) the focal length of the lens? ●●

117. A converging lens for which $f = 50$ mm forms an image that is three times larger than the object. How far from the lens is the object? ●●



118. In vacuum, the wavelength of a certain light wave is 550 nm. (*a*) What is the wavelength in a medium where the wave speed is 2.4×10^8 m/s? What is the frequency of this light (*b*) in vacuum and (*c*) in the medium? ●●

119. The focal length of a lens can be different for different colors of light. (*a*) What optical principle causes this problem? (*b*) Can the problem be corrected? (*c*) Does the same problem affect mirrors? ●●

120. When an object is placed 1.5 m in front of a converging mirror, an image of the object appears twice as high behind the mirror. (*a*) Is the image real or virtual? (*b*) Is it upright or inverted? (*c*) What is the mirror's radius of curvature? ●●

121. The focal points of the two converging lenses shown in Figure P33.121 are denoted by solid dots for the left lens and open dots for the right lens. Draw a simplified ray diagram to locate the final image. ●●

Figure P33.121

122. Using a camera fitted with a lens for which $f = 50$ mm, you take a photograph of a person who is 1.7 m tall and is standing 29 m away from you. What is the height of the person's image on the film? ●●

123. A piece of electronic circuitry embedded in a layer of diamond ($n_{\text{diamond}} = 2.42$) emits light. The diamond is covered by a coating of flint glass ($n_{\text{flint}} = 1.65$). The interface between the two materials is flat, as is the interface between the flint glass and the surrounding air. The two interfaces are parallel. Relative to the direction normal to both interfaces, what are (*a*) the greatest angle at which light emitted in the diamond layer can enter the flint glass and (*b*) the greatest angle at which light emitted in the diamond layer travels through the flint glass and enters the surrounding air? ●●●

124. You and a friend are scuba diving on a calm day when you decide it would be neat to estimate the critical angle for light going from water into air. Your friend is underwater and has a laser pointer and a waterproof earpiece so that he can hear your instructions. He also has a floating marker attached to him that remains on the surface directly above him. Sitting in a small motorboat on the surface, you have a variety of tools for measuring distances (tape measures, fishing line that could be let out and later accurately measured, and so on). You think for a moment and decide on a course of action. ●●● CR

125. You are in charge of the projector in a movie theater. The film passes through a holder, and light from a bright bulb passes first through the film and then through a lens. You have several additional lenses that can be swapped out, and the position of the lens holder is easily adjustable, but moving the film holder seems more troublesome. A single film frame is 20.00 mm tall. You notice that when the lens is placed 100.0 mm from the film, a sharp image 1450 mm tall is formed on the movie screen on the other side of the lens. This image is far too small, filling less than one-third of the screen. If the patrons do not see a much larger, well-focused image, you may be returned to your previous job making popcorn. ●●● CR

126. For a lens in air, you have learned the conditions on its radii of curvature to make the lens converging or diverging. You have done some diving, and you realize that a lens has a different focal length underwater than it does in air. That starts you thinking about what would happen if a lens is placed in a medium with an index of refraction greater than that of the material of which the lens is made, but you are not even sure that it is possible to form images under such conditions. Lost in your thoughts, you drift off into dreamland. ●●● CR

CONCEPTS

QUANTITATIVE TOOLS

In Chapter 33, we considered the propagation of light along a straight path. The chapter title, "Ray Optics," reflects the fact that we considered propagating light only in the simplest way—as straight-line motion. You know from Chapter 30, however, that light is an electromagnetic wave. This means that it must undergo interference and diffraction, just like any mechanical wave. As you will learn in this chapter, light waves can interfere with one another and diffract when they pass through small openings.

Another fact about light you will learn in this chapter is that it has a dual nature: It is a wave, yes, but it also has the properties of a particle!

34.1 Diffraction of light

As we saw in Chapter 17, when a surface water wave strikes a barrier that has a small opening, the wave diffracts (spreads out) after it passes through the opening. **Figure 34.1*a***, for example, shows surface water waves diffracting nearly circularly after they pass through an opening.

Given that light is a wave, as we discussed in Chapter 30, why don't we see light diffract in a similar fashion after it travels through, say, a window? As Figure 34.1*b* shows, after passing through a window, light continues to travel in a straight line, casting a sharp-edged shadow with no discernible diffraction.

The reason light does not diffract through a window is that the wavelength of the light is very much smaller than the size of the window. In Figure 34.1*a*, the wavelength of the water wave is about the same as the width of the opening, but the wavelength of the light in Figure 34.1*b* is about a million times smaller than the width of the window.

Diffraction is indeed observed with light waves but only when the width of the opening through which the light passes is not much greater in size than the wavelength of the light. Empirical evidence shows that diffraction occurs through openings approximately two orders of magnitude greater than the wavelength. Thus, visible light, with a wavelength on the order of 1 μm, diffracts through apertures up to hundreds of micrometers wide.

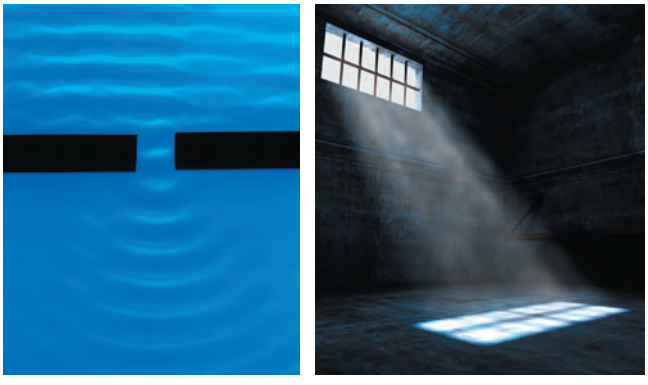
To understand diffraction, it is useful to consider the propagation of wavefronts. As discussed in Sections 17.1 and 33.2, a wavefront is a surface on which a wave spreading through space has constant phase. Wavefronts are everywhere perpendicular to the direction of propagation of the wave. By convention, wavefronts are drawn at the crests of the waves, which means the separation between adjacent wavefronts equals the wavelength (Figure 17.2). Although in principle wavefronts can take any shape, usually we consider only those that are either planar or spherical. Most sources of light, from light bulbs to stars, can be modeled as point sources—single points that produce concentric spherical wavefronts. As discussed in Section 17.1 (see especially Figure 17.7), far away from a point source, the radius of the spherical wavefronts is so great that the wavefronts are very nearly planar. As a result, distant point sources can be considered to be sources of planar waves. Lasers also produce planar waves, even very close to the source. For this reason, we can use a laser beam in seeing how electromagnetic waves behave. Keep in mind, however, that our analysis applies to any type of electromagnetic waves, not just to laser beams.

Let us now determine under what conditions a planar wave spreads out as it propagates—in other words, under what conditions it undergoes diffraction. **Figure 34.2** shows planar wavefronts from a beam of electromagnetic waves propagating to the right, with point Q located at the upper end of the wavefronts and point P located outside the region reached by the wavefronts. Because a wavelet (see Section 17.4) centered on Q radiates toward P along the line QP, we expect the beam to spread out as it propagates. However, such spreading is not observed. The reason is that the wavelets centered on points below Q also radiate toward P, and we need to sum the

CONCEPTS

Figure 34.1 Surface water waves diffract when they pass through a gap, whereas light coming in through a window seems not to diffract—it forms a sharp-edged shadow. Notice that the gap in the barrier is roughly as wide as the wavelength of the water waves.

(*a*) (*b*)



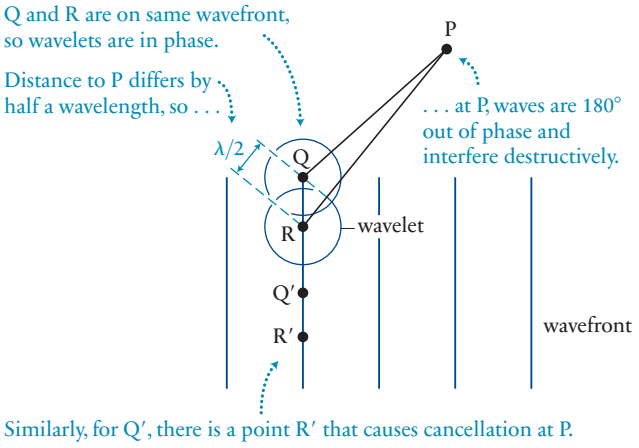


Figure 34.2 The reason we don't usually see diffraction for light beams, provided the beam is very much wider than the wavelength of the light waves.

contributions of all these wavelets. Consider, for example, the wavelet centered on R, for which the distance PR is exactly half a wavelength longer than the distance PQ. Because Q and R lie on the same wavefront, they produce coherent wavelets. (You should review Section 17.4 if you do not see why this is true.) This means that at P the electric field part of the wavelet from Q is 180° out of phase with the electric field part of the wavelet from R. Thus the two electric fields interfere destructively at P. Because the same is true for the magnetic field part of the wavelets, there is complete destructive interference (see Section 16.3) at P.

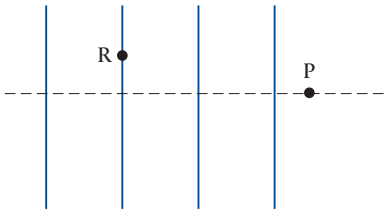
In the same manner, for points Q′ lying below Q on the wavefront, we can find on the same wavefront a point R′ for which the distance R′P is exactly half a wavelength longer than the distance Q′P. Thus the fields from the wavelet traveling along R′P cancel those from the wavelet traveling along Q′P. If the wavefronts extend far enough below Q, we can always find points that cancel the waves from any other point. As a result, we conclude that the light does not spread outside the beam; in other words, there is no diffraction.

34.1 Consider the point P located ahead of the wavefronts shown in **Figure 34.3**. Following the line of reasoning used in the preceding discussion, what can you say about the intensity (power/area, as defined in Eq. 30.34 and Section 17.5) at P once the wave fronts reach it? (Hint: Consider separately points R above, below, and on the ray through P.)

Checkpoint 34.1 demonstrates that the intensity of a planar wave is uniform as the wave propagates forward because the fields from individual wavelets cancel in any outward direction and reinforce only in the direction of propagation. Section 17.3 (especially Figure 17.20) shows that combining the waves from many adjacent point sources indeed produces a planar wave that propagates forward with very little spreading. This is true because the wavelets interfere destructively with one another in any direction other than the direction of propagation of the wavefronts.

The cancellation process we used in Figure 34.2 can be used only when the width of the laser beam, and hence the width of the wavefronts, is much greater than the wavelength of the light. That way, all points on a wavefront can be paired with other points on that wavefront that are half a wavelength or more away, and the wavelets from these points cancel.

Figure 34.3 Checkpoint 34.1.



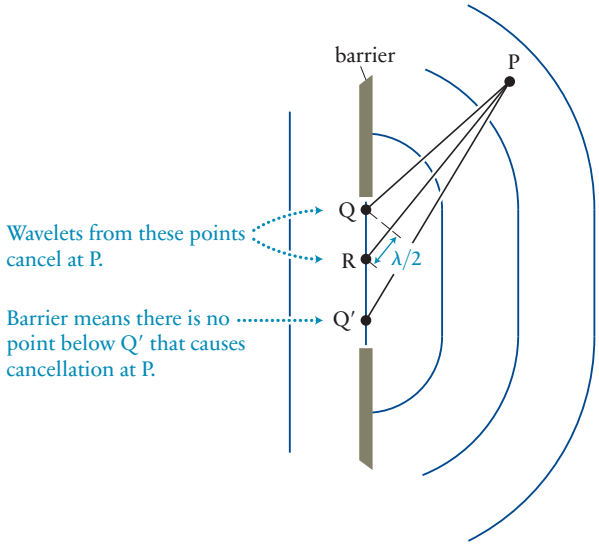


Figure 34.4 The reason we *do* see diffraction when a light beam is transmitted through a small aperture.

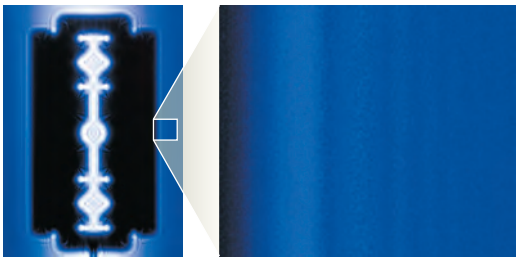


If the width of the beam is comparable to the wavelength of the light, not all points on the wavefronts can be paired in this manner. To see why this is so, let us place a barrier in front of our light source, as in **Figure 34.4**. You can think of this drawing as a bird's-eye view of a beam of light traveling to the right and running into a wall that has a gap in it. Light hitting the wall on either side of the gap cannot pass through. As each wavefront of the beam reaches the barrier, only the portion that hits the gap continues moving to the right. The width of each wavefront that passes through the gap is equal to the gap width.

Suppose the gap in Figure 34.4 has a width equal to 2λ. All waves that reach P from wavelets that originate above Q′ cancel, as indicated by the rays drawn from points Q and R in Figure 34.4; wavelets that originate at or below Q′ are not canceled at P because those wavelets lack corresponding wavelets at an appropriate distance below Q′. As a result, some of the light spreads out past the edges of the original path of the beam—the light is diffracted. Diffraction in this situation occurs for exactly the same reason as the diffraction of water waves pictured in Figure 34.1*a*. Diffraction of light occurs when a planar wave passes through an aperture that is only micrometers wide (much less than the width of a hair). As shown in Figure 34.1*a*, if the width of the aperture is equal to or less than the wavelength, the wavefronts coming from the aperture are spherical. If the aperture is a few wavelengths wide, the wavefronts are elongated right after they pass through the aperture, as shown in Figure 34.4.

An ordinary window, like that shown in Figure 34.1*b*, is effectively infinitely wide relative to the wavelength of the light, so only the light at the very edges of the window diffracts. In practice, not even diffraction from the edge of the window is observed because the edge is not perfectly smooth on a micrometer scale. However, it *is* possible to observe diffraction of light from the edge of a smooth razor blade, as shown in **Figure 34.5** on the next page.

CONCEPTS

Figure 34.5 Edge diffraction is not usually apparent for visible light because most edges are not smooth enough. However, it can be observed around the edge of a razor blade. The blade in this image is illuminated by a point source of monochromatic light.

EXAMPLE 34.1 Spreading out

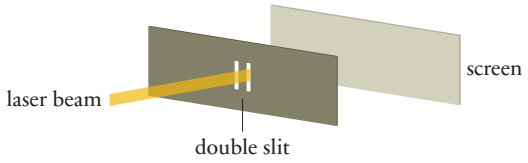
Do you expect to be able to observe the diffraction of light through (*a*) the front door to your house; (*b*) the holes in a button; (*c*) the gaps between threads of the fabric of an umbrella?

❶ **GETTING STARTED** I expect to see noticeable diffraction through openings up to roughly two orders of magnitude times the wavelength of the light. I therefore need to estimate the width of each opening and determine the width-to-wavelength ratio.

❷ **DEVISE PLAN** To estimate the width of the front door and of the holes in the button, I can draw on my experience; to estimate the widths of the gaps between the threads of the fabric of an umbrella, I shall use an upper limit. Then I shall take the ratios of these widths to the wavelength of light in the middle of the visible range, 500 nm.

❸ **EXECUTE PLAN** (*a*) A door is about 1 m wide, so the ratio of the door's width to 500 nm is 2×10^6, much too great to see diffraction. ✔

(*b*) The holes in a button are about 1 mm in diameter, so the ratio of this width to 500 nm is 2×10^3, still too great to see diffraction. ✔



(*c*) I know that a human hair, which is less than 100 μm in diameter, cannot easily be threaded through a piece of fabric. Therefore I estimate the gaps between the threads in the fabric to be one-tenth of a hair diameter, or 10 μm at most. The ratio of a gap width to 500 nm is therefore 20 or less, and I expect to see diffraction through the gaps in the fabric. ✔

❹ **EVALUATE RESULT** I know from experience that I do not see diffraction through a doorway. I can check my answers to parts *b* and *c* by looking through the holes in a button and through an open umbrella. When I do so, I see no diffraction through the button but I can see diffraction through the umbrella if the fabric is dark. (This diffraction is particularly noticeable when I look at a streetlight at night through the umbrella.)

CONCEPTS

34.2 In discussing how a planar wave propagates, we could turn our earlier argument around and say that for each point Q in Figure 34.2 there is a point S somewhere on the wavefront that radiates toward P along a path exactly one wavelength longer than that from Q, and therefore there should be a nonzero intensity at P. What is wrong with this argument?

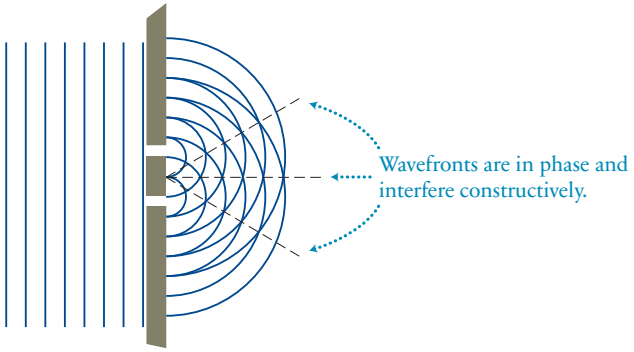
Figure 34.6 When the planar electromagnetic waves of a laser beam pass through a pair of narrow slits, what do we see on the screen?

34.2 Diffraction gratings

What happens if instead of passing through a single small aperture, a planar electromagnetic wave strikes a barrier that contains two narrow slits at normal incidence, as shown in **Figure 34.6**? If the slit width is much less than the wavelength of the wave, the slits serve as two coherent point sources of electromagnetic waves of the same wavelength as the wave striking the barrier, and the waves from the two sources interfere with one another in the manner described in Section 17.3 for two adjacent sources of surface waves. The only difference is that electromagnetic waves are not confined to a planar surface but spread out in three dimensions. If the two slits are either round or square, the waves that emerge from them are spherical. If the slits are much taller than they are wide, as in Figure 34.6, the slits serve as lines of point sources and the waves that emerge from the slits have cylindrical wavefronts.

The crests of the waves from these two coherent point sources overlap in certain directions, as shown in **Figure 34.7** (and Figure 17.13). Between these directions where there is overlap are directions along which the waves from the two sources cancel. If we place a screen to the right of the slits, a pattern of alternating bright and dark bands appears on the screen, as shown in **Figure 34.8**. Such dark and bright bands are commonly called **interference fringes.** The bright fringes are labeled by a number called the **fringe order** m. The central bright fringe is the *zeroth-order bright fringe* ($m = 0$); around it are higher-order bright fringes ($m = 1, 2, \ldots$). Note that the pattern is symmetrical about this zeroth-order bright fringe.

Figure 34.7 Interference between the diffracted waves emerging from the two slits.



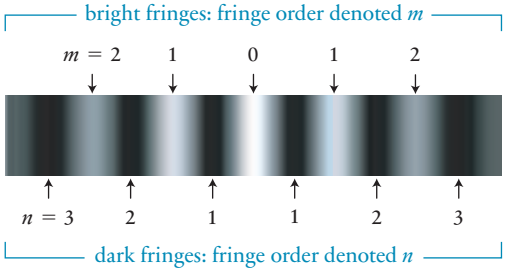


Figure 34.8 The interference pattern produced when the laser beam of Figure 34.6 passes through a pair of slits and strikes the screen.

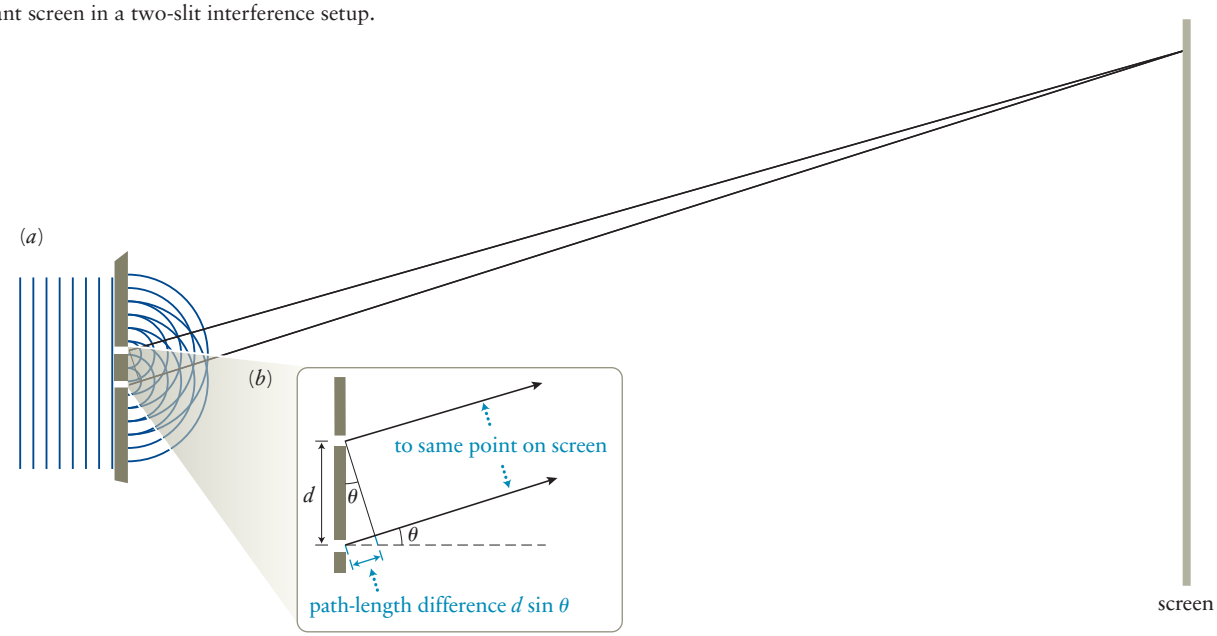
How do we determine the locations of the bright fringes? The central (zeroth-order, $m = 0$) bright fringe is simplest to locate. As shown in Figure 34.7, waves from the two sources interfere constructively along a perpendicular line running through the midpoint between the two slits. Because the waves coming from the two slits travel the same distance to reach any point along this perpendicular line, the waves arrive in phase with each other.

To locate the other bright interference fringes, we need to work out the directions in which the difference in path length between waves coming from the upper source and waves coming from the lower source is an integer number of wavelengths. In these directions, constructive interference between waves from the two sources produces bright fringes.

Let's consider two rays, one from each slit, that meet at the screen to form a fringe, as shown in **Figure 34.9a**. In general we shall take the distance from the sources to the screen to be much greater than the distance between the slits. Note from the figure how, even though the rays eventually meet at the screen, their paths are essentially parallel when they emerge from the slits (Figure 34.9*b*). If we denote the angle between the nearly parallel rays and the normal to the barrier as θ, we can say that the difference in path length for waves emitted at angle θ from the two sources is $d \sin \theta$, where d is the distance between the centers of the slits (Figure 34.9*b*). When this path-length difference is equal to an integer multiple of the wavelength, constructive interference occurs. The central bright fringe corresponds to $d \sin \theta = 0$ or $\theta = 0$. Subsequent bright fringes are located at angles given by $d \sin \theta_m = \pm m\lambda$, where $m = 1, 2, \ldots$ denotes the order of the bright fringe. The plus and minus signs give rise to bright fringes on either side of the central maximum.

Likewise, in directions that correspond to path-length differences of an odd number of half-wavelengths, waves from the two sources interfere destructively, resulting in dark fringes. For these fringes, we use n to denote fringe order. The smallest angle at which destructive interference occurs corresponds to $d \sin \theta = \frac{1}{2}\lambda$. More generally, the angles at which dark fringes occur are given by $d \sin \theta_n = \pm (n - \frac{1}{2})\lambda$, where $n = 1, 2, \ldots$ denotes the order of the dark fringe. The dark fringes around the zeroth-order bright fringe are the first-order dark fringes.



EXAMPLE 34.2 Two-slit diffraction grating

Coherent green light of wavelength 530 nm passes through two very narrow slits separated by 1.00 μm. What is (*a*) the angular location of the first-order bright fringe? (*b*) the angular separation between the $n = 1$ and $n = 2$ dark fringes?

❶ **GETTING STARTED** This problem involves interference between light rays passing through two closely spaced, very narrow slits, as shown in Figure 34.9.

(Continued)

Figure 34.9 Determining the path-length difference between two rays traveling to a point on a distant screen in a two-slit interference setup.

CONCEPTS

2 DEVISE PLAN The angular locations of the centers of the bright fringes are given by the condition for constructive interference, $d \sin \theta_m = m\lambda$; the angular locations of the dark fringes are given by the condition for destructive interference, $d \sin \theta_n = (n - \frac{1}{2})\lambda$. (For both bright and dark fringes, I omit the $\pm$ signs because I'll only consider the fringes on one side of the central maximum.) I therefore need to use these relationships to calculate the angular locations of the fringes. To use the constructive and destructive interference conditions, I need to identify the appropriate values of m and n and then use them with the wavelength and the distance between slits to obtain the angular positions of the bright and dark fringes I am interested in.

3 EXECUTE PLAN (*a*) The first-order bright fringe corresponds to $m = 1$, which means the center of the first-order bright fringe is located at the value θ_1 corresponding to $d \sin \theta_1 = \lambda$. Substituting for d and λ in this expression and solving for θ_1, I obtain

$$\theta_1 = \sin^{-1}\left(\frac{0.530\ \mu\text{m}}{1.00\ \mu\text{m}}\right) = 32.0°. \checkmark$$

(*b*) The two lowest-order dark fringes correspond to $n = 1$ and $n = 2$, and their centers occur at the angles corresponding to $d \sin \theta_1 = \lambda/2$ and $d \sin \theta_2 = 3\lambda/2$. Substituting and solving, I obtain

$$\theta_1 = \sin^{-1}\left(\frac{0.530\ \mu\text{m}}{2 \times 1.00\ \mu\text{m}}\right) = 15.4°$$

$$\theta_2 = \sin^{-1}\left(\frac{3 \times 0.530\ \mu\text{m}}{2 \times 1.00\ \mu\text{m}}\right) = 52.7°.$$

The angular separation is thus $52.7° - 15.4° = 37.3°$. ✔

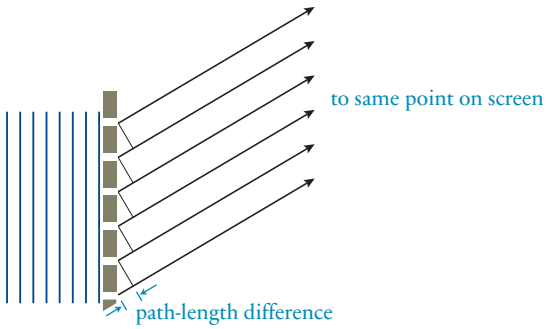
4 EVALUATE RESULT The center of the $m = 1$ bright fringe is roughly halfway between the centers of the $n = 1$ and $n = 2$ dark fringes, as I expect from Figure 34.8.

CONCEPTS

34.3 Does the spacing of the bright fringes in the two-slit arrangement in Figure 34.6 increase, decrease, or stay the same if we (*a*) increase the spacing d of the slits, or (*b*) increase the wavelength λ of the light incident on the arrangement?

Now consider the effect of many equally spaced narrow slits in a barrier on which planar waves are incident normally (**Figure 34.10**). Once again, we can determine

Figure 34.10 Path-length difference for planar waves striking a barrier with multiple slits.



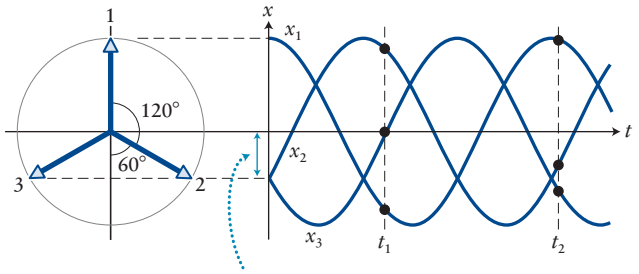


Figure 34.11 Three coherent waves interfere destructively when each is out of phase with the other two by one-third of a cycle.

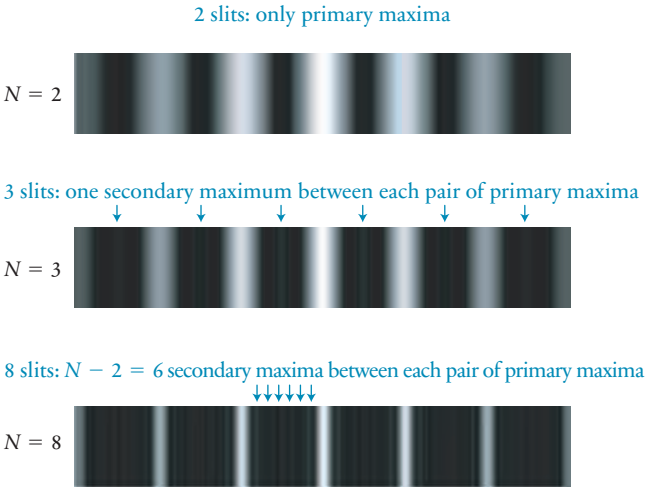
Projection of phasor 2 onto vertical = cos 60° times amplitude = half amplitude.



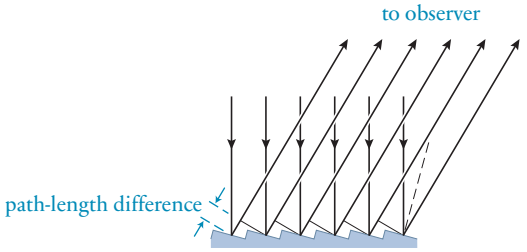
the fringe pattern produced at a given location on a distant screen by combining all the waves (one from each slit) that travel to that location. The condition for constructive interference among all the waves is equivalent to that for two slits. As can be seen from Figure 34.10, the path-length difference between each pair of adjacent waves is the same. This means that if the waves from two of the slits interfere constructively, the waves from *all* of the slits do the same. Bright fringes therefore appear at angles corresponding to $d \sin \theta_m = \pm m\lambda$, with d the separation between adjacent slits. The location of bright fringes therefore does not depend on the number of slits as long as the separation d between adjacent slits is the same for all slits.

34.4 Suppose there are three slits in a barrier on which light is incident normally, with each slit separated from its neighbor by a distance d. Do the waves from all three slits cancel perfectly at angles given by $d \sin \theta = \pm (n - \frac{1}{2})\lambda$?

As Checkpoint 34.4 illustrates, the condition for complete destructive interference of all of the waves is not the same for three slits as for two. Instead, as **Figure 34.11** shows, three coherent waves cancel one another perfectly when each is out of phase with the other two by one-third of a cycle. The three waves also cancel one another perfectly when each is out of phase with the other two by two-thirds of a cycle. In that case, phasors 2 and 3 in Figure 34.11 are interchanged. So there are two dark fringes between each pair of bright fringes. In between these two dark fringes is a faint bright fringe (**Figure 34.12**). The brightest fringes are the *principal maxima* in the interference pattern. These correspond to constructive interference of the waves diffracted by all three slits. The fainter bright fringes are *secondary maxima*. At these locations the cancellation is not complete.

Four coherent waves cancel one another when adjacent waves are out of phase by one-fourth of a cycle. In the same manner, if there are N slits, the condition for complete destructive interference is that each wave must differ in phase by $1/N$ of a cycle from its immediate neighbors. Then the N waves are evenly distributed

Figure 34.12 Interference pattern caused by the diffraction of a coherent beam of light through two, three, and eight narrow slits.



throughout one cycle of oscillation and add to zero. The condition for the path-length differences for the dark fringes is thus $d \sin \theta_k = \pm (k/N)\lambda$, where k is any integer that is *not* a whole-number multiple of N (because when $k/N = m$, we have constructive interference).

Although the bright fringes are in the same location regardless of the number of slits, there are now $N - 1$ dark fringes between the bright fringes and $N - 2$ secondary maxima between each pair of principal maxima. As a result, as N increases, the bright fringes become narrower and brighter, as shown in Figure 34.12. (The brightness of the pattern corresponds to the intensity of the light striking the screen.)

34.5 Why does the brightness of the fringes increase as the number of slits increases?

The interference of a planar electromagnetic wave as it passes through many closely spaced narrow slits is due to the diffraction that occurs at the slits. A barrier that contains a very large number of such slits is therefore called a **diffraction grating.** Diffraction gratings can be either transmissive (such as the one shown in Figure 34.10) or reflective. Reflective diffraction gratings are made by engraving grooves to reflect light from a surface, as shown in **Figure 34.13**. The grooves

Figure 34.13 Reflective diffraction grating.

on a digital video disc (DVD) form a reflective diffraction grating.

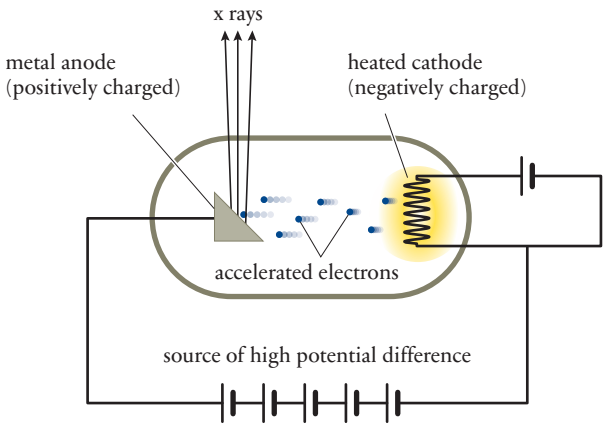
Why is the light reflected from the compact disc surface so colorful? You found in Checkpoint 34.3 that the position of interference fringes produced by light of a single color depends on the wavelength. When white light, which contains many different colors and therefore many different wavelengths, falls on a diffraction grating, the fringes for each wavelength are displaced from each other, producing a series of rainbows.

34.6 Suppose the light striking the reflective diffraction grating in Figure 34.13 is white light—that is, light consisting of all the colors of the rainbow. Red light has the longest wavelength of the colors that make up white light; violet has the shortest. (*a*) Is the angle at which first-order constructive interference occurs for violet light less than, equal to, or greater than the angle for red light? (*b*) Why are multiple rainbows visible in the reflected light?

Very precisely manufactured diffraction gratings have many uses in scientific equipment. They are most widely used to disperse visible, ultraviolet, or infrared light into its constituent wavelengths because the resulting spectrum provides information about the object that emitted the light. For example, astronomers often use a diffraction grating attached to a telescope to identify the wavelengths present in the light from stars, in order to understand the chemical composition of the stars or their distance from Earth.

Certain common objects can also function as diffraction gratings. For example, if you look through a piece of dark, finely woven, taut fabric at a point source of light (say, a distant street light through the fabric of a dark umbrella), you will see fringes.

34.7 Diffraction gratings used in astronomical instruments must be able to separate wavelengths that are quite close together. (*a*) To increase the ability to do this, should the separation between slits be made less or greater? (*b*) Does the width of the slits affect the diffraction pattern?



CONCEPTS

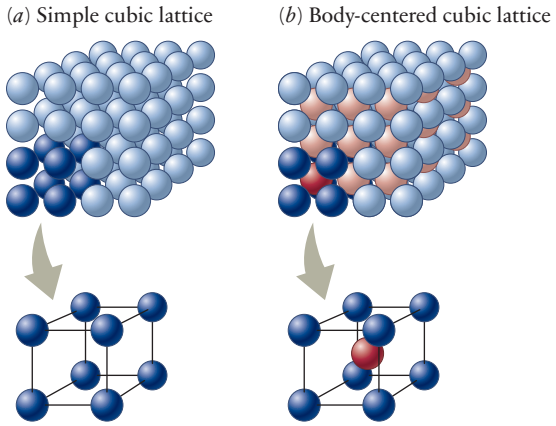
34.3 X-ray diffraction

The interference of very-short-wavelength electromagnetic radiation is widely used to study the structure of materials. **X rays** are electromagnetic waves that have wavelengths ranging from 0.01 nm to 10 nm, more than 100 times less than the wavelengths of visible light.

Figure 34.14 on the next page shows one way to generate x rays. Electrons are ejected from a heated cathode on the right and accelerated by a potential difference of several thousand volts toward a metal anode on the left. The electrons crash into the atoms

Figure 34.14 Schematic diagram for a cathode ray tube x-ray emitter.

that make up the anode; this inelastic collision decelerates the electrons very rapidly and gives the atoms a great deal of internal energy. The atoms then re-emit this energy in the form of x rays. In addition, the rapidly decelerating electrons radiate x rays, typically at a 90° angle to the path of the accelerated electrons.



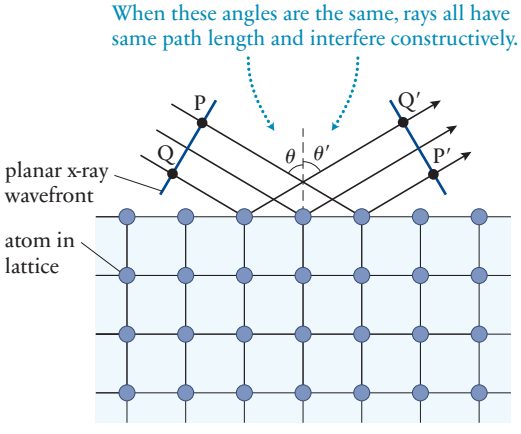
X rays can pass through many materials with low mass density that are opaque to visible light. For example, they pass through soft tissues in the human body but are strongly absorbed by bones and teeth. As a result, x rays are widely used to obtain photographic images of the skeleton (**Figure 34.15**). X-ray imaging of blood vessels or soft internal organs can be done by giving the patient a drug containing dense elements, such as iodine, because dense material absorbs x rays. For example, one way cardiologists diagnose heart problems is to directly observe blood vessels in a patient's heart by injecting a dense-atom drug into the patient's blood and taking x-ray movies of the beating heart as the blood is pumped through.

Because x-ray wavelengths are either shorter than or comparable to the typical distance between atoms in solid materials (0.1 nm to 1 nm), x-ray diffraction can be used to study atomic arrangements in solids. Many solids are

Figure 34.15 Bones and teeth absorb x rays, whereas soft tissues are nearly transparent to them.

Figure 34.16 Two examples of crystal lattices.

crystalline, meaning that their atoms are arranged in a three-dimensional, regularly spaced grid called a *crystal lattice* (**Figure 34.16**). The lattice serves as a three-dimensional diffraction grating for x rays because the lattice spacing is comparable to the x-ray wavelength.



Consider what happens when x rays strike the top plane of atoms in a crystal lattice* at an angle θ (**Figure 34.17**). Each atom that is struck by the beam of x rays acts as the source of a wavelet emitting waves in all directions, much like the slits of the diffraction gratings we discussed in the preceding section. Waves emitted at $\theta' = \theta$ have the same path length and so they add constructively, yielding a strong reflected beam.

34.8 Considering only the top row of atoms in Figure 34.17, are there any other directions in which the x rays diffracted by the atoms interfere constructively?

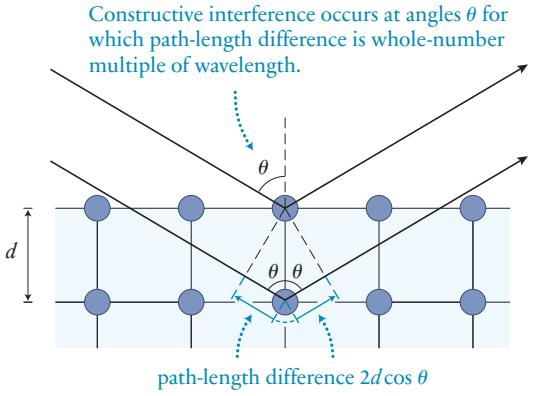
As you saw in Checkpoint 34.8, x rays diffracted by the crystal in directions other than at angle $\theta' = \theta$ are much weaker than those diffracted at angle $\theta' = \theta$. We

*The lattice shown is a so-called cubic lattice. Lattices can be much more complex than the cubic lattice, but the principles of diffraction are the same.

Figure 34.17 Diffraction of x rays by the atoms at the surface of a crystal lattice.

CONCEPTS

Figure 34.18 Interference of x rays diffracted by adjacent planes of a crystal.



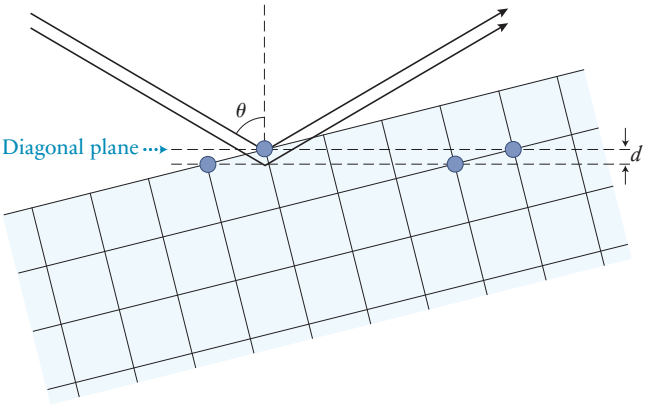


Figure 34.19 Constructive interference of x rays diffracted by two diagonal crystal planes.

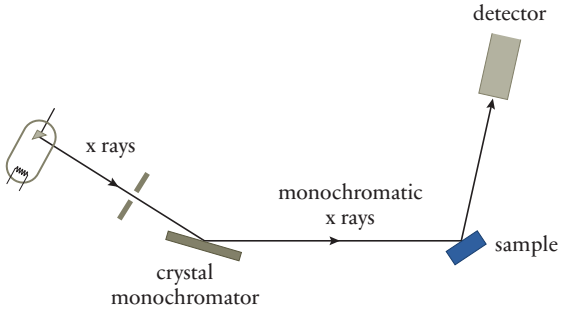
might therefore expect not to see any x-ray diffraction from crystals at other angles. However, a crystal consists of many planes of atoms, and some incident x rays penetrate into the crystal. We thus need to take into account the diffraction of the x rays by the atoms in multiple crystal planes to determine the diffraction of the crystal as a whole.

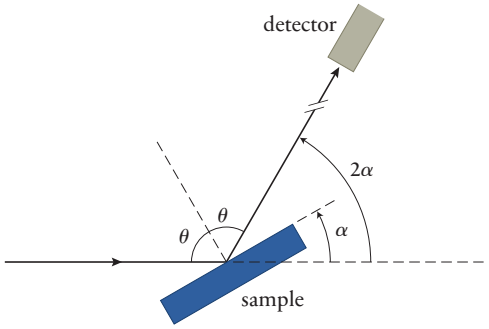
Figure 34.18 shows the x rays diffracted by atoms in two adjacent planes of a crystal. For most angles of incidence, the waves diffracted by atoms in different planes differ in phase and so interfere destructively. However, when the difference in path length between rays diffracted by atoms in different planes is a whole-number multiple of the x rays' wavelength, the rays are in phase and interfere constructively. The path-length difference equals $2d \cos \theta$, where d is the distance between adjacent planes. Therefore the condition for constructive interference is $2d \cos \theta = m\lambda$. This condition is called the **Bragg condition,** after the father-and-son team of physicists who formulated it. Because the atomic spacing and the x-ray wavelength are fixed, crystals reflect x rays only at those angles for which $2d \cos \theta$ is an integer multiple of the x-ray wavelength.

The atoms in the lattice of a crystal define many different lattice planes. **Figure 34.19** shows two sets of lattice planes in a cubic crystal, one indicated by dashed lines (planes parallel to the surface of the crystal) and the other indicated by solid lines (diagonal planes). If we tilt the crystal so that the angle the incident x rays make with its surface is different from the angle shown in Figure 34.18, a different set of planes with a different spacing can produce constructive interference of the diffracted waves.



By measuring the angles at which strong x-ray diffraction occurs, one can determine the arrangement of atoms in a crystalline solid. **Figure 34.20** shows how such a measurement is carried out. An x-ray source like that shown in Figure 34.14 is used to produce a beam of x rays of various wavelengths. The beam is then diffracted from a *crystal monochromator* (which is simply a crystal of known lattice spacing) positioned at an angle chosen so that the Bragg condition is satisfied for one desired wavelength of x rays. Because the other wavelengths in the original beam do not satisfy the Bragg condition, a *monochromatic* (single-wavelength) beam of x rays is diffracted from the monochromator to the sample.

The sample of crystalline material whose lattice is being studied is slowly rotated with respect to the monochromatic beam, and as this rotation takes place, the intensity of x rays diffracted from the sample is measured on a detector as a function of the angle α between the x rays and the sample surface (Figure 34.20*b*). This angle is often called the *Bragg angle* α. As this angle changes, the Bragg condition is generally not satisfied. However, at specific Bragg angles, the various crystal planes in the



CONCEPTS

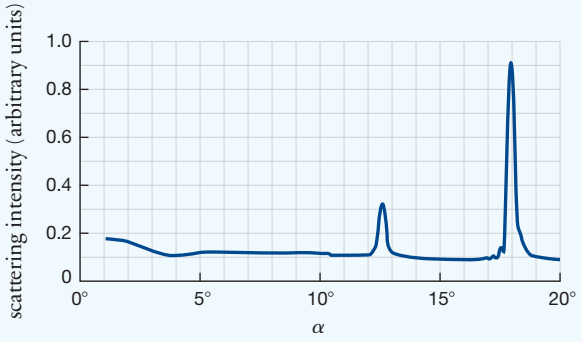
(*a*) Apparatus for studying x-ray diffraction from a crystalline solid

(*b*) Relationship between incident angle θ and Bragg angle α



sample satisfy the Bragg condition, producing a high intensity of x rays on the detector.

34.9 Express the Bragg condition $2d \cos\theta = m\lambda$ in terms of the Bragg angle α between the x rays and the surface of the sample rather than the angle θ between the x rays and the surface normal.

EXAMPLE 34.3 X-ray diffraction

Figure 34.21 shows diffracted x-ray intensity as a function of the Bragg angle α, obtained using x rays having a wavelength of 0.11 nm. (*a*) Without calculating values for the lattice spacing d, identify which of the two peaks corresponds to a greater distance between adjacent planes in the sample being studied. (*b*) Calculate the distance between adjacent planes corresponding to each peak.

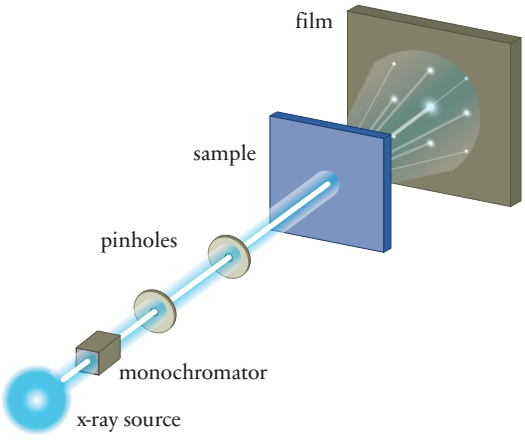
Figure 34.21 Example 34.3.

❶ **GETTING STARTED** The peaks in a graph of x ray intensity as a function of the Bragg angle α correspond to constructive interference and therefore values of α that satisfy the Bragg condition.

❷ **DEVISE PLAN** For part *a*, I can use the Bragg condition, together with the shape of the graph, to deduce which peak results from the greater d value. Because the graph gives intensity in terms of the Bragg angle, I shall need the Bragg condition expressed in terms of the Bragg angle.

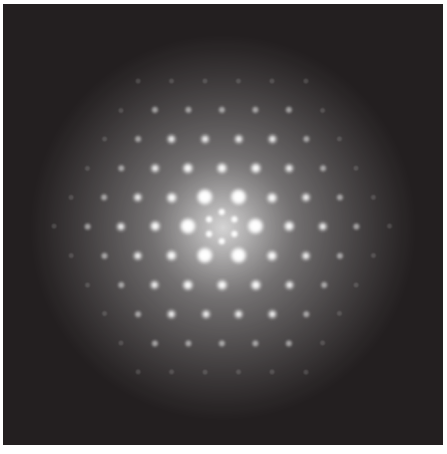
For part *b*, I can solve this form of the Bragg condition for d and then insert my two given α values to determine the plane separation distance in each case. Looking at this form of the Bragg condition, I see that the Bragg angle α at which a peak occurs increases as m increases. Because this graph begins at $\theta = 0°$, the two peaks must correspond to $m = 1$ for the interference patterns when the crystal surface is oriented at the two Bragg angles I am working with.

❸ **EXECUTE PLAN** (*a*) From Checkpoint 34.9 I know that the Bragg condition in terms of the Bragg angle is $2d \sin\alpha = m\lambda$. In order for the product $2d \sin\alpha$ to remain constant, α must decrease as the distance d between adjacent planes increases. Therefore the peak at the smaller α value corresponds to the greater distance between planes. ✔



(*b*) To obtain d for each peak, I solve $2d \sin\alpha = m\lambda$ for d and then substitute $m = 1$ and the values for α and λ. For the short peak, $\alpha = 12.5°$, which gives $d = \lambda/(2 \sin\alpha) = (0.11 \text{ nm})/(2 \sin 12.5°) = 0.25 \text{ nm}$. For the tall peak, $\alpha = 18°$, so $d = \lambda/2 \sin\alpha = (0.11 \text{ nm})/(2 \sin 18°) = 0.18 \text{ nm}$. ✔

❹ **EVALUATE RESULT** The Bragg angle α at which constructive interference occurs decreases as the distance between planes increases. This is consistent with what I found previously for interference between two slits (Checkpoint 34.3), in which increasing the distance between slits also causes the angle between fringes to decrease. In general, the size of an interference pattern decreases as the distances between interfering sources increase. Finally, the smaller value of d multiplied by $\sqrt{2}$ gives the greater value of d, as it should for the distances between planes for the cubic lattice in Figure 34.19.



Many studies of crystal structure are done by passing x rays through the crystal rather than reflecting them from the various crystal planes. The crystal then acts like a three-dimensional transmissive diffraction grating for the x-ray beam. Instead of a single line of slits, the beam encounters many rows of slits. As a result, many rows of fringes usually called "spots" are formed. The experimental apparatus for such a measurement is shown in **Figure 34.22a**.

Figure 34.22 X-ray crystallography.

(*a*) Schematic apparatus for x-ray crystallography

(*b*) X-ray diffraction pattern of diamond lattice

CONCEPTS

From the position and intensity of the spots in the resulting diffraction pattern (Figure 34.22*b*), we can deduce the arrangement of the atoms in the sample.

The earliest x-ray diffraction studies of crystals were done on simple crystals, such as metals that form cubic or other very simple lattices. However, x-ray diffraction has also been used to study the atomic structure of much more complicated molecules, by crystallizing solutions of such molecules. The double helical structure of DNA was determined using x-ray diffraction, also called *x-ray crystallography*, and crystallography is widely used today to determine the atomic structure of even more complicated biological molecules.

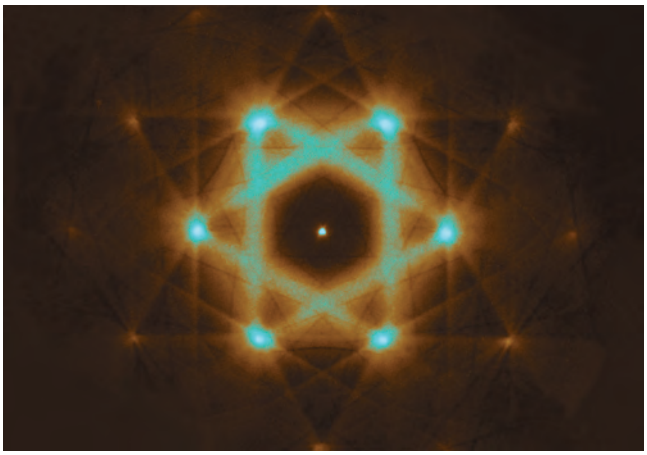
34.10 While comparing the x-ray diffraction patterns from two crystals, you determine that crystal A produces a pattern with more widely spaced diffraction spots than crystal B. Which crystal has the greater atomic spacing?

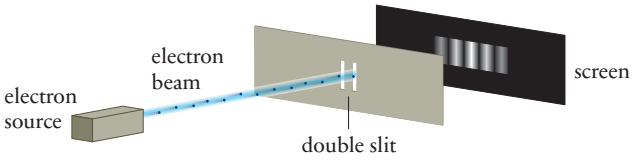
34.4 Matter waves

Patterns remarkably similar to x-ray diffraction patterns can be obtained by aiming a narrow beam of electrons at a crystal. **Figure 34.23** shows the pattern obtained by sending a beam of high-speed electrons through a solid crystalline sample in an instrument called an electron microscope. The shape of the pattern is similar to that obtained with x rays (Figure 34.22*b*), which tells us that electrons are also diffracted by crystals. This discovery, in turn, suggests that the electrons behave like waves because interference and diffraction are wave phenomena. Indeed, electrons have been found to exhibit interference in many other experiments. For example, a beam of electrons aimed at two very narrow slits produces an interference pattern similar to that of a beam of light aimed at two narrow slits (**Figure 34.24**).

Varying the speed of the electrons changes the spacing of the interference pattern, which indicates that the electron wavelength depends on speed.

Figure 34.23 Electron diffraction pattern for a diamond lattice. Notice the similarity to the x-ray pattern in Figure 34.22*b*.





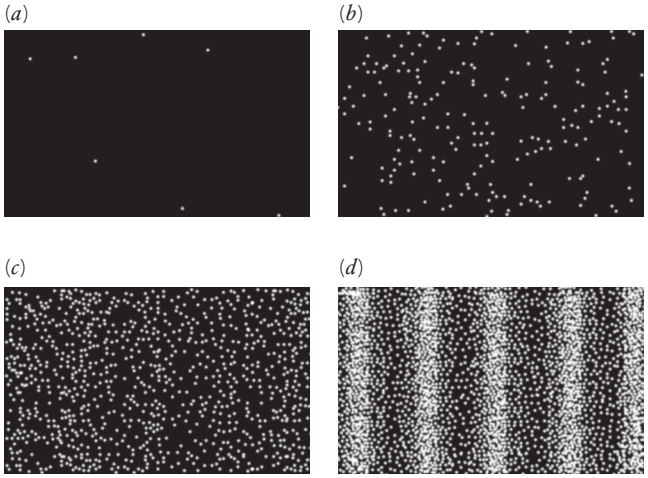


Figure 34.24 Apparatus for observing two-slit interference with an electron beam.

34.11 Spots in an electron diffraction pattern, such as that in Figure 34.23, move closer together as the speed of the electrons is increased. Does this mean the wavelength of the electrons increases or decreases with increasing speed?

Up to now we have considered electrons as being nearly pointlike particles, so it is surprising—to say the least—to discover that they also behave like waves. In fact, electrons can exhibit both particle behavior and wave behavior in a single experiment! This dual behavior was vividly demonstrated in an experiment done in 1989 in Japan using an apparatus similar to that shown in Figure 34.24. The number of electrons emitted by the source was kept very low, so as to ensure that at any given instant at most one electron was traveling from the source to the screen. The screen shows the place where each electron arrives as a bright dot, and at first these dots appear at seemingly random locations, as shown in **Figures 34.25*a*** and *b*. However, as more and more electrons reach the screen one after another, it becomes clear that the electron impacts are not randomly located (Figures 34.25*c* and *d*). Rather, they are arranged exactly in the two-slit interference pattern observed for a higher-intensity electron beam. Covering one slit and forcing the electrons to pass through the other makes the interference pattern disappear, just as it would for a light wave or a water wave.

Figure 34.25 When we perform two-slit diffraction with a very weak electron beam, we can see the pattern build up over time. At first (*a*, *b*), the dots that mark electron impacts seem to be scattered randomly, but as more accumulate (*c*, *d*), the diffraction pattern becomes evident.

CONCEPTS

Experiments show that after many electrons are allowed to pass one at a time through the apparatus, the number of electrons arriving on each small region of the screen per unit time is proportional to the intensity that would be observed at that region if light of the appropriate wavelength were shone on the slits. In other words, the *probability* of any single electron arriving at that small region in a fixed time interval corresponds to the intensity of the two-slit interference pattern at that location.

The observation of individual electrons arriving at the screen one after another indicates that the electrons are individual particles. However, if they are particles in the sense we think of for material objects, they must pass through either the right slit or the left slit, and so how can they produce an interference pattern?

The very counterintuitive conclusion is that each electron somehow travels through *both* slits simultaneously! Such a statement is not surprising for a wavefront hitting the two slits, but it goes completely against our intuitive notion of what we call a "particle."

We cannot explain the results of this experiment by concluding that electrons are *waves* because a classical wave could not produce the individual pinpoint images on the screen shown in, say, Figure 34.25*a*. If electrons were waves, the full diffraction pattern would be visible from the start (although it would be very faint). Scientists have concluded that electron behavior can be explained only if an electron has both particle properties and wave properties. This **wave-particle duality**—the possession of both wave properties and particle properties—has been observed not only for electrons but also for all other subatomic particles, for individual atoms, and, as we shall see in the next section, for light.

An expression for the wavelength of a particle, called the **de Broglie wavelength,** was proposed in 1924 by the French physicist Louis de Broglie* and confirmed experimentally a few years later. The de Broglie wavelength is inversely proportional to the momentum of the particle, $\lambda = h/p$, and the proportionality constant, called **Planck's constant,** is $h = 6.626 \times 10^{-34}\ \text{J}\cdot\text{s}$. That this constant is a very small number indicates that the wavelength of macroscopic objects is extremely small. Because waves exhibit diffraction and interference only on length scales comparable to their wavelength, the wave nature of matter has been observed only with subatomic particles, atoms, and molecules. Exercise 34.4 illustrates this point.

EXERCISE 34.4 Electron versus baseball

Calculate the de Broglie wavelength associated with (*a*) a 0.14-kg baseball thrown at 20 m/s and (*b*) an electron of mass 9.1×10^{-31} kg moving at 5.0×10^{6} m/s.

SOLUTION I use the expression $\lambda = h/mv$ for the de Broglie wavelength.

(*a*) $$\lambda_{\text{de Broglie, baseball}} = \frac{6.626 \times 10^{-34}\ \text{J}\cdot\text{s}}{(0.14\ \text{kg})(20\ \text{m/s})} = 2.4 \times 10^{-34}\ \text{m}.$$ ✔

This is 24 orders of magnitude less than the diameter of an atom!

(*b*) $$\lambda_{\text{de Broglie, electron}} = \frac{6.626 \times 10^{-34}\ \text{J}\cdot\text{s}}{(9.1 \times 10^{-31}\ \text{kg})(5.0 \times 10^{6}\ \text{m/s})} = 1.5 \times 10^{-10}\ \text{m} = 0.15\ \text{nm}.$$ ✔

Electron diffraction takes place on distances comparable to the spacing between atoms, whereas a baseball would diffract only through apertures more than 10^{24} times smaller than the typical spacing between atoms. (But the diameter of a baseball is about 0.10 m, so such an experiment is not possible.)

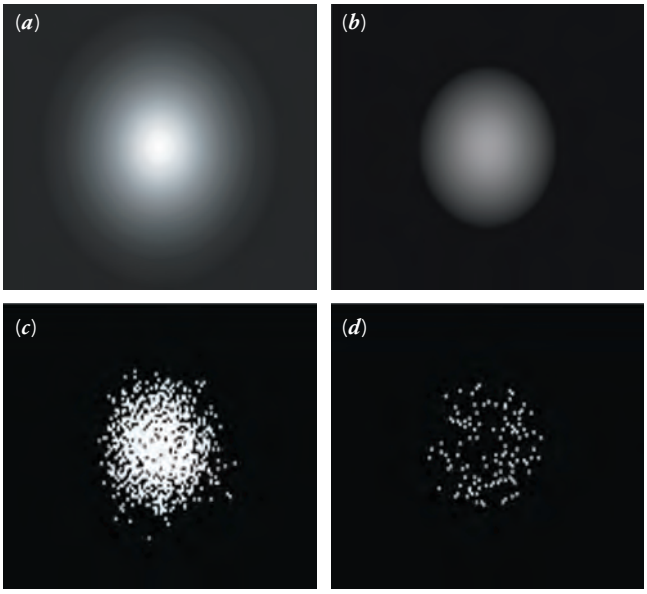
CONCEPTS

34.12 How would the electron diffraction pattern in Figure 34.23 change if the electrons were traveling more slowly?

34.5 Photons

We have now found that particles have wave properties, but these properties are observed only when the particle wavelength is comparable to the size of the objects the particles interact with. Up until now, you have most probably thought of light as being solely a wave. However, the dual wave-particle nature of particles may lead you to wonder whether light, too, is not just a wave but also a particle.

CONCEPTS



34.13 Compare the two-slit interference pattern obtained with electrons (Figure 34.25) with the two-slit interference pattern obtained with light (Figure 34.8). If light and electrons exhibit a similar wave-particle duality, how might you modify the two-slit experiment with light shown in Figure 34.6 to observe light behaving like a particle?

Figure 34.26*a* shows the image obtained by shining a beam of light onto the sensor chip of a digital camera. Pixels in the center of the beam register more light, and therefore the image of these pixels is brighter. The pixels at the edge of the beam are dimmer than those at the center, and outside the beam the pixels are black. If we place in front of the sensor chip a filter that lets only 50% of the light through, the image darkens because the brightness measured by each camera pixel is cut in half (Figure 34.26*b*).

Suppose we keep adding such filters, cutting the beam intensity in half with each addition. Does the image keep getting proportionally darker? If you carry out the experiment, you will discover that it does not, for one of two reasons. The first reason is mechanical: If you use the sensor chip of a digital camera, it stops detecting below a certain level. As you decrease the

*"de Broglie" is pronounced "duh-Br-uh-y," the "y" sounding as in "yikes."

Figure 34.26 Images formed by using the sensor of a digital camera to record increasingly faint beams of light for the same exposure period. The separate dots recorded for the faintest beams reveal the particle-like behavior of light.

intensity of the beam by adding more and more filters, the image first gets grainy and then turns black.

The second reason has to do with the fundamental nature of light. Even if you use an extremely sensitive detector, you will still see that once the beam becomes very weak, adding another filter does not simply halve the image intensity. Instead, as shown in Figure 34.26*c* and *d*, the image of the beam breaks up into individual point-like flashes of equal intensity, resembling the impacts of individual particles. The impacts may at first appear to be randomly distributed within the profile of the beam, but if you accumulate many of these impacts, you discover that the probability of observing a flash in a given location follows the intensity profile of the beam—the impacts are more likely to occur near the center of the beam. In fact, the probability of observing an impact in a particular location is proportional to the intensity of the beam at that location.

As the beam intensity is reduced, the individual impacts become separated in time. No two impacts occur at the same instant. Nor are any "half impacts" ever recorded. From these observations, we conclude that light indeed has particle properties as well as wave properties. The "particles" of light are called **photons.** As we discuss further in Section 34.10, a photon represents the basic unit of a light wave and carries a certain amount of light energy. For a photon of frequency f, this energy equals hf, where h is again Planck's constant. Photons thus represent the quantum of electromagnetic energy—they cannot be subdivided.

EXAMPLE 34.5 Photons from a light bulb

A 50-W incandescent light bulb emits about 5.0 W of visible light. (The rest is converted to thermal energy.) If a circular aperture 5.0 mm in diameter is placed 1.0 km away from the light bulb, approximately how many photons reach the aperture each second?

❶ **GETTING STARTED** This problem asks me to relate the power of light emitted by a light bulb to the rate at which photons pass through a certain area at a particular distance from the bulb. I can approximate the light bulb as a point source of light, meaning that its light is radiated uniformly in all directions. I can also simplify the problem by assuming that all of the light has the same wavelength, and I choose 500 nm for that wavelength. (This is a significant simplification because real light bulbs emit all visible wavelengths of light as well as infrared.)

❷ **DEVISE PLAN** I begin by determining the intensity—the power per unit area—of light produced by the light bulb over a sphere of radius 1 km, which tells me the intensity at the aperture. I can then multiply this intensity by the area of the aperture to obtain the power passing through the aperture, and I multiply that by 1 s to calculate the energy passing through the aperture in 1 s. Finally I shall use the relationship between photon energy and wavelength to determine the number of photons corresponding to that amount of energy.

❸ **EXECUTE PLAN** The intensity at the aperture is given by the power emitted by the bulb divided by the surface area of a sphere of radius 1.0 km:

$$\frac{(5.0\ \text{W})}{(4\pi)(1.0\times10^{3}\ \text{m})^{2}} = 4.0\times10^{-7}\ \text{J/m}^2\cdot\text{s},$$

and therefore the amount of energy passing through a circular hole of radius 2.5 mm in 1.0 s is

$$(4.0\times10^{-7}\ \text{J/m}^2\cdot\text{s})[\pi(2.5\times10^{-3}\ \text{m})^2] = 7.8\times10^{-12}\ \text{J}.$$

The energy of a single photon of wavelength 500 nm is

$$\begin{aligned} E = hf &= \frac{hc_0}{\lambda} \\ &= \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{(500\times10^{-9}\ \text{m})} \\ &= 3.98\times10^{-19}\ \text{J}, \end{aligned}$$

and so the number of photons that corresponds to the amount of energy passing through the hole is

$$\frac{7.8\times10^{-12}\ \text{J}}{3.98\times10^{-19}\ \text{J}} = 2.0\times10^{7}\ \text{photons.}\ \checkmark$$

❹ **EVALUATE RESULT** The number of photons I obtain is great even though I know from experience that the amount of light entering my eye 1.0 km from a 50-W bulb is exceedingly small. However, photons contain a vanishingly

(Continued)

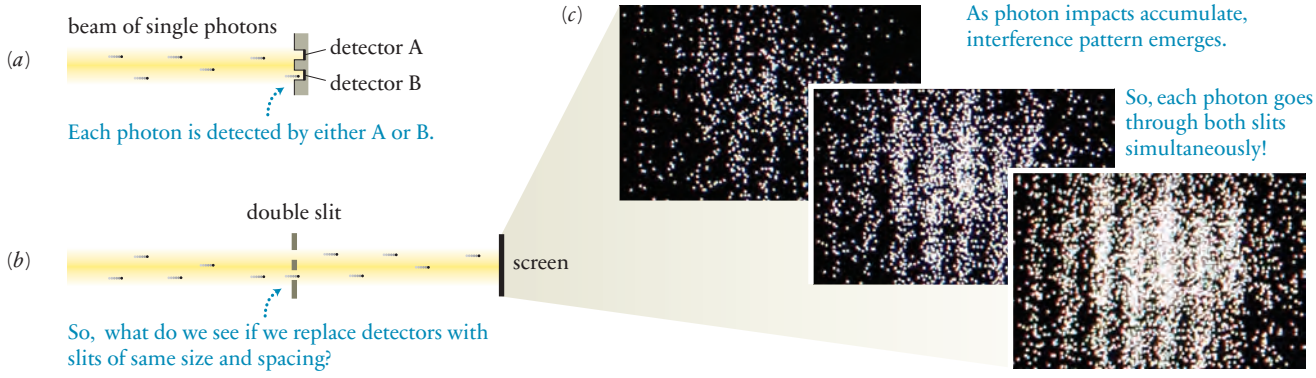
CONCEPTS

small amount of energy (about 10^{-19} J per photon), and so my answer is not implausible.
I assumed that all the photons have the same 500-nm wavelength. In reality the light bulb emits both longer- and shorter-wavelength photons. Suppose various wavelengths are equally distributed on both sides of 500 nm in the spectrum of the light emitted by the bulb. Photons with longer wavelengths have less energy and therefore there are more of them, but photons with shorter wavelengths have greater energy, and so there are fewer of them. The overall result is therefore about the same number of photons as the number I calculated using 500 nm as the only wavelength. To a first approximation, therefore, my result should be correct.

What are photons? How can light be a wave *and* consist of photons that behave like particles? I cannot answer this question because no one really knows the answer. I can, however, describe how photons behave. As you will see, their behavior defies common sense—it is unlike anything we ever experience.

If we reduce the intensity of a light beam (or a beam of any other type of electromagnetic radiation) so greatly that the flashes from the impacts of individual photons are well separated in time and then aim this beam at two very small, very closely spaced detectors (**Figure 34.27*a***), we see that each photon is detected by either one detector or the other. A simultaneous impact on both detectors is never recorded. (The detectors can be made as small as 1 μm wide and spaced by just a fraction of a micrometer.) This observation suggests that each photon takes a definite path—toward either detector A or detector B.

Now imagine replacing the two detectors in Figure 34.27*a* by two narrow slits of the same size as the detectors and placing a screen some distance back from the two slits (Figure 34.27*b*). The pattern on the screen initially looks like random impacts from photons that make it through either one slit or the other. As we accumulate the impacts of many photons, however, an interference pattern emerges (Figure 34.27*c*) that is identical to the one obtained by shining an intense beam of light on the two slits.



Notice that replacing the two detectors with two slits doesn't change anything about the beam or the photons contained in it. However, the experiment using the two detectors suggests that photons are particles detected by one or the other of the detectors; the experiment using the two slits indicates that each photon is a wave traveling through both slits simultaneously! So which is it? Do the photons travel through one slit only or through both? If we physically cover one of the slits (and therefore *force* the photons to go through the other slit), the interference pattern disappears. The pattern that emerges after accumulating many photons behind the slit corresponds to the diffraction pattern of light behind a single slit.

What this means is that photons behave as discrete particles when they are being detected. In transit, however, the wave nature of photons dictates their behavior. In other words, light behaves *both* like a wave and like a particle. It is impossible to explain the results of the above set of experiments by treating light as only a wave or only a particle; it must have qualities of both.

34.14 Figure 34.8 shows the interference pattern obtained by shining a strong laser beam on a pair of slits. If instead a very weak beam is shone on the same slits, so that the photons pass through the slits one photon at a time, at what angles is the probability of observing a particular photon the greatest?

CONCEPTS

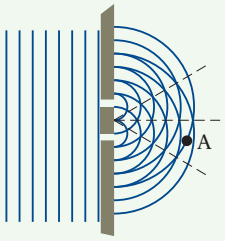


Figure 34.27 When we record a low-intensity beam of light with individual detectors, the beam acts like a stream of particles. Passing it through a double slit, however, causes an interference pattern to emerge.

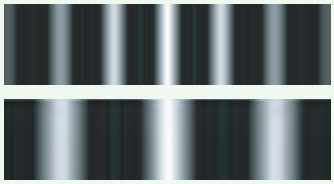
Self-quiz



1. At point A in **Figure 34.28**, do the waves from the two slits add or cancel?

Figure 34.28

2. If the two sets of fringes shown in **Figure 34.29** were produced by the same diffraction grating, which set is the product of the longer-wavelength radiation?

Figure 34.29

3. Coherent light of wavelength λ is normally incident on two slits separated by a distance d. What is the greatest possible fringe order?
4. Consider a proton and an electron moving at the same speed. Which has the longer wavelength?
5. Given the relationship between the energy E of a photon and its frequency f and the de Broglie expression relating momentum $p = mv$ and wavelength λ, determine the ratio E/p for a photon.

Answers

1. At A, the crest of one wave overlaps the trough of the other wave, which means the waves cancel.
2. Because the wavelength is proportional to the sine of the angle the rays make with the normal to the diffraction grating, the fringes with the greater spacing were produced by the longer-wavelength radiation.
3. The fringe order is given by $d \sin\theta = \pm m\lambda$. Because the maximum value of $\sin\theta$ is 1, $d = m_{\max}\lambda$ and so the maximum fringe order is $m_{\max} = d/\lambda$. (Because $m_{\max}$ is an integer, you must truncate the value you obtain by dividing d by λ. For example, if $d/\lambda = 2.8$, then the greatest fringe order is 2.)
4. Because a proton has greater mass than an electron and because the de Broglie wavelength is inversely proportional to mass, $\lambda = h/mv$, the electron has a longer wavelength than the proton.
5. The relationship between the energy of a photon and its frequency is $E = hf$ (see Section 34.5). The de Broglie wavelength is given by $\lambda = h/mv = h/p$, so $p = h/\lambda$. Therefore $E/p = hf/(h/\lambda) = f\lambda = c$, where c is the speed of light.

34.6 Multiple-slit interference

Let us now calculate the interference pattern produced by an electromagnetic wave normally incident on a barrier pierced by multiple closely spaced, very narrow slits. The width of each slit is much less than the wavelength of the radiation, so each slit serves as a point source of radiation. We begin by determining the pattern created when the barrier has just two very narrow slits.

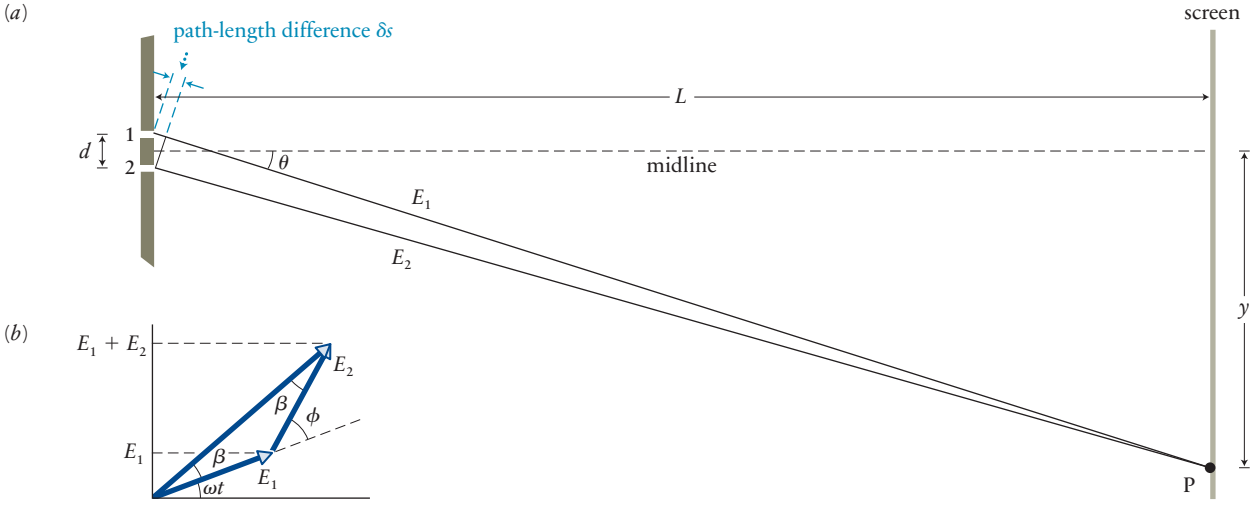
As discussed earlier, the point sources corresponding to the two slits are in phase. Therefore the electric fields of the two waves that reach the screen differ in phase only due to any difference in the distance each wave travels from its slit to the screen. We shall refer to this difference as the *path-length difference* δs (**Figure 34.30*a***). Taking the screen to be at position $x = 0$, we can write the electric fields of the waves traveling in the directions shown in Figure 34.30*a* as

$$E_1 = E_0 \sin \omega t \tag{34.1}$$

and

$$E_2 = E_0 \sin (\omega t + \phi), \tag{34.2}$$

where E_0 is the amplitude of the electric field and ϕ is a phase constant that is equal to the phase difference that results from the path-length difference between the two waves. The phase difference divided by 2π is the fraction of a cycle by which the two waves differ. This equals the path-length difference δs divided by the wavelength, or $\phi/2\pi = \delta s/\lambda$, and so



$$\phi = \frac{2\pi}{\lambda} d \sin \theta, \tag{34.3}$$

where d is the distance between the slits and θ is the angular position where the two rays meet on the screen.

We observe a bright fringe—a maximum in the intensity—when the two rays interfere constructively. This is the case when the phase difference ϕ equals an integer number times 2π:

$$\phi_m = \pm m(2\pi), \quad \text{for } m = 0, 1, 2, 3, \ldots. \tag{34.4}$$

Figure 34.30 (*a*) Interference of light diffracted by two very narrow slits. (*b*) We sum the phasors associated with the electric fields of the coherent light sources at slits 1 and 2.

Combining Eqs. 34.3 and 34.4 and solving for $\sin\theta$ determine the angles θ_m for which bright fringes occur:

$$\sin\theta_m = \pm\frac{m\lambda}{d}, \quad \text{for } m = 0, 1, 2, 3, \ldots. \quad \text{(bright interference fringes)}, \tag{34.5}$$

as we found in Section 34.2.

A dark fringe—a minimum in the intensity—occurs when the two rays interfere destructively. This is the case when the phase difference equals a odd number times π:

$$\phi_n = \pm(2n-1)\pi, \quad \text{for } n = 1, 2, 3, \ldots. \tag{34.6}$$

Substituting ϕ into Eq. 34.3 and solving for $\sin\theta$ determine the angles θ_n for which dark fringes occur:

$$\sin\theta_n = \pm\frac{(n-\frac{1}{2})}{d}\lambda, \quad \text{for } n = 1, 2, 3, \ldots \quad \text{(dark interference fringes)}. \tag{34.7}$$

To calculate the light intensity as a function of θ, we start by determining the sum of the electric fields E_1 and E_2 (Eqs. 34.1 and 34.2) using phasors. The amplitude of the sum of two sinusoidal quantities is equal to the vector sum of the phasors representing those two quantities (see Section 32.6). The phasors that represent E_1 and E_2 and their sum phasor are shown in Figure 34.30*b*. For the isosceles triangle formed by the E_1 and E_2 phasors, the exterior angle ϕ is equal to the sum of the two opposite interior angles β, and so $\beta = \frac{1}{2}\phi$. From this, we calculate the amplitude E_{12} of the sum of the two electric fields:

$$E_{12} = 2(E_0\cos\beta) = 2(E_0\cos\tfrac{1}{2}\phi). \tag{34.8}$$

Because this combined electric field oscillates at the same frequency as the incident wave, the time-dependent electric field at the screen is $E = E_{12}\sin\omega t$. At the central bright fringe, $\theta = 0$ and the two beams are in phase, so $\phi = 0$. The amplitude of E_{12} at the central bright fringe is therefore twice the amplitude of the incident wave, as we would expect.

We found in Chapter 30 (Eq. 30.36) that the intensity S of an electromagnetic wave is proportional to the product of the magnitudes of the electric and magnetic fields E and B: $S = EB/\mu_0$. Because B is proportional to E (Eq. 30.24, $E = Bc_0$), the intensity of light is commonly written in terms of E^2:

$$S = \frac{1}{\mu_0}EB = \frac{E(E/c_0)}{\mu_0}. \tag{34.9}$$

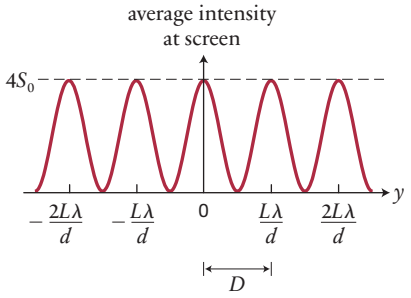
Substituting Eqs. 34.8 and 34.3 into Eq. 34.9 yields

$$S = \frac{4E_0^2}{\mu_0 c_0}\cos^2\left(\frac{\pi d\sin\theta}{\lambda}\right)\sin^2\omega t. \tag{34.10}$$

Visible electromagnetic waves oscillate at such high frequencies (10^{14} Hz to 10^{15} Hz) that we ordinarily measure the time-averaged intensity. The time average of $\sin^2\omega t$ is $\frac{1}{2}$. We can then write the time-averaged intensity of the interference pattern in terms of the time-averaged intensity of the

incident wave: $S_{0,\text{av}} = E_0^2/(2\mu_0 c_0)$. Thus substituting $\frac{1}{2}$ for $\sin^2 \omega t$ and $S_{0,\text{av}}(2\mu_0 c_0)$ for E_0^2 in Eq. 34.10 gives us

$$S_{\text{av}} = 4S_{0,\text{av}} \cos^2\left(\frac{\pi d \sin\theta}{\lambda}\right). \tag{34.11}$$



The maximum intensity of the interference pattern is *not* just the sum of the intensities of the two interfering waves—it is twice the sum! Because intensity is proportional to the square of the electric field, we must add the electric fields and then calculate the intensity from the square of the combined electric field.

34.15 How can the energy of the closed system made up of the two interfering waves remain constant (as the energy law states it must) if the maximum time-averaged intensity is four times the individual time-averaged intensities of the two waves?

Now let us work out how this pattern looks on the screen. If we consider only small angles θ, we can approximate $\sin\theta \approx \tan\theta = y/L$, where y is the position on the screen corresponding to the angle θ measured from the midline between the slits and L is the distance between the screen and the barrier that contains the slits, as shown in Figure 34.30*a*. (Positive y corresponds to positions above the midline; negative y to positions below the midline.) We can then write the time-averaged intensity as

$$S_{\text{av}} = 4S_{0,\text{av}} \cos^2(\phi/2) \approx 4S_{0,\text{av}} \cos^2\left(\pi d \frac{y}{L\lambda}\right). \tag{34.12}$$

Figure 34.31 Average intensity produced on a screen by two-slit interference.

The intensity varies periodically with the phase difference ϕ. Near the central maximum, where θ is small, the intensity also varies periodically with y (**Figure 34.31**).

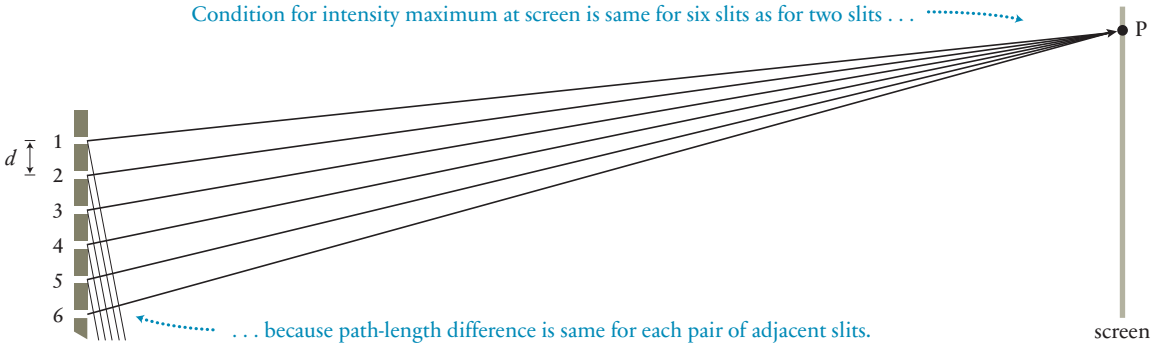
What is the distance D between adjacent intensity maxima of this pattern? Substituting y/L for $\sin\theta$ in Eq. 34.5, we obtain, for the positions of the maxima corresponding to any two values m and $m+1$ of our order integer m,

$$m\lambda = d\frac{y_m}{L} \quad \text{and} \quad (m+1)\lambda = d\frac{y_{m+1}}{L}. \tag{34.13}$$

Subtracting the first of these equation from the second yields

$$\lambda = \frac{d}{L}(y_{m+1} - y_m). \tag{34.14}$$

The distance between adjacent maxima is $y_{m+1} - y_m = D$, so



$$D = \frac{L}{d}\lambda. \tag{34.15}$$

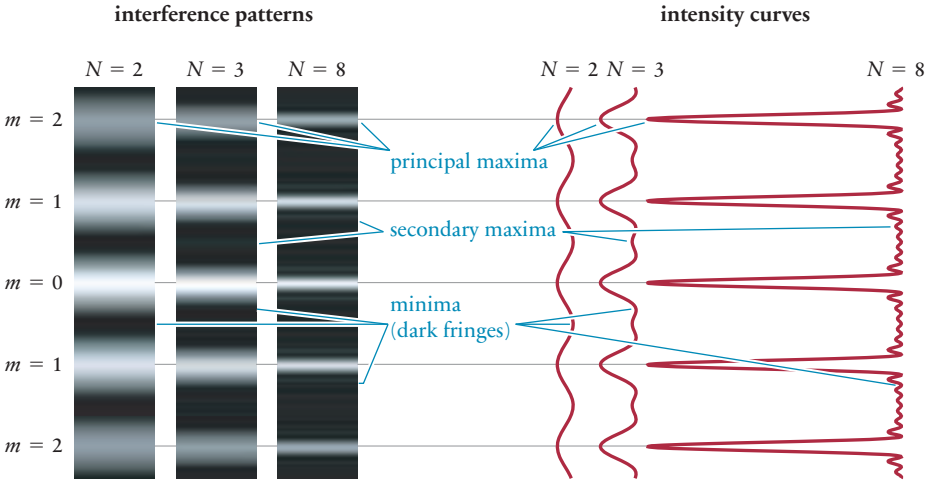
This expression tells us that the distance between the maxima is proportional to the wavelength of the light. The interference pattern "magnifies" the wavelength by the factor L/d.

If there are more than two slits in the barrier, the analysis proceeds in the same fashion as before. **Figure 34.32** shows a wave diffracting through six slits, each separated from its immediate neighbors by distance d. The

QUANTITATIVE TOOLS

Figure 34.32 Interference of light diffracted by six narrow slits.

condition for a maximum in the intensity pattern is the same regardless of the number of slits because if the difference in path length for waves from slits 1 and 2 is λ, then the difference in path length for any pair of adjacent slits is also λ. The principal maxima therefore appear at those locations where



$$d \sin \theta_m = \pm m\lambda, \quad \text{for } m = 0, 1, 2, 3, \ldots \text{ (principal maxima)}, \tag{34.16}$$

just as we found for a two-slit barrier (Eq. 34.5).

The principal maxima occur at the same angles regardless of the number of slits. However, as discussed in Checkpoint 34.5, the *intensity* at the maxima increases with the number of slits. As we found in Section 34.2, as the number of slits increases, the interference fringes also become narrower (**Figure 34.33**). This is so because the minima closest to the m^{th} principal maximum occur for the ratio k/N that is as close as possible to m—namely, $(mN \pm 1)/N$. As the number of slits N becomes very great, the minima lie very close to m and so the interference pattern has extremely sharp maxima separated by broad dark regions with very faint secondary maxima.

As discussed in Section 34.2, an important use of diffraction gratings is to disperse (separate) light into its constituent wavelengths in order to better understand the light source. The amount of information that can be obtained from a spectrum depends on whether the wavelengths of interest can be distinguished from one another in the spectrum (such wavelengths are said to be *resolved*).

Figure 34.33 Interference pattern produced by gratings with two, three, and eight slits.

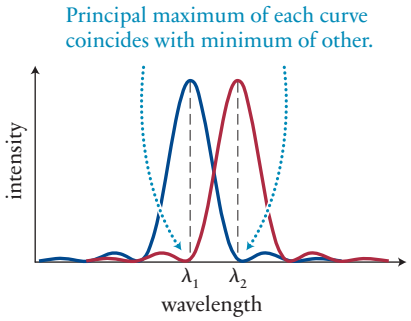


Figure 34.34 Two clearly separated bright fringes for light of different wavelengths.

Two wavelengths can be distinguished from each other if the principal maximum of one falls in the first dark region of the other, as shown in **Figure 34.34**. We found in Section 34.2 that, in general, a minimum occurs for interference through N slits when

$$d \sin \theta_{\text{min}} = \pm \frac{k}{N} \lambda, \quad \text{for integer } k \text{ that is not an integer multiple of } N \text{ (dark interference fringes).} \tag{34.17}$$

The angular position of the principal maxima increases with wavelength. Therefore, two wavelengths λ_1 and λ_2 can be distinguished from each other if the principal maximum for the longer wavelength falls at an angle greater than or equal to the angle for the $n = 1$ minimum for the shorter wavelength. As we first explored in Checkpoint 34.7, the separation between the slits is critical in determining the smallest wavelength difference that can be distinguished (this wavelength difference is called the *resolution*).

EXAMPLE 34.6 Resolution of wavelengths in a diffraction grating

An astronomer wishes to determine the relative heights of the intensity peaks for the bright fringes produced by two wavelengths of radiation emitted by sodium atoms. The wavelengths are 589.0 nm and 589.6 nm, and she uses a diffraction grating with 500.0 slits/mm to disperse the light collected by her telescope. (*a*) In which order are the intensity maxima for these two wavelengths farthest apart from each other: $m = 0$, $m = 1$, or $m = 2$? (*b*) If the part of the diffraction grating covered by the light is 4.000 mm wide, are the second-order principal maxima produced by these two spectral lines distinguishable from each other?

❶ **GETTING STARTED** This problem is about the overlapping diffraction patterns produced by two very similar wavelengths of light as the light passes through a diffraction grating. To answer the questions, I need to calculate the angular positions of the principal intensity maxima for each wavelength in three orders of diffraction. I also need to determine the angular position of the minimum adjacent to the second-order principal maximum for each wavelength, in order to determine whether the second-order principal maxima of the two wavelengths are distinguishable.

❷ **DEVISE PLAN** For part *a*, I can use Eq. 34.16 to locate the $m = 0$, 1, and 2 principal maxima for both wavelengths. For part *b*, I can locate the minimum adjacent to the second-order principal maximum for $\lambda = 589.0$ nm by applying the discussion following Eq. 34.17 and then compare that location with the location of the second-order principal maximum for $\lambda = 589.6$ nm.

❸ **EXECUTE PLAN** (*a*) I start by solving Eq. 34.16 for θ:

$$\theta_m = \pm \sin^{-1}\left(\frac{m\lambda}{d}\right). \tag{1}$$

This result indicates that the principal maxima are farthest apart for $m = 2$.

To calculate the positions of the principal maxima, I substitute the appropriate values of m, λ, and d in Eq. 1. The separation d between the slits is $1/(500 \text{ slits/mm}) = 2.000 \times 10^{-3}$ mm $= 2000$ nm. The $m = 0$ principal maximum occurs at $\theta = 0$ for any wavelength. The first-order principal maxima are located at

$$\theta_{589.0} = \pm \sin^{-1}\left(\frac{589.0 \text{ nm}}{2000 \text{ nm}}\right) = \pm 17.13°$$

$$\theta_{589.6} = \pm \sin^{-1}\left(\frac{589.6 \text{ nm}}{2000 \text{ nm}}\right) = \pm 17.15°,$$

and the second-order principal maxima are located at

$$\theta_{589.0} = \pm \sin^{-1}\left(\frac{2 \times 589.0 \text{ nm}}{2000 \text{ nm}}\right) = \pm 36.09°$$

$$\theta_{589.6} = \pm \sin^{-1}\left(\frac{2 \times 589.6 \text{ nm}}{2000 \text{ nm}}\right) = \pm 36.13°.$$

For these two wavelengths, the second-order principal maxima are the ones farthest apart from each other. ✔

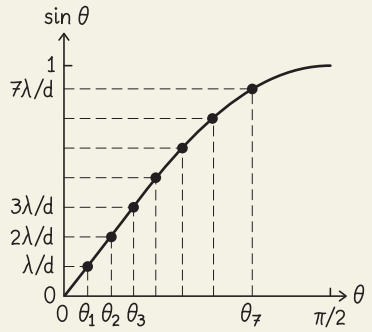
(*b*) Using the information given in the discussion following Eq. 34.17, I can write that the condition for the minimum adjacent to the second-order principal maximum for $\lambda = 589.0$ nm is

$$d \sin \theta_{\text{min},589.0} = \pm \lambda \frac{mN + 1}{N},$$

where I have replaced k in Eq. 34.17 by $mN + 1$ as explained in the discussion preceding that equation. Solving this expression for $\theta_{\text{min},589.0}$ gives

$$\theta_{\text{min},589.0} = \pm \sin^{-1}\left(\frac{\lambda}{d} \frac{mN + 1}{N}\right).$$

A region of the grating 4.000 mm wide contains 2000 slits. Substituting in the preceding expression, I get that, for $\lambda = 589.0$ nm, the minimum adjacent to the second-order principal maximum is at



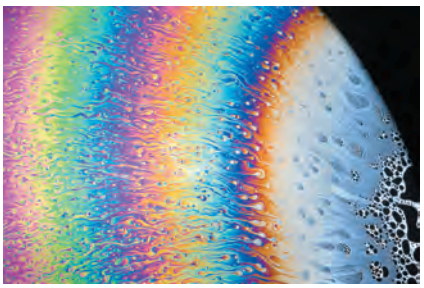
$$\theta_{\text{min},589.0} = \pm \sin^{-1}\left(\frac{589.0 \text{ nm}}{2000 \text{ nm}} \times \frac{4001}{2000}\right) = \pm 36.10°. \checkmark$$

QUANTITATIVE TOOLS

This minimum lies between 36.09°, the second-order principal maximum for $\lambda = 589.0$ nm, and 36.13°, the second-order principal maximum for $\lambda = 589.6$ nm, telling me that the second-order principal maxima for these two wavelengths are distinguishable from each other.

4 EVALUATE RESULT Equation 34.16 tells me that the angles at which principal maxima occur are equal to the inverse sine of integer multiples of λ/d. For small angles $\sin\theta_m \approx \theta_m$, and so the angles θ_m are approximately equally spaced (**Figure 34.35**). As the curve for $\sin\theta$ bends toward the horizontal, however, the distance between adjacent θ_m values increases, in agreement with the result I obtained.

Figure 34.35



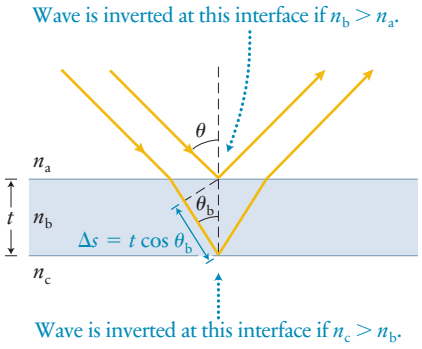
34.16 As the above discussion indicates, the separation distance between the principal maxima for different wavelengths increases as the fringe order m increases. Can you obtain an arbitrarily great separation distance by going to extremely high orders?

34.7 Thin-film interference

A familiar manifestation of the interference of light is the rainbow of colors reflected from thin films such as soap bubbles (**Figure 34.36**). This type of interference occurs in transparent materials whose thickness is comparable to the wavelengths of visible light. When such a thin material (we refer to it as a *film*) is either suspended in air, as in a soap bubble, or supported on a much thicker material with a different index of refraction, as in an oil slick on a puddle of water, white light reflecting from both the front and back surfaces of the film interferes, in the same manner as x rays reflecting from adjacent layers of atoms in a crystal. This is shown schematically in **Figure 34.37**. The film thickness t and index of refraction n_b, together with the angle of incidence, determine the path-length difference and corresponding phase difference between the reflected beams, and therefore determine which colors undergo constructive interference and which undergo destructive interference in any given direction.

Figure 34.36 Soap bubble.

To identify the conditions for constructive and destructive interference, we begin by expressing the electric fields of the waves reflected from the two surfaces, just as we did for waves passing through two slits in the preceding section:



$$E_1 = E_0 \sin(\omega t) \tag{34.18}$$

$$E_2 = E_0 \sin(\omega t + \phi). \tag{34.19}$$

The phase difference ϕ is due to the path-length difference $2\Delta s$ and the effect of the reflections on the phases of each wave. The path-length difference gives rise to a phase difference

$$\phi_{\text{path}} = \frac{2\pi\Delta s}{\lambda_b} = \frac{2\pi(2t\cos\theta_b)}{\lambda/n_b} = \frac{4\pi n_b t\cos\theta_b}{\lambda}, \tag{34.20}$$

Figure 34.37 Thin-film interference.

QUANTITATIVE TOOLS

where the path-length difference Δs and the angle θ_b of the ray relative to the surface normal inside the film are shown in Figure 34.37, and $\lambda_b = \lambda/n_b$ is the wavelength of light inside the film (see Eq. 33.3). Because of refraction, expressing Δs in terms of the angle of incidence θ, instead of the angle in the film θ_b, involves Snel's law and produces a rather complicated result. However, for normal incidence $\cos \theta_b = 1$, and so the expression is greatly simplified.

To determine the phase difference due to the reflections from the two film surfaces, recall the discussion of mechanical waves at boundaries from Section 16.4. We saw there that when a wave pulse is launched in a first medium and travels into a second medium, the pulse is partially reflected and partially transmitted at the boundary. The reflected pulse is inverted relative to the incident pulse if the wave speed c_1 in the first medium is greater than the speed c_2 in the second medium. When $c_1 < c_2$, the incident pulse is not inverted upon reflection.

Let us now extend these ideas to sinusoidal electromagnetic waves. When the incident wave in medium 1 reflects at the boundary with medium 2 of greater index of refraction ($n_1 < n_2$), the speed is less in medium 2 ($c_2 < c_1$), and so the wave is inverted upon reflection. This inverting of the wave is equivalent to the wave undergoing a phase shift of π upon reflection. If instead $n_1 > n_2$, the wave is not inverted and there is no phase shift upon reflection.

A phase shift of π can occur at each of the two interfaces, depending on the refractive indices n_a, n_b, and n_c of the three media, as indicated in Figure 34.37. Thus the phase difference associated just with the reflections for the two reflected waves is

$$\phi_r = \phi_{r2} - \phi_{r1}, \tag{34.21}$$

where ϕ_{r1} and ϕ_{r2} are either π or 0, depending on the values of the indices of refraction. Therefore the total phase difference between the two reflected waves is

$$\phi = \frac{4\pi n_b t \cos \theta_b}{\lambda} + \phi_{r2} - \phi_{r1}. \tag{34.22}$$

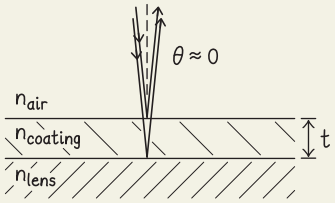
Because ϕ_{r1} and ϕ_{r2} must each be π or 0, the effect of the two reflections on the phase cancels out when $\phi_{r1} = \phi_{r2}$, and the phase difference is due entirely to ϕ_{path}. If ϕ_{r1} is not equal to ϕ_{r2}, then ϕ differs from ϕ_{path} by π, causing the constructive and destructive interference conditions to be switched from what they would be due to just ϕ_{path}.

In our discussion of x-ray diffraction, the light source consisted of monochromatic x rays, and we found that constructive interference between adjacent planes takes place at only certain angles. In the current context—light reflections from thin films—we usually deal with light across the visible spectrum. Therefore ϕ depends on both wavelength and angle of incidence. For normal incidence, Eq. 34.22 simplifies to

$$\phi = \frac{4\pi n_b t}{\lambda} + \phi_{r2} - \phi_{r1} \quad \text{(normal incidence)}. \tag{34.23}$$

Then as before, constructive interference occurs when the phase difference corresponds to an integer number times 2π, and destructive when it corresponds to an odd number times π.

QUANTITATIVE TOOLS



EXAMPLE 34.7 Antireflective coating

Eyeglass lenses made of crown glass ($n = 1.52$) are given a thin coating of magnesium fluoride ($n = 1.38$) to minimize reflection of light from the lens surface. What is the minimum coating thickness for which reflection from the lens surface is minimized?

❶ **GETTING STARTED** Reflection is minimized at all values of the coating thickness that cause the waves reflected from the front coating surface to interfere destructively with those reflected from the back coating surface. My task therefore is to obtain the minimum thickness needed for destructive interference.

❷ **DEVISE PLAN** I see from Eq. 34.22 that the condition for destructive interference depends not only on the coating thickness t and index of refraction n_b but also on two variables I have no values for: the angle of incidence and the wavelength of the light. Thus I must make some simplifying assumptions to solve this problem. As in the text discussion, I shall consider only light normally incident on the coated lens and shall assume the lens and coating surfaces are flat, as shown in my sketch (**Figure 34.38**). I choose a representative visible wavelength, 500 nm—in the middle of the visible spectral range.

Figure 34.38

To obtain the condition for destructive interference, I can use Eq. 34.23 to determine the phase difference ϕ at normal incidence and equate it to an odd number times π radians. To work out the phase shifts ϕ_{r1} and ϕ_{r2} that occur at each reflection, I note that at the air-coating interface the light reflects from a medium for which the index of refraction is greater than that of the medium through which the incident wave travels, and so this wave undergoes a π phase shift upon reflection: $\phi_{r1} = \pi$. The wave that reflects from the coating-lens interface likewise reflects from a medium for which the index of refraction is greater than that of the medium through which the incident wave travels and thus also undergoes a π phase shift ($\phi_{r2} = \pi$). Consequently, ϕ_{r1} and ϕ_{r2} in Eq. 34.23 cancel, leaving only the phase difference due to the path-length difference. The minimum thickness produces a phase difference corresponding to the smallest number of cycles that gives destructive interference—namely, half a cycle.

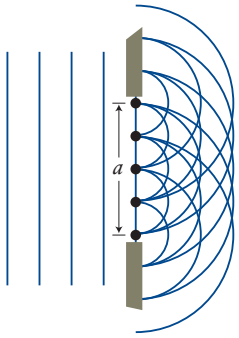
❸ **EXECUTE PLAN** To determine the thickness that produces destructive interference for 500 nm light, I express the phase difference using Eq. 34.23 and equate it to a half-cycle phase difference:

$$\frac{4\pi n_b t}{\lambda} + \phi_{r2} - \phi_{r1} = \pi.$$

Substituting $\phi_{r1} = \phi_{r2} = \pi$, solving for the thickness t, and substituting values give

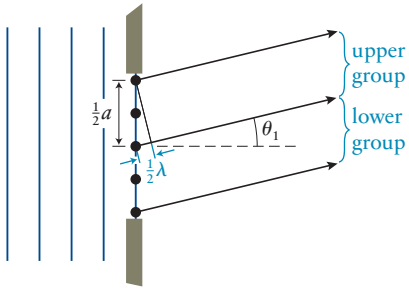
$$t = \frac{\lambda}{4n_b} = \frac{500\text{ nm}}{4(1.38)} = 90.6\text{ nm}. \checkmark$$

❹ **EVALUATE RESULT** The coating is thinner than the wavelength of the light traveling through the coating. That makes sense because, to create destructive interference, the wave that travels through the coating and reflects from the coating-lens interface must travel only half a wavelength farther than the wave that reflects from the air-coating interface.



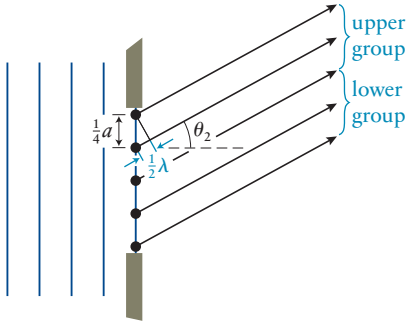
34.17 When oil spreads on water, bands of different colors are visible. What causes the different colors?

34.8 Diffraction at a single-slit barrier



Let us now describe quantitatively the diffraction by a single slit. Huygens' principle (see Section 17.4) allows us to describe the wavefront that reaches the opening as a series of point sources that emit spherical wavelets (**Figure 34.39*a*** on the next page). The wave beyond the slit is the superposition of all these spherical wavelets. In the original direction of propagation, all of the waves add in phase, and as a result the amplitude of the transmitted wave is the maximum possible: the sum of all the individual wave amplitudes. If we divide the rays representing the wavelets into two equal groups, as shown in Figure 34.39*b*, we can pair each ray in the upper half with a corresponding ray in the lower half. In Figure 34.39*b*, for example, we can pair the top ray in the upper group with the top ray in the bottom group. As we discussed in Section 34.2, these rays are essentially parallel when they emerge from the slits; as they travel and intersect at some

Figure 34.39 Diffraction through a narrow slit.



(*a*) Wavefront in slit treated as a series of point sources

(*b*) Condition for first-order dark fringe: path lengths differ by $(\frac{1}{2}a)\sin\theta_1 = \lambda/2$

(*c*) Condition for second-order dark fringe: path lengths differ by $(\frac{1}{4}a)\sin\theta_2 = \lambda/2$

location on a screen placed far to the right of the slits, the rays must travel different distances to reach that location. For rays traveling at an angle θ to the original propagation direction, the difference in path length from two such corresponding rays is $(a/2)\sin\theta$, where a is the width of the aperture. When the path lengths differ by half a wavelength, $(a/2)\sin\theta_1 = \lambda/2$, the rays interfere destructively, which means that the direction for the first-order dark fringe in a single-slit diffraction pattern is given by

$$\sin\theta_1 = \frac{\lambda}{a} \quad \text{(first-order dark diffraction fringe).} \tag{34.24}$$

Dividing the rays into four groups (Figure 34.39*c*) leads to a dark fringe (that is, a minimum in transmitted intensity) when $(a/4)\sin\theta = \frac{1}{2}\lambda$. Thus the direction for the second-order dark fringe is given by

$$\sin\theta_2 = 2\frac{\lambda}{a} \quad \text{(second-order dark diffraction fringe).} \tag{34.25}$$

The general condition for a dark fringe is thus

$$\sin\theta_n = \pm n\frac{\lambda}{a}, \quad n = 1, 2, 3, \ldots$$
$$\text{(dark diffraction fringes).} \tag{34.26}$$

Positive values of $\sin\theta_n$ correspond to dark fringes above the midline, while negative values correspond to dark fringes below the midline.

Calculation of the detailed intensity pattern is beyond the scope of this text, but we can examine some of the details of a representative pattern (**Figure 34.40**). In this single-slit diffraction pattern, the intensity of the first-order ($m = 1$) bright fringe is less than 5% of the intensity of the central ($m = 0$) bright fringe; the intensity of the second-order ($m = 2$) bright fringe is less than 2% of the central bright fringe intensity. In other words, most of the transmitted energy falls within the central peak. In general, in a single-slit diffraction pattern, the intensity is greatest at the central bright fringe and decreases rapidly with distance from the center of the pattern.

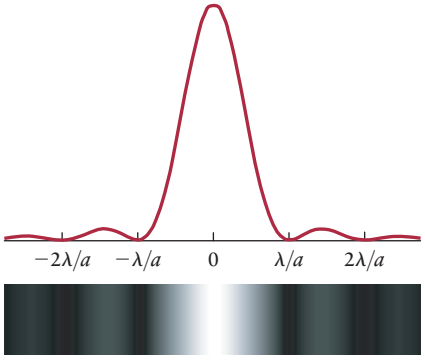
What if we want to calculate the linear positions of the dark diffraction fringes on a screen located a distance L away from a barrier containing a single slit (**Figure 34.41**) rather than the angular positions? For dark fringes located at small angles θ_n from the original direction of wave propagation, we can approximate $\tan\theta_n$ as $\sin\theta_n$:

$$y_n = L\tan\theta_n \approx L\sin\theta_n, \tag{34.27}$$

and so, from Eq. 34.26,

$$y_n = \pm n\frac{\lambda L}{a} \quad \text{(dark diffraction fringes).} \tag{34.28}$$

Figure 34.40 Intensity plot for a single-slit diffraction pattern.



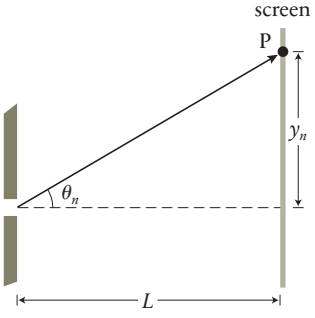


Figure 34.41 Calculating the positions of the dark fringes of a single-slit diffraction pattern.

QUANTITATIVE TOOLS

EXAMPLE 34.8 Spreading light

Consider the diffraction pattern shown actual size in Figure 34.40. If the pattern was formed by light from a 623-nm (red) laser passing through a single narrow slit and the screen on which the pattern was cast was 1.0 m away from the slit, what is the slit width?

❶ **GETTING STARTED** This problem asks me to relate the diffraction pattern in Figure 34.40, which was produced by a setup such as the one shown in Figure 34.41, to the width of the slit that produced it. Thus I need to relate the slit width to fringes whose position I can calculate from the parameters of the problem and can also measure on the image. Because the only variable I know how to calculate is the positions of minima in the diffraction pattern, I can measure the distance between the two first-order minima and relate that distance to the slit width and the geometry of the setup.

❷ **DEVISE PLAN** The positions of the two first-order minima, in terms of wavelength λ, slit-to-screen distance L, and slit width a, are given by Eq. 34.28 with $n = 1$. Subtracting the two values I obtain from each other gives me an expression for the distance between these two minima in terms of λ, L, and a. I am given the values of λ and L, and my task is to determine a. Thus if I know the distance between the n_1 minima, I can calculate a. Because the image in Figure 34.40 is actual size, I can measure this distance directly. Then I can solve Eq. 34.28 for a and insert my known values.

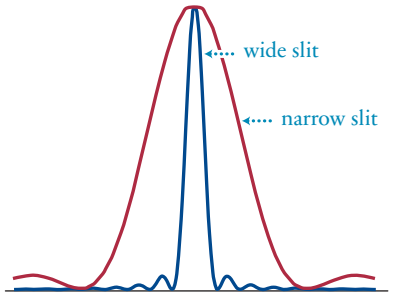
❸ **EXECUTE PLAN** Substituting $n = 1$ into Eq. 34.28 gives the linear positions of the two first-order minima:

$$y_1 = \pm\frac{\lambda L}{a},$$

so the distance w between the two minima is

$$w = \frac{2\lambda L}{a}. \tag{1}$$

I measure the distance between the centers of the two dark fringes on either side of the central bright fringe in Figure 34.40 to be 20 mm. Solving Eq. 1 for the slit width thus gives me



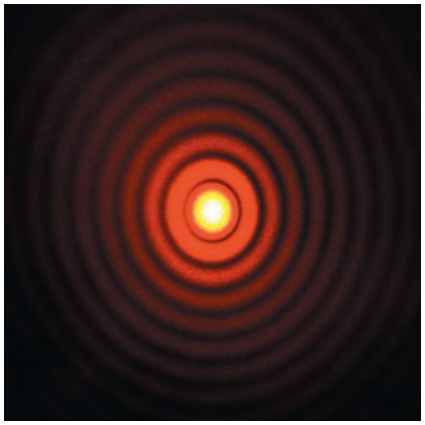
$$a = \frac{2\lambda L}{w} = \frac{2(623\times10^{-9}\text{ m})(1.0\text{ m})}{20\times10^{-3}\text{ m}}$$
$$= 6.2\times10^{-5}\text{ m} = 0.062\text{ mm} \quad ✔$$

❹ **EVALUATE RESULT** The slit width is about a factor of 100 greater than the wavelength of the light, and that ratio is consistent with the general range of slit sizes that produce noticeable diffraction of visible light.

As long as λ is small relative to the slit width a, so that the small-angle approximation for θ_n is valid, most of the diffracted light intensity falls within this region defined by Eq. 1 in Example 34.8. Note that w increases with decreasing a: The narrower the slit, the more the wave spreads out after passing through the slit (**Figure 34.42**). If the slit width is equal to or less than the wavelength of the light, there are no dark fringes, as we found in Checkpoint 34.16. The wave simply spreads out in all directions behind the slit, which means the slit behaves as a point source.

34.18 Using Eq. 34.24, calculate the angle at which the first dark fringe occurs when (*a*) $a < \lambda$ and (*b*) $a \gg \lambda$. Interpret your results.

Figure 34.42 The width of the central maximum in a diffraction pattern decreases as the slit is widened.



34.9 Circular apertures and limits of resolution

When light passes through a circular aperture, the symmetry of the aperture causes the resulting diffraction pattern also to be circular (**Figure 34.43**). A circular central bright fringe is surrounded by circular dark diffraction fringes and additional diffraction bright fringes. The central bright fringe is called the *Airy disk*, after the British astronomer and mathematician Sir George Airy, who developed the first detailed description of diffraction in 1835. Calculation of the circular diffraction pattern is rather involved, so all I shall do here is state the location of the first dark fringe. When light is diffracted by a circular aperture of diameter d, the first dark fringe occurs at angle θ_1 given by

$$\sin\theta_1 = 1.22\,\frac{\lambda}{d}. \tag{34.29}$$

The result is similar to the one obtained in Eq. 34.24 for a slit of width a, except that now the sine of the angle is increased by a factor of 1.22.

Figure 34.43 Diffraction pattern of light passing through a circular aperture.

The increase in the angle for the same wavelength and aperture size can qualitatively be understood as follows: Equation 34.24 is obtained by considering the interference between wavelets coming from a slit whose width is a everywhere. A circular aperture has width d only across a diameter; the rest of the aperture is narrower. As the aperture gets narrower, diffraction through it becomes more pronounced. The factor of 1.22 quantitatively accounts for the varying horizontal width of the circular aperture.

The angular size of the Airy disk given in Eq. 34.29 determines the minimum angular separation of two point sources that can be distinguished by observing them with a (circular) lens—*regardless* of the magnification of the lens! To understand what this means, imagine imaging two distant, closely spaced point sources with a lens. These sources could be anything, from stars to organelles in a biological cell. The sources are not coherent, and so we can consider the Airy disks formed by the light from each source separately without considering interference between sources.

If there is overlap in the Airy disks of the images observed through the lens, it is difficult to tell whether there are two point sources or just one. Two objects being observed through a lens are just barely distinguishable when the center of one diffraction pattern is located at the first minimum of the other diffraction pattern. This happens when the angular separation between the two objects is at least the angle given in Eq. 34.29. If this is the case, we say that the two objects are *resolved*. This condition for distinguishability is called **Rayleigh's criterion.**

Because the diameter d of the lens is always much greater than the wavelength of the light, the angle in Eq. 34.29 is always small. Thus the minimum angular separation θ_r for which two sources can be resolved is approximately equal to the sine of the angle

$$\theta_r \approx \sin \theta_r = 1.22 \frac{\lambda}{d}. \tag{34.30}$$

Two objects that are separated by an angle equal to or greater than θ_r satisfy Rayleigh's criterion. For this reason, the closest two objects can be to each other and still be distinguished with an optical instrument such as a microscope or telescope depends not on the magnification but on the wavelength of the light and the size of the smallest aperture in the instrument.

Figure 34.44 The resolution of these two stars improves as the aperture is made larger.

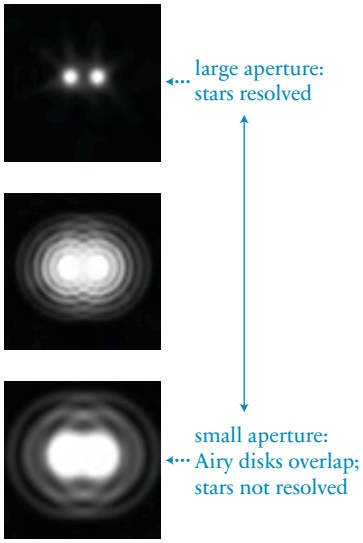


Figure 34.44 shows the images of two stars obtained with a telescope. An aperture placed in front of the lens shows the effects of diffraction. When the opening of the aperture is small (bottom image in Figure 34.44), the images of the two stars are merged—the two stars cannot be resolved. As the aperture is opened, θ_r decreases and the two images separate cleanly.

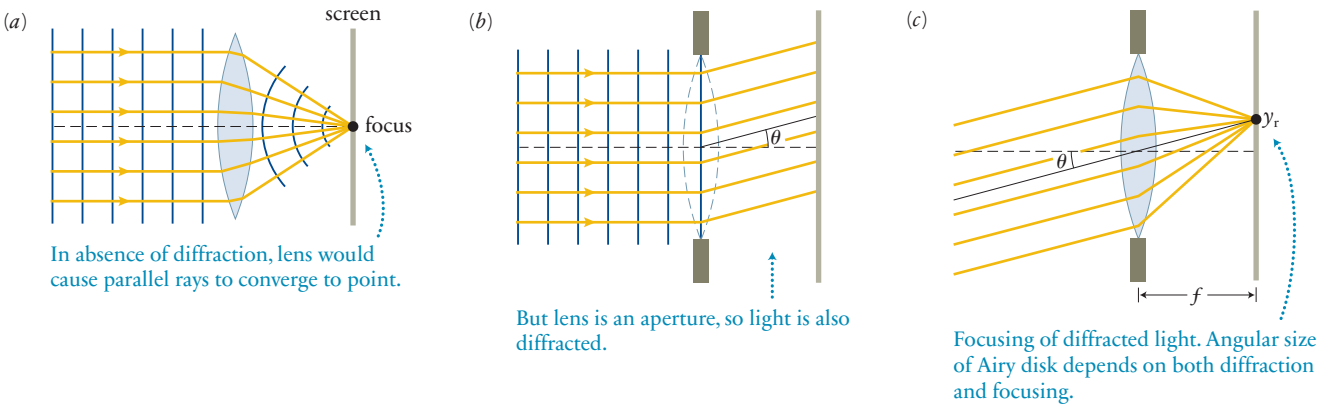


Diffraction also determines the linear size of the images of point sources. In Chapter 33, we stated that the image of a point source formed on a screen by a lens is a point. **Figure 34.45*a*** shows parallel rays from a distant point source focused by a lens onto a screen placed in the focal plane of the lens. Without diffraction, the image formed by these rays would be an infinitesimally small point. In fact, because the aperture through which the light passes—the lens—has a finite diameter, such rays do not focus to an infinitely small point, and the image formed is a diffraction pattern just like that shown in Figure 34.43. The angular size of the central bright fringe of this diffraction pattern—in other words, the Airy disk—is given by Eq. 34.29.

To calculate the radius of the Airy disk formed in the focal plane of the lens,* we must account for both diffraction and focusing. Figure 34.45*b*

*The radius of the Airy disk is smallest when the screen is in the focal plane of the lens, and it increases as the screen is moved closer to or farther from the lens.

QUANTITATIVE TOOLS

Figure 34.45 Analyzing the diffraction limit of a lens.

shows the diffraction of light through an aperture of the same diameter as the lens. Light that originally traveled parallel to the lens axis is diffracted by an angle θ. Now consider how the lens focuses the diffracted light. Parallel rays that make an angle θ with the lens axis are focused at a point located a distance y above the axis (Figure 34.45*c*, see also Figure 33.27). This distance y is given by $y = f \tan\theta$, where f is the focal length of the lens.

Our next step in determining the Airy disk radius is to calculate the distance y_r from the center of the disk to the first dark fringe in the diffraction pattern, which is found at the angle given by Eq. 34.29. In the small-angle limit, $\sin\theta \approx \tan\theta$ and so we can substitute $\sin\theta_r = y_r/f$ into Eq. 34.29, giving

$$y_r = 1.22\,\frac{\lambda f}{d}. \tag{34.31}$$

This expression gives the radius y_r of the Airy disk and the minimum size of the area to which light can be focused with light of wavelength λ by a lens of focal length f and diameter d. The best ratio of f/d that can be achieved with a lens is approximately equal to one, and so the smallest diameter to which light can be focused is about 2.5λ. This means that the smallest diameter of "points" in the resulting image is also 2.5λ.

This diffraction-determined minimum size of the features in an image is commonly called the *diffraction limit*. An industry in which the diffraction limit poses a serious problem is the manufacture of integrated circuits, such as computer chips. The transistors and logic gates described in Section 32.4 are produced by a series of processes known as *photolithography*, in which the semiconductor substrate is coated with a polymer that is sensitive to ultraviolet light. The polymer is then exposed to ultraviolet light in the pattern of the desired metal electrodes. This pattern of light is produced by illuminating a metal mask with holes in the shape of the electrodes and then imaging the resulting pattern of light onto the surface. Finally, the exposed polymer is dissolved with a chemical rinse, leaving the semiconductor surface exposed where metal is desired. The metal is then deposited in a subsequent step.

The smallest electrode that can be made by this process is therefore determined by the diffraction limit for the ultraviolet light ($\lambda \leq 150$ nm) used to produce the pattern. With ordinary optical technology, this requires electrodes to be at least 300 nm wide. Many researchers are searching for other ways to produce electrodes that are not limited by diffraction.

EXERCISE 34.9 A point is not a point

A magnifying glass that has a focal length of 0.25 m and a diameter of 0.10 m is used to focus light of wavelength 623 nm. (*a*) What is the radius of the smallest Airy disk that can be produced by focusing light with this lens? (*b*) How large is the Airy disk formed when this lens focuses a laser beam that has a 2.0-mm diameter?

SOLUTION (*a*) The radius of the smallest Airy disk is given by Eq. 34.31 with d equal to the diameter of the lens:

$$y = 1.22\frac{(623\times10^{-9}\text{ m})(0.25\text{ m})}{0.10\text{ m}} = 1.9\times10^{-6}\text{ m} = 1.9\ \mu\text{m}.$$ ✔

The minimum spot size is about three times greater than the wavelength of the light.

(*b*) In this case the radius is given by Eq. 34.31 with d equal to the diameter of the laser beam. I must use the beam diameter because the beam does not make use of most of the area of the lens but effectively defines its own aperture. I therefore have

$$y = 1.22\frac{(623\times10^{-9}\text{ m})(0.25\text{ m})}{0.0020\text{ m}} = 9.5\times10^{-5}\text{ m} = 95\ \mu\text{m}.$$ ✔

This Airy disk is much bigger than the one found in part *a*. This Airy disk radius means the central bright fringe has a diameter of 190 μm = 0.19 mm, which is smaller than the original beam diameter due to the focusing of the lens. Because the laser beam is much smaller than the diameter of the lens, it cannot be effectively focused by this lens. The diffraction partially cancels the focusing.

EXAMPLE 34.10 Blurry images

The width of one pixel in the sensor for a digital camera is about 2.0 μm. If the camera lens has a diameter of 40 mm and a focal length of 30 mm, is the resolution of the resulting image limited by the lens or the sensor?

❶ **GETTING STARTED** This problem involves comparing, for the image formed by a digital camera, the resolution limit due to diffraction and the limit due to the size of the pixels in the sensor. The limit due to diffraction is the size of the image of a point source; the limit due to the sensor is the width of a single pixel. The greater limit determines the image resolution. The problem does not specify the wavelength of the light involved, but because the problem is concerned with forming images with visible light, I choose λ = 500 nm, near the center of the visible spectrum.

❷ **DEVISE PLAN** The diffraction-limited image of a point source is the Airy disk at the center of the diffraction pattern, so I can use Eq. 34.31 to obtain the radius of the Airy disk formed by the camera. I can then compare the diameter (not the radius) of that disk with the width of a pixel. Whichever is greater limits the resolution possible for the image.

❸ **EXECUTE PLAN** Substituting the values given into Eq. 34.31, I obtain for the Airy disk radius

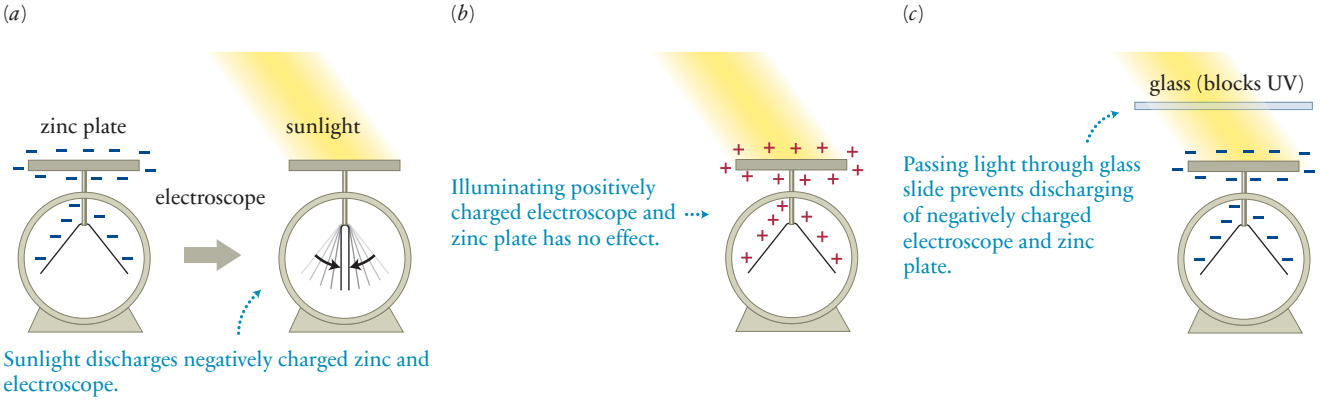
$$y = 1.22\frac{\lambda f}{d} = 1.22\frac{(0.500\times10^{-6}\text{ m})(30\times10^{-3}\text{ m})}{40\times10^{-3}\text{ m}} = 0.46\times10^{-6}\text{ m} = 0.46\ \mu\text{m}.$$

The diameter of the Airy disk is thus $2y$ = 0.92 μm. This is significantly less than the pixel width, which means the resolution of the image is limited by pixel width rather than by diffraction. ✔

❹ **EVALUATE RESULT** My result for the radius of the Airy disk is reasonable because typically the diffraction-limited width of the image of a point source is comparable to the wavelength of light emitted by the source. (Note that if I had chosen λ = 700 nm, the longest visible wavelength, the Airy disk radius would increase only by a factor of 700/500 = 1.4 and thus its diameter, 1.3 μm, would still not exceed the pixel width. If I had chosen a wavelength shorter than 500 nm, the Airy disk diameter would be less than my calculated value. So my conclusion is the same for any visible wavelength: The resolution is limited by the pixel width.)

34.19 Which of these three lenses offers (*a*) the highest resolution and (*b*) the lowest resolution: (*i*) f = 10 mm, d = 8 mm; (*ii*) f = 15 mm, d = 10 mm, (*iii*) f = 20 mm, d = 18 mm?

34.10 Photon energy and momentum



In Chapter 30 we described light as an electromagnetic wave that has a wavelength λ and a frequency f and moves in vacuum at speed c_0, such that

$$c_0 = \lambda f. \tag{34.32}$$

We also found that the energy density in the electromagnetic wave is proportional to the square of the amplitude of the electric field oscillation. In

QUANTITATIVE TOOLS

Figure 34.46 The photoelectric effect.

addition, the experiment described in Section 34.4 suggests that light has particle properties. If light always propagates at speed c_0 in vacuum, what determines its energy? And if light is a particle that has energy, shouldn't it also have momentum?

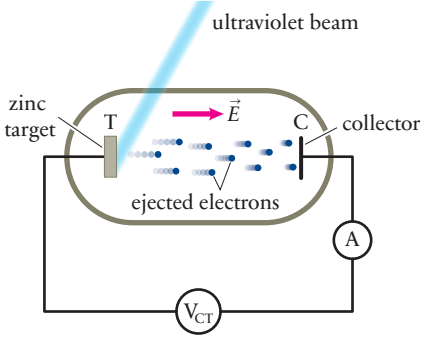
The answer to the first question is provided by the **photoelectric effect,** a surprising phenomenon that cannot be explained by thinking of light as a wave (**Figure 34.46**). Place a piece of metal, such as zinc, on an electroscope (see Section 22.3) that is negatively charged, as shown in Figure 34.46*a*. Some of the charge immediately moves to the zinc so that it, too, is negatively charged. If you then shine sunlight on the metal, the light discharges the zinc and the electroscope. If the electroscope is positively charged, however, as in Figure 34.46*b*, nothing happens when light shines on it. If we place a piece of glass in the beam of light (Figure 34.46*c*), nothing happens even if the zinc plate is negatively charged and the light is very intense.

What is going on? In the situations of Figures 34.46*a* and *b*, the light knocks electrons out of the zinc plate. When the plate is initially negatively charged, like-charge repulsion causes the ejected electrons to accelerate away from the plate. When the plate is initially positively charged, opposite-charge attraction causes the ejected electrons to be attracted back to the plate, so that the charge on the plate does not change. Ultraviolet radiation cannot pass through ordinary glass, and thus we conclude from the situation in Figure 34.46*c* that ultraviolet light is essential in order for electrons to be ejected.

The apparatus illustrated in **Figure 34.47** is used to study the photoelectric effect. It allows us to measure the energy of the ejected electrons while separately controlling either the wavelength or the intensity of the light. A zinc target T is placed in an evacuated quartz bulb (quartz is transparent to ultraviolet light), along with another metal electrode called the collector (C). A power supply is used to maintain a constant potential difference V_{CT} between the target and the collector. The current from the target to the collector is measured with an ammeter. If the target is kept at a lower potential relative to the collector, so that V_{CT} is negative, any electrons ejected from the target by the light are accelerated by the electric field and move to the collector. With negative V_{CT}, the current measured is proportional to the intensity of the light source, suggesting that ejecting each electron requires a certain amount of light energy.

If the potential difference V_{CT} is made slightly positive (so that the target is at a higher potential relative to the collector), there is a small current detected, but the electric field between T and C now *slows down* any ejected electrons that initially move toward the collector. As V_{CT} increases, there is a certain value of V_{CT} at which the flow of electron stops completely, as

Figure 34.47 Apparatus to study the photoelectric effect. The potential difference V_{CT} is positive when $V_T > V_C$.



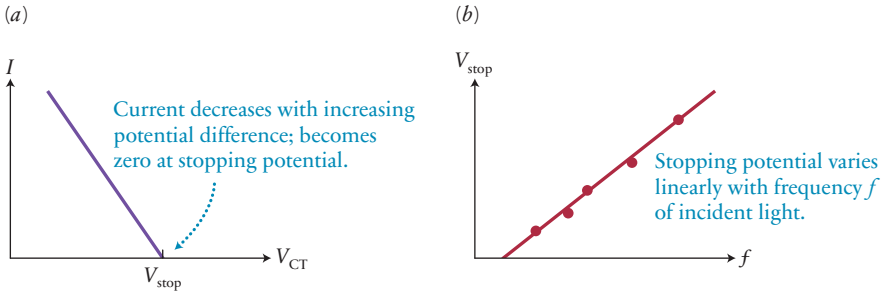


Figure 34.48 For the circuit in Figure 34.47, the current as a function of potential difference and the stopping potential difference as a function of the frequency of the incident light.

shown in the graph of current I versus V_{CT} in **Figure 34.48a**. At this potential difference, called the *stopping potential difference*, the current is zero regardless of the intensity of the incident light. No matter how bright the light, there is no current between the target and the collector. This finding implies that the maximum kinetic energy with which the electrons leave the target does not depend on the intensity (and thus the incident power) of the light.

If we measure the kinetic energy of the ejected electrons (for $V_{CT} < V_{stop}$) directly, we discover that not all of them have the same kinetic energy. This happens because although the amount of energy absorbed from the photons is the same for all electrons, the energy required for the electron to make its way from its initial location in the target to the surface depends on the depth from which the electron is liberated. As a result, electrons released from the surface of the target have the maximum possible kinetic energy, which equals the amount of energy transferred to each electron by the light minus the energy required to liberate the electron from the metal.

For a given potential difference between the target and the collector, the electric field does work $-eV_{CT}$ on an electron as the electron moves from the target to the collector (see Eq. 25.17). The change in the electron's kinetic energy is thus

$$\Delta K = -eV_{CT}. \tag{34.33}$$

Given that the electrons just barely reach the collector at the stopping potential difference, we know that their final kinetic energy is zero, and so for these electrons $\Delta K = K_f - K_i = -K_i$. The maximum kinetic energy with which the electrons leave the target is thus

$$K_{max} = K_i = eV_{stop}. \tag{34.34}$$

Another clue to understanding the experiment in Figure 34.47 emerges when we change the frequency of the incident light and again measure the target-to-collector current as a function of V_{CT}. We observe that the stopping potential difference depends on the frequency; plotting this stopping potential difference as a function of the frequency of the light yields the results shown in Figure 34.48*b*.

34.20 (*a*) What does Figure 34.48*b* tell you about the relationship between the frequency of the incident light and the maximum kinetic energy of the ejected electrons? (*b*) What does the intercept of the line through the data points and the horizontal axis represent?

As Checkpoint 34.20, part *a* shows, the maximum kinetic energy of the ejected electrons depends on the frequency of the incident light, not its intensity. Electrons ejected by ultraviolet light, which has a higher frequency

QUANTITATIVE TOOLS

than visible light, have more kinetic energy than electrons ejected by visible light. (This is why putting glass in the beam of light in the experiment shown in Figure 34.46 essentially eliminates the effect. Although some electrons are ejected by the visible light, those electrons are liberated with less kinetic energy and are more likely to return to the target.) Furthermore, as you discovered in answering Checkpoint 34.20, part *b*, there is a certain minimum frequency of light below which electrons are not ejected at all, regardless of the intensity of the light.

Why does the photoelectric effect require us to think of light as a particle rather than as a wave? The stopping potential difference gives us the maximum kinetic energy with which electrons are released; the light must supply at least this much energy to the electrons in order to eject them. If light could be understood solely as a wave, the intensity of the wave, not its frequency, would determine the maximum amount of energy it could deliver to the electrons. Because the stopping potential difference depends not on light intensity but on frequency, we infer that light carries its energy in energy quanta and that the energy in each quantum is proportional to the frequency.

The photons described in Section 34.5 are these quanta. When an electron absorbs a photon, the electron acquires the photon's entire energy—the electron cannot absorb just part of a photon. The photon's energy frees the electron from the material and gives it additional kinetic energy. If we denote the minimum energy required to free the electron by E_0, we have

$$E_{\text{photon}} = hf = K_{\max} + E_0, \tag{34.35}$$

where $K_{\max}$ is the maximum kinetic energy of the electron as it is ejected. The energy E_0, called the **work function** of the target metal, is a property of the metal that measures how tightly electrons are bound to the metal.

The value of Planck's constant h can be determined by using the relationship between V_{stop} and f given in Figure 34.48*b*. Substituting Eq. 34.34 into Eq. 34.35 and solving the result for V_{stop}, we get

$$V_{\text{stop}} = \frac{h}{e} f - \frac{E_0}{e}. \tag{34.36}$$

This result shows that V_{stop} depends linearly on f and that the slope of the line in Figure 34.48*b* is h/e. By measuring the slope in Figure 34.48*b* and dividing that slope by the charge e of the electron, one obtains $h = 6.626 \times 10^{-34}$ J·s, the value given in Section 34.4.

As discussed in Section 34.5 and expressed in Eq. 34.35, Planck's constant relates the energy and frequency of a photon, $E_{\text{photon}} = hf_{\text{photon}}$, and in Section 34.4 we learned the relationship between the momentum and the wavelength of an electron (or anything else that is ordinarily thought of as a particle): $\lambda_{\text{electron}} = h/p_{\text{electron}}$. Because of the wave-particle duality, we can apply this expression for wavelength to photons as well as electrons: $\lambda_{\text{photon}} = h/p_{\text{photon}}$. If we calculate the momentum of a photon from its wavelength using this expression and then substitute $\lambda = c_0/f$, we see that the momentum of a photon is proportional to its energy:

$$p_{\text{photon}} = \frac{h}{\lambda_{\text{photon}}} = \frac{hf_{\text{photon}}}{c_0} = \frac{E_{\text{photon}}}{c_0}. \tag{34.37}$$

If we substitute this result into the equation relating energy and momentum derived in Chapter 14 (Eq. 14.57)

$$E^2 - (c_0 p)^2 = (mc_0^2)^2, \tag{34.38}$$

the left side of this equation becomes zero, and so we see that photons have zero mass ($m_{\text{photon}} = 0$). We derived Eq. 34.38 for particles that have nonzero mass. Now we see that we can treat photons as massless "particles of light." While these particles have no mass, they do have both momentum and energy:

$$E_{\text{photon}} = hf_{\text{photon}} \tag{34.39}$$

$$p_{\text{photon}} = \frac{hf_{\text{photon}}}{c_0}, \tag{34.40}$$

and, unlike ordinary particles, they always move at the speed of light c_0 in vacuum (or air). Remember also that the mass of a particle is associated with the internal energy of that particle (Eq. 14.54), so $m_{\text{photon}} = 0$ means that photons have no internal energy and therefore no internal structure.

EXAMPLE 34.11 Photoelectric effect

Light of wavelength 380 nm strikes the metal target in Figure 34.47. As long as the potential difference V_{CT} between the target and the collector is no greater than +1.2 V, there is a current in the circuit. Determine the longest wavelength of light that can eject electrons from this metal.

❶ **GETTING STARTED** To solve this problem, I recognize that the longest wavelength of light that can eject electrons corresponds to the lowest-energy photon that can eject an electron; this energy is equal to the work function. I therefore need to use the idea of stopping potential difference to determine the work function from the information given in the problem.

❷ **DEVISE PLAN** The fact that the current is zero when $V_{CT} > +1.2$ V tells me that the stopping potential difference is 1.2 V. Equation 34.36 gives the relationship between photon frequency and stopping potential difference. I can use the relationship between photon frequency and wavelength to rewrite Eq. 34.36 in terms of wavelength. Finally, Eq. 34.35 shows that the lowest photon energy comes when $K_{\max} = 0$, so that the lowest energy equals the work function E_0. Therefore I must determine the wavelength of a photon that has an energy equal to the work function, and for this I can use the expression I developed for the relationship between photon energy and wavelength.

❸ **EXECUTE PLAN** Solving Eq. 34.36 for E_0, then substituting c_0/λ for f and inserting numerical values, I obtain

$$\begin{aligned} E_0 &= \frac{hc_0}{\lambda} - eV_{\text{stop}} \\ &= \frac{(6.626 \times 10^{-34}\ \text{J}\cdot\text{s})(2.998 \times 10^{8}\ \text{m/s})}{380 \times 10^{-9}\ \text{m}} \\ &\quad - (1.602 \times 10^{-19}\ \text{C})(1.2\ \text{V}) \\ &= 3.3 \times 10^{-19}\ \text{J}, \end{aligned}$$

where I have used the equality 1 V ≡ 1 J/C (Eq. 25.16). Because the longest wavelength that can eject electrons has energy equal to the work function, I solve $E_0 = hc_0/\lambda$ for λ and substitute the value of E_0 I just calculated to obtain this maximum wavelength:

$$\begin{aligned} \lambda = \frac{hc_0}{E_0} &= \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{3.3 \times 10^{-19}\ \text{J}} \\ &= 0.60\ \mu\text{m}. \checkmark \end{aligned}$$

❹ **EVALUATE RESULT** This value for the longest wavelength that can eject electrons is greater than 380 nm, the wavelength corresponding to the stopping potential difference of 1.2 V, as it should be.

34.21 A photon enters a piece of glass for which the index of refraction is about 1.5. What happens to the photon's (*a*) speed, (*b*) frequency, (*c*) wavelength, and (*d*) energy?

QUANTITATIVE TOOLS

Chapter Summary

Diffraction (Sections 34.1–34.3, 34.6)

Concepts Light is diffracted as it passes through an opening only when the width of the opening is either comparable to or smaller than the wavelength of the light.

Interference fringes are a pattern of alternating bright and dark bands (called *fringes*) cast on a screen by coherent light passing through two or more slits. **Fringe order** is the numerical ordering of bright and dark fringes. The central bright fringe is the *zeroth-order bright fringe*, the bright fringes to the left and right of it are the first-order bright fringes, the next bright fringes to the left and right are the second-order bright fringes, and so on. The two dark fringes bordering the central bright fringe are the first-order dark fringes, and so on.

When the light passes through two slits, the interference pattern formed on a screen behind the slits consists of alternating bright and dark fringes. When light passes through three or more slits, each dark fringe contains one or more regions that are not as bright as the bright fringes but not completely dark. In these patterns, the brightest fringes are *principal maxima*, and the fainter bright regions are *secondary maxima*.

A **diffraction grating** is a barrier containing a large number of equally spaced slits or grooves. A transmissive diffraction grating contains slits that transmit light, and a reflective diffraction grating contains grooves that reflect light.

The **Bragg condition** states that a crystal reflects x rays of wavelength λ only at angles of incidence relative to the crystal plane given by $2d \cos\theta = m\lambda$, where m is an integer and d is the distance between adjacent crystal planes.

Quantitative Tools When light of wavelength λ passes through two slits a distance d apart, the bright fringes occur at angles given by

$$\sin\theta_m = \pm\frac{m\lambda}{d}, m = 0, 1, 2, 3, \ldots, \tag{34.5}$$

and the dark fringes occur when

$$\sin\theta_n = \pm\frac{\left(n-\frac{1}{2}\right)}{d}\lambda, n = 1, 2, 3, \ldots. \tag{34.7}$$

The integers m and n give the **fringe order.**

For light passing through N slits, the *principal maxima* occur when

$$d\sin\theta_m = \pm m\lambda, m = 0, 1, 2, 3, \ldots, \tag{34.16}$$

and the dark fringes occur when

$$d\sin\theta_{\text{min}} = \pm\frac{k}{N}\lambda, \tag{34.17}$$

where k is an integer that is not an integer multiple of N.

Thin-film interference (Section 34.7)

Concepts Thin-film interference occurs in transparent materials whose thickness is comparable to one of the wavelengths of visible light. Light reflecting from the front surface of the material interferes with light reflecting from the back surface.

Quantitative Tools Light reflects from a thin film of thickness t and index of refraction n_b. At normal incidence of the light, the phase difference ϕ between the light rays reflected from the front and back surfaces of the film is

$$\phi = \frac{4\pi n_b t}{\lambda} + \phi_{r2} - \phi_{r1}, \tag{34.23}$$

where the phase shifts ϕ_{r1} and ϕ_{r2} are due to reflection at the front and back surfaces. Each phase shift must be either 0 or π, depending on the indices of refraction of the media in front of and behind the film.

Diffraction by single slits and circular apertures (Sections 34.8, 34.9)

Concepts Light passing through a circular aperture is diffracted, and the interference fringes are circular. The central bright fringe is called the *Airy disk*.

Quantitative Tools When light is diffracted by a thin slit of thickness a, the dark fringes occur when

$$\sin\theta_n = \pm n\frac{\lambda}{a},\ n = 1, 2, 3, \ldots. \tag{34.26}$$

When light is diffracted by a small circular aperture of diameter d, the first dark fringe occurs when

$$\sin\theta_1 = 1.22\frac{\lambda}{d}. \tag{34.29}$$

Rayleigh's criterion: The minimum angular separation θ_r for which two light sources can be *resolved* by a lens of diameter d is

$$\theta_r \approx 1.22\frac{\lambda}{d}. \tag{34.30}$$

Matter waves and photons (Sections 34.4, 34.5, 34.10)

Concepts **Wave-particle duality** says that particles and light have both wave and particle properties.

The **de Broglie wavelength** expresses the wavelength of a particle.

A **photon** is the "particle" of light. It is an indivisible, discrete unit of light.

Photoelectric effect: When photons of light of sufficiently high frequency shine on a metal, electrons are ejected from the metal. The *stopping potential difference* is the potential needed to stop the ejected electrons. The **work function** E_0 of a metal is the minimum energy needed to free an electron from the metal surface.

Quantitative Tools **Planck's constant** is

$$h = 6.626 \times 10^{-34}\ \text{J}\cdot\text{s}.$$

The **de Broglie wavelength** of a particle having momentum p is

$$\lambda = h/p.$$

In the **photoelectric effect,**

$$E_{\text{photon}} = hf = K_{\max} + E_0, \tag{34.35}$$

where f is the frequency of the light hitting the metal, $K_{\max}$ is the maximum kinetic energy of the ejected electron, and E_0 is the work function of the metal.

The energy of a photon is

$$E_{\text{photon}} = hf_{\text{photon}}, \tag{34.39}$$

and its momentum is

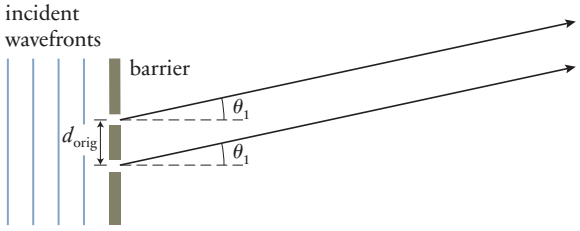
$$p_{\text{photon}} = \frac{hf_{\text{photon}}}{c_0}. \tag{34.40}$$

Questions and Problems

For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

34.1 Diffraction of light



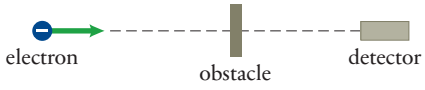
1. Name some characteristics that allow you to observe light diffraction. •
2. Which wavelength of electromagnetic radiation do you expect to be diffracted by a window screen? What is the frequency of this radiation? •
3. Planar waves from a monochromatic light source are normally incident on a circular obstacle, which casts a shadow on a screen positioned behind the obstacle. What do the wave properties of light predict about how dark the center of the shadow is? ••
4. Light of wavelength λ is incident on an aperture of width a, producing diffraction. Describe the change(s) in the diffracted waves (*a*) when the aperture width is doubled and (*b*) when the wavelength is doubled. ••
5. A friend is standing behind a large tree and yelling. You can hear him, but not see him. Why? ••

34.2 Diffraction gratings

6. Coherent green light of wavelength 540 nm passes through two narrow slits for which the center-to-center separation distance is 150 μm. What is the difference in phase between the waves from the two slits for those that arrive at a distant screen at an angular position θ of (*a*) 10.37° and (*b*) 14.6°? •

7. A diffraction grating has adjacent slits separated by 5.00 μm. When yellow light (λ = 570 nm) is incident on the grating, what are the angular positions of the third order bright fringes? •
8. You shine a yellow laser beam on a diffraction grating and then shine a blue laser beam on the same grating. Is the spacing of the bright fringes for the yellow laser beam greater than, smaller than, or equal to the spacing of the bright fringes for the blue laser beam? •
9. A reflection diffraction grating of width w has N grooves and is illuminated by normally incident monochromatic light. What condition determines how many orders of constructive interference can be seen in the interference pattern? ••
10. Light from a He-Cd laser (λ = 442 nm) passing through a two-slit diffraction grating forms a pattern on a screen 2.0 m away from the grating. If the first bright fringe is located at a linear distance y = 22.1 mm to the left of the central bright fringe, what is the slit spacing? What is the position of the second dark fringe? ••
11. Light passing through a two-slit grating makes a pattern on a screen located 500 mm away. In this pattern, the fifth-order dark fringe is 45.0 mm from the central bright fringe. How far from the central bright fringe is the third-order bright fringe? ••
12. A diffraction grating casts a pattern on a screen located a distance L from the grating. The central bright fringe falls directly in the center of the screen. For the highest-order bright fringe that hits the screen, $m = x$, and this fringe hits exactly on the screen edge. This means that $2x + 1$ bright fringes are visible on the screen. What happens to the number of bright fringes on the screen (*a*) if the wavelength of the light passing through the grating is doubled and (*b*) if the spacing d between adjacent slits is doubled? •••
13. (*a*) For the two-slit barrier shown in Figure P34.13, calculate the angle θ_1 for the first-order bright fringe if the slit separation distance is d_{orig} = 1.0 μm and the wavelength of the light passing through the slits is 546 nm. (*b*) Now consider a barrier in which one of the slits oscillates vertically and as a result the slit separation distance varies with time according to $d(t) = d_{orig} + A \sin \omega t$. Calculate θ_1 for the first-order bright fringe as a function of time for A = 0.25 μm and ω = 100 s^{-1}. (*c*) At what instant after t = 0 does θ_1 have its maximum value for the first time? What is this maximum value? (*d*) At what instant after t = 0 does θ_1 have its minimum value for the first time? What is this minimum value? (*e*) Which of the parameters A, ω, λ, d_{orig} affect the values of these angles?

Figure P34.13



34.3 X-ray diffraction

14. Why are x rays rather than visible light used to determine structure in crystals? •
15. Do the bright spots in an x-ray diffraction pattern get closer together, get farther apart, or not change position when the energy of the x rays is doubled? •
16. A monochromatic x-ray beam that has a wavelength of 0.5×10^{-10} m strikes a sodium chloride crystal. The m = 1 Bragg angle is observed to be 5.12°. What is (*a*) the lattice spacing and (*b*) the highest-order Bragg angle? •
17. In an x-ray diffraction experiment on a crystal that has a cubic lattice, the smallest Bragg angle at which you see a peak in the intensity of diffraction pattern is 15.00°. If the x-ray are produced from a copper source (0.154 nm), what is the atomic spacing in the crystal? Assume that only first-order interference fringes are visible in the diffraction pattern of this crystal. ••
18. You are doing x-ray diffraction on a crystal that has a cubic structure, using 0.1-nm x-rays. If the two greatest Bragg angles at which you observe peaks in the intensity of the diffracted rays are 76° and 63.6°, what is the lattice spacing of the crystal? ••

34.4 Matter waves

19. What is the order of magnitude of the de Broglie wavelength of a person walking down the street? •
20. How fast must a helium atom move in order to have a de Broglie wavelength of 1.5×10^{-10} m? •
21. A narrow solid obstacle is placed in the path of the electron in Figure P34.21. Does the electron have a chance of reaching the detector? •

Figure P34.21

22. What is the de Broglie wavelength of a 0.43-kg soccer ball moving at 30 m/s? •
23. An alpha particle, which consists of two neutrons and two protons, has a mass of 6.645×10^{-27} kg. What is the de Broglie wavelength of an alpha particle that has been accelerated from rest by means of a potential difference of 100 V? ••
24. Rank the following types of radiation and types of particles in order of increasing spacing between bright fringes in their diffraction patterns: yellow light, blue light, electrons moving at a speed of 1.04×10^3 m/s, protons moving at a speed of 1.04×10^3 m/s, and neutrons moving at a speed of 1.04×10^3 m/s. ••
25. You are using a 2000 V potential difference to accelerate electrons toward a diffraction grating and produce a diffraction pattern. If you observe the first intensity peak at an angle of 2.2°, what is the lattice spacing of the crystal? •••

34.5 Photons

26. Which photons contain more energy: those of blue light or those of red light? •
27. In a region of Earth's surface where the average amount of solar energy striking a square meter of ground each second is 200 J, how many photons strike each square meter each second? Use 580 nm for the average wavelength of this solar radiation. •
28. What is the smallest amount of (*a*) momentum and (*b*) energy that can be delivered using violet light for which $\lambda = 400$ nm? •
29. At what rate do photons emitted by a laser ($\lambda = 650$ nm) hit a wall 3.00 m from the laser if the power rating is 6.00 mW? What assumption must you make to solve this problem? ••
30. The sun has a power output of 3.83×10^{26} W. (*a*) How many photons does the Sun emit each second? What assumption(s) must you make to answer this question? (*b*) Installed on your roof is a solar panel that has a surface area of 1.00 m^2. How many photons from the Sun reach the panel? What assumption(s) must you make? ••
31. (*a*) What is the energy of a 540-nm photon emitted by a green laser source? (*b*) There are two green lasers that both emit 540-nm photons. Laser A has a power rating of 1.5 mW, but laser B has a power rating of only 0.75 mW. Why do the power ratings differ when the lasers emit the same wavelength of light? ••

34.6 Multiple-slit interference

32. Near the center of a diffraction pattern, adjacent maxima are separated by a distance of 20 mm. The diffraction grating is 0.200 m from the screen and has a slit spacing of 4.5 μm. What is the wavelength of light being used? •
33. A red laser beam ($\lambda = 647$ nm) is sent through a double slit to a screen that is 15 cm wide and 2.00 m away from the slits. (*a*) If the separation distance between the slits is 200 μm, how many bright fringes appear on the screen? (*b*) Verify your answer to part *a* by calculating the distance between the adjacent bright fringes. •
34. Laser light passes through a double-slit barrier with slit separation $d = 0.120$ mm onto a screen a distance $L = 6.00$ m away. The distance between the central and first-order bright fringes is $y = 27.0$ mm. What is the wavelength and color of the laser light? •
35. Using a diffraction grating with 100 slits/mm to create a diffraction pattern on a screen 2.50 m away from the grating, you see two neighboring bright fringes 150 mm apart. What is the wavelength and the color of the light? •
36. Green light ($\lambda = 510$ nm) shines through two slits separated by 2.30×10^{-6} m. The resulting diffraction pattern is cast on a screen 450 mm away. How far from the central bright fringe is the time-averaged intensity reduced to 12% of its maximum? ••
37. The radiation emitted by mercury vapor lamps includes green 546.1-nm light and blue 435.8-nm light. If this radiation passes through a transmission grating that has 600 slits/mm to form a diffraction pattern on a screen 0.500 m from the grating, what are the positions of the first-order and second-order bright fringes for each wavelength? Report your answers in terms of the linear distance *y* from the central bright fringe. ••
38. Cell phone radiation has a wavelength of about 300 mm. You are in the lobby of an office building in which the façade is a series of large, multistory panes of glass separated by vertical aluminum beams installed every 500 mm across the width of the building. Aluminum shields electromagnetic radiation. You are 10 m from the glass trying to make a phone call, but you don't get any reception. Could this have to do with interference? ••
39. You pass 589.0-nm radiation and 589.6-nm radiation through a diffraction grating that has 500.0 slits/mm. (*a*) In the diffraction pattern, what is the angular separation between the $m = 3$ peak for the 589.0-nm radiation and the $m = 3$ peak for the 589.6-nm radiation? (*b*) Are there fourth-order fringes in the diffraction pattern? ••
40. A beam of 550-nm light illuminates six parallel slits spaced 0.125 mm apart, and the resulting pattern is viewed on a screen. (*a*) What are the angular positions of the first-order and second-order principal maxima? (*b*) What are the angular positions of all the dark fringes between the central maximum and the first-order principal maximum? Between the central maximum and the first-order principal maximum, (*c*) how many dark fringes (minima) are there and (*d*) how many secondary maxima? ••
41. You shine a red ($\lambda = 650$ nm) laser beam and a green ($\lambda = 532$ nm) laser beam at a diffraction grating that has 400 slits/mm to create an interference pattern on a wall 3.00 m from the grating. If the two lasers are directly on top of each other, how far apart are the two $m = 1$ bright fringes from each other? Report your answer as a linear distance. ••
42. Is it possible to shine two laser beams of visible light into the same diffraction grating so that the dark fringes created by one beam overlay the bright fringes created by the other beam for all values of *m*? ••
43. Light of wavelength 570 nm passes through a pair of parallel slits that are 0.115 mm apart. It then falls on a screen that is 45.0 mm from the slits and centered directly opposite them. What must the minimum screen width be in order to have all the bright fringes fall on it? ••
44. A beam of light containing all the visible wavelengths from 400 nm to 700 nm passes through a pair of parallel slits that are 2.50 μm apart. These slits spread the beam into a series of full-color spectra. How many complete full-color spectra are formed? ••
45. You are designing a diffraction grating that, for 566.0-nm light, will produce second-order bright fringes that are an angular distance of 22.00° from the central bright fringe. How many equally spaced slits should this grating contain across its width if it is 24.00 mm wide? ••
46. You want to use a diffraction grating to resolve a beam of visible light into its component wavelengths, from 390 nm to 750 nm. Do the spectra from different orders overlap; that is, does a color from one order overlap with a different color from another order? If so, for which orders? ••
47. The spectrum of the radiation emitted by hydrogen atoms has a peak at $\lambda_r = 656.3$ nm (red) and a peak at $\lambda_b = 486.1$ nm (blue-green). (*a*) If this radiation is passed through a double-slit apparatus in which the slit separation is $d = 0.100$ mm and is then incident on a

screen placed a distance $L = 2.10$ m from the slits, how far apart are the $m = 1$ maxima for the two wavelengths? Can these two maxima be resolved? (*b*) If, instead, a grating with 600 slits/mm is used, how far apart are the maxima now? •••

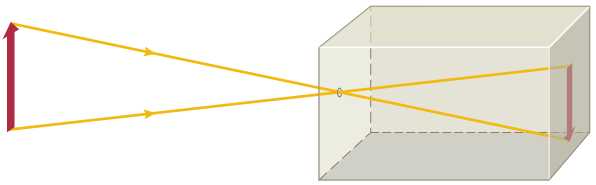
48. How many slits are needed in a diffraction grating that must resolve the $m = 1$ maxima of two spectral lines at $\lambda_s = 610$ nm and $\lambda_l = 615$ nm? •••

34.7 Thin-film interference

49. A 0.500-μm-thick flake of glass ($n_{glass} = 1.52$) from a broken cover slip is floating on water ($n_{water} = 1.33$). If white light initially traveling in the air ($n_{air} = 1.00$) is incident normal to the surface of the glass, what wavelengths in the visible spectrum undergo constructive interference as the white light is reflected from the top and bottom surfaces of the glass? •
50. You are designing a thin transparent reflective coating for the front surface of a sheet of glass. The index of refraction of the glass is 1.52, and when it is in use the coated glass has air on both sides. Because the coating is expensive, you want to use a layer that has the minimum thickness possible, which you determine to be 104 nm. What should the index of refraction of the coating be if it must cancel 550-nm light that hits the coated surface at normal incidence? ••
51. A sheet of glass ($n_{glass} = 1.5$) is coated with a 90.6-nm-thick layer of magnesium fluoride ($n_{coating} = 1.38$) to prevent reflection in the visible spectrum. What is the longest wavelength of light strongly reflected from this coated surface? Assume the incoming light is normal to the surface. ••
52. The thin film that forms a soap bubble has an index of refraction of 1.42. When white light strikes the outer surface of the film at normal incidence, 625-nm reflected light is especially bright. Derive an expression for the possible thicknesses of the film. ••
53. You are working with the mineral fluorite (CaF_2, $n_{fluorite} = 1.43$) and have a sample that is coated with a layer of liquid 158 nm thick. When you shine visible light of various wavelengths at normal incidence onto the surface of the liquid, you observe very strong reflection for green light ($\lambda = 510$ nm), essentially zero reflection for red light ($\lambda = 750$ nm), and intermediate levels of reflection for all wavelengths between the red and green extremes. What is the index of refraction of the liquid? •••
54. A thin film that is 175 nm thick and has an index of refraction smaller than 1.56 covers the front surface of a vertical sheet of glass that has an index of refraction of 1.56. The back surface of the glass interfaces with air, as does the front surface of the film. When a beam of light of variable wavelength is normally incident on the front surface of the film, we observe that, as the wavelength of the light is varied, 473-nm light reflects strongly from the front film surface. We also determine that if the film is any thinner than 175 nm, no constructive interference occurs. When the beam direction is changed so that the angle of incidence at which the light strikes the air–film interface is 51.0°, what is the angle of refraction for the beam in the film? •••

34.8 Diffraction at a single-slit barrier

55. When a green laser light ($\lambda = 550$ nm) shines on a fracture-line crack in a thin piece of metal, a diffraction pattern is observed on a screen located $L = 0.80$ m from the metal. If the width of the central bright fringe is $w = 10$ mm, what is the width of the crack in the metal? •
56. How wide does a single slit have to be so that 684-nm light passing through the slit has its first dark fringe 20.0° from the center of the interference pattern? •
57. You send light through a slit that is 150 μm wide. What is the wavelength of the light that you must use so that the $n = 1$ fringes are 1.8 cm apart on a screen 2.0 m from the slits? •
58. Blue laser light ($\lambda = 476.5$ nm) passes through a slit of width $a = 0.150$ mm. On a screen a distance $L = 2.500$ m from the slit, what is the linear distance between the central bright fringe and either first-order dark fringe? •
59. Monochromatic 647-nm light is incident on a single slit. If the diffraction pattern is cast on a screen 3.0 m from the slit, and the $n = 3$ dark fringe is 2.5 cm from the center of the pattern, what is the width of the slit? •
60. A student makes the following claim: For radiation of any wavelength passing through a single slit, the separation distance between any two adjacent dark fringes is twice the source–screen distance when the slit width equals the wavelength. Evaluate this claim. ••
61. At sunset, red light travels horizontally through the doorway in the western wall of your beach cabin, and you observe the light on the eastern wall. What is the width of the central maximum in the interference pattern created by the doorway "slit"? ••
62. An experimental setup consists of a 550-nm laser, a screen at a distance of 0.50 m, and an adjustable-width single slit. At what slit width is the width of the central maximum of the interference pattern the same as that of the bright spot it would make in the absence of diffraction? In other words, for what slit width are the effects of wave optics and geometric optics comparable? ••
63. When 440-nm light is incident on a slit that is 75 μm wide, the diffraction pattern is cast on a screen 0.450 m from the slit. How wide is the central bright fringe? ••
64. A slit 0.002470 mm wide is used to study a light ray made up of two wavelengths, 482.0 nm and 517.3 nm, and the diffraction pattern is viewed on a screen 0.220 m from the slit. In the pattern, what is the distance between the $n = 2$ dark fringe for the 482.0-nm light and the $n = 2$ dark fringe for the 517.3-nm light? (Take both dark fringes to be on the same side of the central maximum.) ••
65. A 485-nm light beam passes through a slit and forms a diffraction pattern on a screen 0.320 m from the slit. The $n = 1$ and $n = -1$ dark fringes are 22.4 mm apart on the screen. (*a*) How wide is the slit? (*b*) What is the greatest angle from the original beam direction at which a dark fringe occurs? ••
66. Two extremely narrow, parallel slits are cut in a sheet of cardboard, with the width a of each slit very much smaller than the distance d between them. When the slits are illuminated by a coherent beam of 620-nm light, the angular position of the two third-order bright fringes is $\pm 4.27°$. The cardboard between the slits is then cut out



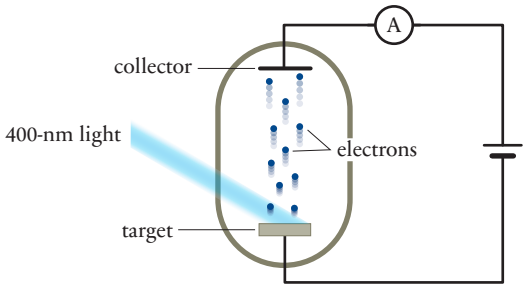
so that the sheet contains only a single opening. When this opening is illuminated by the 620-nm light, what are the angular positions of the $n = 1, 2, 3$ dark fringes? ●●

67. In the interference pattern created by 800-nm radiation passing through a single slit 45 μm wide, what is the angular separation between the $n = 3$ and $n = 5$ dark fringes on the same side of the central maximum? ●●
68. In the interference pattern created by light diffracted from a single slit, which are wider: the first-order bright fringes or the third-order bright fringes? (Hint: Plot or plug in typical numerical values for the slit width and wavelengths to make an educated guess.) ●●●
69. A laser beam passes through a slit that is 1500 nm wide. In the interference pattern created on a distant screen, the angular positions of the two first-order dark fringes are $\pm 25.0°$. The beam then is shone on a soap film ($n_{film} = 1.40$) floating on water ($n_{water} = 1.33$). What is the minimum film thickness that causes light reflected at normal incidence from the air–film interface to cancel light reflected at normal incidence from the film–water interface? ●●●

34.9 Circular apertures and limits of resolution

70. A pinhole of diameter 0.20 mm is illuminated with 550-nm light. What is the width of the Airy disk on a screen 1.5 m away? ●
71. The human eye is most sensitive to green light at 550 nm, which is why this wavelength is most frequently used when calculating the resolution limits of telescopes. A telescope for amateur astronomers has a focal length of 1200 mm and an aperture diameter of 200 mm. What is the radius of the Airy disk? ●
72. You wish to use a lens to focus a beam of light that has a diameter of 40.0 mm. Which lens focuses the beam to the smallest point: lens A, 10.0-mm diameter, 25.0-mm focal length; lens B, 150-mm diameter, 50.0-mm focal length; or lens C, 30.0-mm diameter, 30.0-mm focal length? ●
73. The Spitzer Space Telescope, launched in 2003, has a mirror that is 0.85 m in diameter and detects infrared light with wavelengths from 3.00 μm to 180 μm. If the instrument is used to study a pair of stars, what are the resolvable angular separations of the stars for the minimum and maximum wavelengths? ●
74. For an eye in which the pupil has a radius of 3.0 mm, what is the smallest angular separation that can be resolved (*a*) when two violet ($\lambda = 400$ nm) objects are placed side by side and (*b*) when two red ($\lambda = 650$ nm) objects are placed side by side? When the objects are 100 m away from this eye, what minimum linear separation distance is needed for resolution (*c*) of the two violet objects and (*d*) of the two red objects? ●●
75. A 530-nm laser beam passes through a circular aperture that has diameter 0.400 mm. What is the diameter of the first dark fringe on a screen 800 mm away from the aperture? ●●
76. The pupil of the human eye can vary in diameter from 2.00 mm in bright light to 8.00 mm in dim light. The eye has a focal length of about 25 mm, and the visible spectrum extends from 390 nm (violet) to 750 nm (red). What range of Airy disk radii is possible for the eye? (Note that the light-sensitive cells on the retina have radii ranging from 0.75 μm to 3.0 μm.) ●●
77. In vacuum, the Airy disk generated by a pinhole in a metal sheet has radius $y_{r,vac}$. How does the disk radius change when the sheet is submerged in water ($n = 1.33$)? ●●
78. When 500-nm light is incident on a circular aperture that has diameter $d = 30.0$ μm, a diffraction pattern forms on a screen 350 mm from the aperture. Calculate the area of the central bright fringe. ●●
79. Two objects emitting 550-nm light are placed side by side 30.0 mm apart. For an eye in which the pupil has a diameter of 6.00 mm, what is the minimum eye–objects distance L at which the objects are not resolvable? ●●
80. You are using your telescope to view stars by observing the visible light they emit. If the diameter of the lens is 60.0 mm, what must the minimum angular separation of two stars be in order for you to resolve them? ●●
81. A satellite studying Earth's surface uses a telescope mirror 2.75 m in diameter to focus light of wavelength 525 nm. If the satellite orbits at an altitude of 25,000 km and points the mirror straight downward, what is the diameter of the smallest surface feature it can resolve? ●●
82. A beam of 650-nm light passes through a small round hole and falls on a screen 350 mm past the hole. If the diameter of the Airy disk on the screen is 139 mm, what is the diameter of the hole? ●●
83. The red brake lights of a car are 2.00 m apart. Standing 300 m away from the rear of the car, you use a $f = 50$ mm lens with an aperture of diameter $d = 4.00$ mm to photograph the illuminated brake lights. Are the lights likely to be resolved in the photograph, or will they blur together? ●●●
84. You are building a pinhole camera, which uses a small hole instead of a lens to produce an image (Figure P34.84). (*a*) If the distance between the hole and the film is 100 mm and the hole diameter is 0.300 mm, what is the smallest resolved image point you can have on the film for light ranging from 390 nm to 750 nm? Consider both geometric optics (simply considering the shadow) and wave optics. (*b*) How can you determine the optimum pinhole size for a given wavelength of light? ●●●

Figure P34.84



34.10 Photon energy and momentum

85. What happens to (*a*) the kinetic energy of a marble when its speed is reduced to half its initial speed and (*b*) the energy of a photon when its speed is reduced to half its initial speed (as, for instance, when the photon travels from a medium with an index of refraction of 1 into a medium with an index of refraction of 2)? ●
86. What is the difference of the energies of a 500-nm photon and a 600-nm photon? ●
87. What is the wavelength of a gamma-ray photon that has energy of 8.0×10^{-14} J? ●
88. What is the momentum of a photon that has energy of 5.0×10^{-15} J? ●

89. Aluminum has a work function of $E_0 = 6.54 \times 10^{-19}$ J. What is the maximum wavelength of light that can free electrons from the surface? •
90. If the work function of a material is such that red light of wavelength 700 nm just barely initiates the photoelectric effect, what must the maximum kinetic energy of ejected electrons be when violet light of wavelength 400 nm illuminates the material? ••
91. When 420-nm light is incident on a sheet of metal, the electric potential needed to stop the electrons ejected from the metal surface is measured to be 0.67 V. What is the work function of the metal? ••
92. When three metals, 1, 2, and 3, are illuminated with light of frequency f in a photoelectric-effect experiment, the relationship of the stopping potential differences is found to be $V_{\text{stop},1} > V_{\text{stop},2} > V_{\text{stop},3}$. Which material has (*a*) the lowest frequency below which no electrons are ejected and (*b*) the highest frequency below which the effect does not happen? ••
93. In a photoelectric-effect experiment, the stopping potential difference is found to be 3.4 V when 140-nm light is used. What is the work function of the metal? ••
94. A metal alloy has a work function of $E_0 = 4.6 \times 10^{-19}$ J. It is irradiated with light of different wavelengths, and the maximum kinetic energy of ejected electrons is measured. What are the maximum kinetic energy and the maximum electron speed (*a*) when 390-nm light is used and (*b*) when 750-nm light is used? ••
95. You determine that the maximum wavelength of the light needed to eject electrons from the surface of a certain metal is 683 nm. What is the wavelength of the light if the potential needed to stop ejected electrons is 0.8 V? ••
96. A helium-neon laser that has a power rating of 0.250 mW operates at a wavelength of 633 nm and a beam diameter of 2.00 mm. Calculate (*a*) the energy per photon, (*b*) the number of photons emitted per second, (*c*) the momentum per photon, and (*d*) the pressure exerted on an absorber on which the beam is incident. ••
97. (*a*) If the kinetic energy of an electron and the energy of a photon are both 2.00×10^{-18} J, calculate the ratio of the de Broglie wavelength of the electron to the wavelength of the photon. Which particle has the shorter wavelength? (*b*) If the wavelength of a photon and the de Broglie wavelength of an electron are both 250 nm, calculate the ratio of the energy of the photon to the kinetic energy of the electron. Which particle has greater energy? ••
98. A 3.50-W beam of 216-nm laser light shines on the surface of a metal for which the work function is 2.00×10^{-19} J. What is the maximum number of electrons per second the beam can cause to be ejected from the metal? ••
99. A laser beam with an intensity of 60 W/m^2 shines on a black object of mass 2.3 mg. The beam hits an area of 4.5 mm^2 head-on (that is, the beam is perpendicular to the surface). Assuming a totally inelastic collision (meaning the incident photons are absorbed by the black object) and ignoring friction, what is the resulting acceleration of the object? •••
100. In the vacuum tube of Figure P34.100, the lower metal plate, the target, is irradiated with 400-nm light of intensity 5.50 W/m^2. The frequency of the light is great enough to cause electrons to be ejected from the target and travel to the upper metal plate, the collector. What is the maximum possible current in the circuit if the area of the target is 600 mm^2? •••

Figure P34.100

101. When 550-nm light passes through a thin slit and then travels to a screen, the first-order dark fringe in the interference pattern is at 32.5° from the center of the screen. When a beam of electrons, each having kinetic energy equal to the energy of the photons in the 550-nm beam, passes through the slit and travels to the screen, what is the smallest angle from the screen center at which no electrons are found? •••
102. A uniform film of a material that has index of refraction 1.30 covers the front surface of a pane made of glass with index of refraction 1.55. When a beam of monochromatic light initially traveling in air strikes the film at normal incidence, the minimum film thickness for which the light reflected from the air–film interface and the light reflected from the film–glass interface cancel is 123 nm. What is the energy of each photon in the light beam? •••

Additional Problems

103. Monochromatic light of which wavelength diffracts the most through a 3.0-μm aperture: 400 nm, 500 nm, or 600 nm? •
104. A double-slit barrier with slit separation distance d is a distance L from a screen, with $L \gg d$. When green laser light ($\lambda_g = 543$ nm) passes through the barrier, the bright fringes on the screen are a distance y_g apart. When red laser light ($\lambda_r = 694$ nm) passes through the barrier, the bright fringes on the screen are a distance y_r apart. Determine the ratio y_r/y_g. •
105. You cut a slit in a sheet of paper and use it to produce a diffraction pattern on a screen 2 m away from the slit. If, using a laser of wavelength 543.5 nm, you measure a separation distance of 4 mm between the $n = 1$ and $n = 2$ dark fringes of the interference pattern, what is the width of the slit? •
106. NASA plans to use x-ray diffraction to identify minerals on the surface of Mars. If the wavelength of the x rays is 0.155 nm, what is the lattice spacing in a crystalline sample if the crystal strongly reflects x rays at an incident angle of 51.7° in the first order? •
107. Babinet's principle states that, except for differences in intensity, the interference pattern created by light passing around an opaque object is the same as the pattern

created by the same light passing through a hole of the same size and shape as the object. You shine a 690-nm laser beam on a human hair and observe an interference pattern on a screen 1.2 m from the hair. If each first-order dark fringe is 16 mm from the center of the pattern, what is the diameter of the hair? ●●

108. Many hundreds of planets beyond our solar system have been discovered in recent years, but they have all been too far away to be resolved by present-day optical telescopes. Using light of wavelength 525 nm, what must the minimum mirror diameter of a space telescope be in order to resolve an Earth-sized planet at a distance of 10 light years? Are our present space telescopes nearing this size? The diameter of Earth is 1.27×10^7 m. ●●

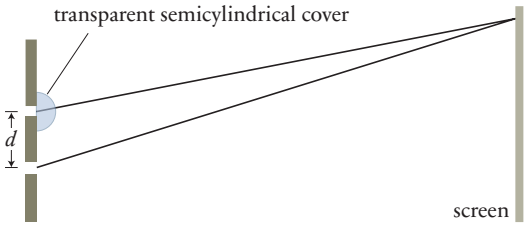
109. You shine light of frequency f_i on a diffraction grating and create a diffraction pattern on a screen made up of tiny photon detectors. (*a*) How does the pattern change if you increase the frequency of the light? (*b*) How does the pattern change if you replace the initial light source with a source that emits brighter light of the same frequency f_i? (*c*) For the source in part *b*, is the number of photons detected at the screen smaller than, equal to, or greater than the number detected with the initial source? ●●

110. A layer of oil ($n_{oil} = 1.48$) 0.0100 mm thick is resting on a puddle of water ($n_{water} = 1.33$). If white light is incident on the oil, what is the smallest angle from normal at which green light ($\lambda = 510$ nm) is strongly reflected? ●●

111. When a laser beam of wavelength 694 nm passes through a thin slit of width 200 μm, what is the angular separation between the $n = 5$ dark fringe and the adjacent $n = 6$ dark fringe? ●●

112. In a double-slit interference pattern, it is the amplitudes of the light waves from each slit that add, not the light intensities. Usually, in the analysis of interference patterns, the radiation intensity (or amplitude) is assumed to be exactly the same for both slits. Because of inaccurate optical alignment, however, the illumination is often not the same for the two slits. If the intensity of light going through one slit is 0.010 mW/mm^2 while the intensity going through the second slit is 0.030 mW/mm^2, what is the intensity at an interference maximum and at an interference minimum? ●●

113. Electrons are accelerated from rest through a 2.0-kV potential difference. What are (*a*) their speed after this acceleration and (*b*) their wavelength? (*c*) If the accelerated electrons are incident on a graphite crystal that has a lattice spacing of 0.123 nm, do you expect to observe diffraction? ●●



114. You are designing a diffraction grating that will disperse white light into its spectrum (400-nm violet to 700-nm red). In the first-order spectrum, you want the angular separation between the shortest and longest wavelengths to be 12.0°. (*a*) How many slits per millimeter should the grating have? (*b*) How many complete full-color spectra will the grating produce, not counting the central bright fringe? ●●

115. Monochromatic light passes through a small round hole 1.36 μm in radius. The light then strikes a detector 120 mm away from the hole and is absorbed by the detector surface. If the radius of the Airy disk on the detector is 33.3 mm, how much energy and momentum does each photon transfer to the detector? ●●●

116. A young adult with good vision is reading a document placed at her near point. She is using ordinary reading light of wavelength 500 nm, and the diameter of her pupil is 3.0 mm. Under these conditions, what is the height of the smallest letter she can resolve on the document? ●●●

117. In experiment 1, a laser beam of 750-nm light is passed through a double-slit barrier and creates a diffraction pattern on a screen. In experiment 2, one slit is covered with a semicylindrical piece of material that has an index of refraction of $n = 1.001$, as shown in Figure P34.117, and the 750-nm beam again passes through and creates a diffraction pattern on the screen. If the distance between the slits is $d = 1.2$ mm, what is the smallest radius of the semicylindrical piece that results in the screen locations that were bright fringes in experiment 1 being dark fringes in experiment 2, and the screen locations that were dark fringes in experiment 1 being bright fringes in experiment 2? ●●●

Figure P34.117

118. You have an unlabeled container in the laboratory that contains the solid lithium fluoride (LiF) and an identical unlabeled container that contains the solid sodium chloride (NaCl). You know that both materials crystallize in a cubic structure, with alternating Na and Cl ions in the NaCl lattice and alternating Li and F ions in the LiF lattice. The only testing instrument available is a diffraction apparatus that uses monochromatic 0.154-nm x rays. After reading in the literature that the lattice spacing is 0.202 nm for LiF and 0.283 nm for NaCl, you test one of the samples in the apparatus and observe the first intensity peak at a Bragg angle of 22.4°. ●●● CR

119. As a mission engineer for NASA, you are working on a mission to map the surface of Mars. Your boss asks you to design the optical system for a satellite that can resolve surface features as small as 2.00 m across in the visible part of the electromagnetic spectrum. He tells you the instrument has to fit in a cubic bay of 1.0-m width. You know that to get sharp pictures, the satellite must take at least 17 hours to orbit the planet. Luckily you remember your physics classes on gravity, so you sit down to evaluate whether the job is feasible. ●●● CR

Appendix A

Notation

Notation used in this text, listed alphabetically, Greek letters first.
For information concerning superscripts and subscripts, see the explanation at the end of this table.

Symbol	Name of Quantity	Definition	Where Defined	SI units
α (alpha)	polarizability	scalar measure of amount of charge separation occurring in material due to external electric field	Eq. 23.24	$C^2 \cdot m/N$
α	Bragg angle	in x-ray diffraction, angle between incident x rays and sample surface	Section 34.3	degree, radian, or revolution
α_ϑ	(ϑ component of) rotational acceleration	rate at which rotational velocity ω_ϑ increases	Eq. 11.12	s^{-2}
β (beta)	sound intensity level	logarithmic scale for sound intensity, proportional to $\log(I/I_{th})$	Eq. 17.5	dB (not an SI unit)
γ (gamma)	Lorentz factor	factor indicating how much relativistic values deviate from nonrelativistic ones	Eq. 14.6	unitless
γ	surface tension	force per unit length exerted parallel to surface of liquid; energy per unit area required to increase surface area of liquid	Eq. 18.48	N/m
γ	heat capacity ratio	ratio of heat capacity at constant pressure to heat capacity at constant volume	Eq. 20.26	unitless
Δ	delta	change in	Eq. 2.4	
$\Delta\vec{r}$	displacement	vector from object's initial to final position	Eq. 2.8	m
$\Delta\vec{r}_F$, Δx_F	force displacement	displacement of point of application of a force	Eq. 9.7	m
Δt	interval of time	difference between final and initial instants	Table 2.2	s
Δt_{proper}	proper time interval	time interval between two events occurring at same position	Section 14.1	s
Δt_v	interval of time	time interval measured by observer moving at speed v with respect to events	Eq. 14.13	s
Δx	x component of displacement	difference between final and initial positions along x axis	Eq. 2.4	m
δ (delta)	delta	infinitesimally small amount of	Eq. 3.24	
ϵ_0 (epsilon)	electric constant	constant relating units of electrical charge to mechanical units	Eq. 24.7	$C^2/(N \cdot m^2)$
η (eta)	viscosity	measure of fluid's resistance to shear deformation	Eq. 18.38	$Pa \cdot s$
η	efficiency	ratio of work done by heat engine to thermal input of energy	Eq. 21.21	unitless
θ (theta)	angular coordinate	polar coordinate measuring angle between position vector and x axis	Eq. 10.2	degree, radian, or revolution
θ_c	contact angle	angle between solid surface and tangent to liquid surface at meeting point measured within liquid	Section 18.4	degree, radian, or revolution
θ_c	critical angle	angle of incidence greater than which total internal reflection occurs	Eq. 33.9	degree, radian, or revolution
θ_i	angle of incidence	angle between incident ray of light and normal to surface	Section 33.1	degree, radian, or revolution

Symbol	Name of Quantity	Definition	Where Defined	SI units
θ_i	angle subtended by image	angle subtended by image	Section 33.6	degree, radian, or revolution
θ_o	angle subtended by object	angle subtended by object	Section 33.6	degree, radian, or revolution
θ_r	angle of reflection	angle between reflected ray of light and normal to surface	Section 33.1	degree, radian, or revolution
θ_r	minimum resolving angle	smallest angular separation between objects that can be resolved by optical instrument with given aperture	Eq. 34.30	degree, radian, or revolution
ϑ (script theta)	rotational coordinate	for object traveling along circular path, arc length traveled divided by circle radius	Eq. 11.1	unitless
κ (kappa)	torsional constant	ratio of torque required to twist object to rotational displacement	Eq. 15.25	$N \cdot m$
κ	dielectric constant	factor by which potential difference across isolated capacitor is reduced by insertion of dielectric	Eq. 26.9	unitless
λ (lambda)	inertia per unit length	for uniform one-dimensional object, amount of inertia in a given length	Eq. 11.44	kg/m
λ	wavelength	minimum distance over which periodic wave repeats itself	Eq. 16.9	m
λ	linear charge density	amount of charge per unit length	Eq. 23.16	C/m
μ (mu)	reduced mass	product of two interacting objects' inertias divided by their sum	Eq. 6.39	kg
μ	linear mass density	mass per unit length	Eq. 16.25	kg/m
$\vec{\mu}$	magnetic dipole moment	vector pointing along direction of magnetic field of current loop, with magnitude equal to current times area of loop	Section 28.3	$A \cdot m^2$
μ_0	magnetic constant	constant relating units of electric current to mechanical units	Eq. 28.1	$T \cdot m/A$
μ_k	coefficient of kinetic friction	proportionality constant relating magnitudes of force of kinetic friction and normal force between two surfaces	Eq. 10.55	unitless
μ_s	coefficient of static friction	proportionality constant relating magnitudes of force of static friction and normal force between two surfaces	Eq. 10.46	unitless
ρ (rho)	mass density	amount of mass per unit volume	Eq. 1.4	kg/m^3
ρ	inertia per unit volume	for uniform three-dimensional object, amount of inertia in a given volume divided by that volume	Eq. 11.46	kg/m^3
ρ	(volume) charge density	amount of charge per unit volume	Eq. 23.18	C/m^3
σ (sigma)	inertia per unit area	for uniform two-dimensional object, inertia divided by area	Eq. 11.45	kg/m^2
σ	surface charge density	amount of charge per unit area	Eq. 23.17	C/m^2
σ	conductivity	ratio of current density to applied electric field	Eq. 31.8	$A/(V \cdot m)$
τ (tau)	torque	magnitude of axial vector describing ability of forces to change objects' rotational motion	Eq. 12.1	$N \cdot m$
τ	time constant	for damped oscillation, time for energy of oscillator to decrease by factor e^{-1}	Eq. 15.39	s
τ_ϑ	(ϑ component of) torque	ϑ component of axial vector describing ability of forces to change objects' rotational motion	Eq. 12.3	$N \cdot m$
Φ_E (phi, upper case)	electric flux	scalar product of electric field and area through which it passes	Eq. 24.1	$N \cdot m^2/C$

Symbol	Name of Quantity	Definition	Where Defined	SI units
Φ_B	magnetic flux	scalar product of magnetic field and area through which it passes	Eq. 27.10	Wb
ϕ (phi)	phase constant	phase difference between source emf and current in circuit	Eq. 32.16	unitless
$\phi(t)$	phase	time-dependent argument of sine function describing simple harmonic motion	Eq. 15.5	unitless
Ω (omega, upper case)	number of basic states	number of basic states corresponding to macrostate	Section 19.4, Eq. 19.1	unitless
ω (omega)	rotational speed	magnitude of rotational velocity	Eq. 11.7	s^{-1}
ω	angular frequency	for oscillation with period T, $2\pi/T$	Eq. 15.4	s^{-1}
ω_0	resonant angular frequency	angular frequency at which current in circuit is maximal	Eq. 32.47	s^{-1}
ω_ϑ	(ϑ component of) rotational velocity	rate at which rotational coordinate ϑ changes	Eq. 11.6	s^{-1}
A	area	length $\times$ width	Eq. 11.45	m^2
A	amplitude	magnitude of maximum displacement of oscillating object from equilibrium position	Eq. 15.6	m (for linear mechanical oscillation; unitless for rotational oscillation; various units for nonmechanical oscillation)
$\vec{A}$	area vector	vector with magnitude equal to area and direction normal to plane of area	Section 24.6	m^2
$\vec{a}$	acceleration	time rate of change in velocity	Section 3.1	m/s^2
$\vec{a}_{\mathrm{Ao}}$	relative acceleration	value observer in reference frame A records for acceleration of object o in reference frame A	Eq. 6.11	m/s^2
a_c	magnitude of centripetal acceleration	acceleration required to make object follow circular trajectory	Eq. 11.15	m/s^2
a_r	radial component of acceleration	component of acceleration in radial direction	Eq. 11.16	m/s^2
a_t	tangential component of acceleration	component of acceleration tangent to trajectory; for circular motion at constant speed $a_t = 0$	Eq. 11.17	m/s^2
a_x	x component of acceleration	component of acceleration directed along x axis	Eq. 3.21	m/s^2
$\vec{B}$	magnetic field	vector field providing measure of magnetic interactions	Eq. 27.5	T
$\vec{B}_{\mathrm{ind}}$	induced magnetic field	magnetic field produced by induced current	Section 29.4	T
b	damping coefficient	ratio of drag force on moving object to its speed	Eq. 15.34	kg/s
C	heat capacity per particle	ratio of energy transferred thermally per particle to change in temperature	Section 20.3	J/K
C	capacitance	ratio of magnitude of charge on one of a pair of oppositely charged conductors to magnitude of potential difference between them	Eq. 26.1	F
C_P	heat capacity per particle at constant pressure	ratio of energy transferred thermally per particle to change in temperature, while holding pressure constant	Eq. 20.20	J/K
C_V	heat capacity per particle at constant volume	ratio of energy transferred thermally per particle to change in temperature, while holding volume constant	Eq. 20.13	J/K
$\mathrm{COP}_{\mathrm{cooling}}$	coefficient of performance of cooling	ratio of thermal input of energy to work done on a heat pump	Eq. 21.27	unitless

Symbol	Name of Quantity	Definition	Where Defined	SI units
$\mathrm{COP}_{\mathrm{heating}}$	coefficient of performance of heating	ratio of thermal output of energy to work done on a heat pump	Eq. 21.25	unitless
c	shape factor	ratio of object's rotational inertia to mR^2; function of distribution of inertia within object	Table 11.3, Eq. 12.25	unitless
c	wave speed	speed at which mechanical wave travels through medium	Eq. 16.3	m/s
c	specific heat capacity	ratio of energy transferred thermally per unit mass to change in temperature	Section 20.3	J/(K · kg)
c_0	speed of light in vacuum	speed of light in vacuum	Section 14.2	m/s
c_V	specific heat capacity at constant volume	ratio of energy transferred thermally per unit mass to change in temperature, while holding volume constant	Eq. 20.48	J/(K · kg)
$\vec{D}$	displacement (of particle in wave)	displacement of particle from its equilibrium position	Eq. 16.1	m
d	diameter	diameter	Section 1.9	m
d	distance	distance between two locations	Eq. 2.5	m
d	degrees of freedom	number of ways particle can store thermal energy	Eq. 20.4	unitless
d	lens strength	1 m divided by focal length	Eq. 33.22	diopters
E	energy of system	sum of kinetic and internal energies of system	Table 1.1, Eq. 5.21	J
$\vec{E}$	electric field	vector field representing electric force per unit charge	Eq. 23.1	N/C
E_0	work function	minimum energy required to free electron from surface of metal	Eq. 34.35	J
E_{chem}	chemical energy	internal energy associated with object's chemical state	Eq. 5.27	J
E_{int}	internal energy of system	energy associated with an object's state	Eqs. 5.20, 14.54	J
E_{mech}	mechanical energy	sum of system's kinetic and potential energies	Eq. 7.9	J
E_{s}	source energy	incoherent energy used to produce other forms of energy	Eq. 7.7	J
E_{th}	thermal energy	internal energy associated with object's temperature	Eq. 5.27	J
$\mathscr{E}$	emf	in charge-separating device, nonelectrostatic work per unit charge done in separating positive and negative charge carriers	Eq. 26.7	V
$\mathscr{E}_{\mathrm{ind}}$	induced emf	emf resulting from changing magnetic flux	Eqs. 29.3, 29.8	V
$\mathscr{E}_{\mathrm{max}}$	amplitude of emf	amplitude of time-dependent emf produced by AC source	Section 32.1, Eq. 32.1	V
$\mathscr{E}_{\mathrm{rms}}$	rms emf	root-mean-square emf	Eq. 32.55	V
e	coefficient of restitution	measure of amount of initial relative speed recovered after collision	Eq. 5.18	unitless
e	eccentricity	measure of deviation of conic section from circular	Section 13.7	unitless
e	elementary charge	magnitude of charge on electron	Eq. 22.3	C
$\vec{F}$	force	time rate of change of object's momentum	Eq. 8.2	N
$\vec{F}^B$	magnetic force	force exerted on electric current or moving charged particle by magnetic field	Eqs. 27.8, 27.19	N
$\vec{F}^{\mathrm{b}}$	buoyant force	upward force exerted by fluid on submerged object	Eq. 18.12	N
$\vec{F}^{\mathrm{c}}$	contact force	force between objects in physical contact	Section 8.5	N

Symbol	Name of Quantity	Definition	Where Defined	SI units
$\vec{F}^{\mathrm{d}}$	drag force	force exerted by medium on object moving through medium	Eq. 15.34	N
$\vec{F}^{E}$	electric force	force exerted between electrically charged objects or on electrically charged objects by electric field	Eq. 22.1	N
$\vec{F}^{EB}$	electromagnetic force	force exerted on electrically charged objects by electric and magnetic fields	Eq. 27.20	N
$\vec{F}^{\mathrm{f}}$	frictional force	force exerted on object due to friction between it and a second object or surface	Eq. 9.26	N
$\vec{F}^{G}$	gravitational force	force exerted by Earth or any object having mass on any other object having mass	Eqs. 8.16, 13.1	N
$\vec{F}^{k}$	force of kinetic friction	frictional force between two objects in relative motion	Section 10.4, Eq. 10.55	N
$\vec{F}^{n}$	normal force	force directed perpendicular to a surface	Section 10.4, Eq. 10.46	N
$\vec{F}^{s}$	force of static friction	frictional force between two objects not in relative motion	Section 10.4, Eq. 10.46	N
f	frequency	number of cycles per second of periodic motion	Eq. 15.2	Hz
f	focal length	distance from center of lens to focus	Section 33.4, Eq. 33.16	m
f_{beat}	beat frequency	frequency at which beats occur when waves of different frequency interfere	Eq. 17.8	Hz
G	gravitational constant	proportionality constant relating gravitational force between two objects to their masses and separation	Eq. 13.1	$\mathrm{N \cdot m^2/kg^2}$
g	magnitude of acceleration due to gravity	magnitude of acceleration of object in free fall near Earth's surface	Eq. 3.14	$\mathrm{m/s^2}$
h	height	vertical distance	Eq. 10.26	m
h	Planck's constant	constant describing scale of quantum mechanics; relates photon energy to frequency and de Broglie wavelength to momentum of particle	Eq. 34.35	$\mathrm{J \cdot s}$
I	rotational inertia	measure of object's resistance to change in its rotational velocity	Eq. 11.30	$\mathrm{kg \cdot m^2}$
I	intensity	energy delivered by wave per unit time per unit area normal to direction of propagation	Eq. 17.1	$\mathrm{W/m^2}$
I	(electric) current	rate at which charged particles cross a section of a conductor in a given direction	Eq. 27.2	A
I	amplitude of oscillating current	maximum value of oscillating current in circuit	Section 32.1, Eq. 32.5	A
I_{cm}	rotational inertia about center of mass	object's rotational inertia about an axis through its center of mass	Eq. 11.48	$\mathrm{kg \cdot m^2}$
I_{disp}	displacement current	current-like quantity in Ampère's law caused by changing electric flux	Eq. 30.7	A
I_{enc}	enclosed current	current enclosed by Ampèrian path	Eq. 28.1	A
I_{ind}	induced current	current in loop caused by changing magnetic flux through loop	Eq. 29.4	A
I_{int}	intercepted current	current intercepted by surface spanning Ampèrian path	Eq. 30.6	A
I_{rms}	rms current	root-mean-square current	Eq. 32.53	A
I_{th}	intensity at threshold of hearing	minimum intensity audible to human ear	Eq. 17.4	$\mathrm{W/m^2}$
i	time-dependent current	time-dependent current through circuit; $I(t)$	Section 32.1, Eq. 32.5	A
i	image distance	distance from lens to image	Section 33.6, Eq. 33.16	m

Symbol	Name of Quantity	Definition	Where Defined	SI units
$\hat{i}$	unit vector ("i hat")	vector for defining direction of x axis	Eq. 2.1	unitless
$\vec{J}$	impulse	amount of momentum transferred from environment to system	Eq. 4.18	$kg \cdot m/s$
$\vec{J}$	current density	current per unit area	Eq. 31.6	A/m^2
J_ϑ	rotational impulse	amount of angular momentum transferred from environment to system	Eq. 12.15	$kg \cdot m^2/s$
$\hat{j}$	unit vector ("j hat")	vector for defining direction of y axis	Eq. 10.4	unitless
K	kinetic energy	energy object has because of its translational motion	Eqs. 5.12, 14.51	J
K	surface current density	current per unit of sheet width	Section 28.5	A/m
K_{cm}	translational kinetic energy	kinetic energy associated with motion of center of mass of system	Eq. 6.32	J
K_{conv}	convertible kinetic energy	kinetic energy that can be converted to internal energy without changing system's momentum	Eq. 6.33	J
K_{rot}	rotational kinetic energy	energy object has due to its rotational motion	Eq. 11.31	J
k	spring constant	ratio of force exerted on spring to displacement of free end of spring	Eq. 8.18	N/m
k	wave number	number of wavelengths in 2π units of distance; for wave with wavelength λ, $2\pi/\lambda$	Eqs. 16.7, 16.11	m^{-1}
k	Coulomb's law constant	constant relating electrostatic force to charges and their separation distance	Eq. 22.5	$N \cdot m^2/C^2$
k_B	Boltzmann constant	constant relating thermal energy to absolute temperature	Eq. 19.39	J/K
L	inductance	negative of ratio of induced emf around loop to rate of change of current in loop	Eq. 29.19	H
L_ϑ	(ϑ component of) angular momentum	capacity of object to make other objects rotate	Eq. 11.34	$kg \cdot m^2/s$
L_m	specific transformation energy for melting	energy transferred thermally per unit mass required to melt substance	Eq. 20.55	J/kg
L_v	specific transformation energy for vaporization	energy transferred thermally per unit mass required to vaporize substance	Eq. 20.55	J/kg
ℓ	length	distance or extent in space	Table 1.1	m
ℓ_{proper}	proper length	length measured by observer at rest relative to object	Section 14.3	m
ℓ_v	length	measured length of object moving at speed v relative to observer	Eq. 14.28	m
M	magnification	ratio of signed image height to object height	Eq. 33.17	unitless
M_θ	angular magnification	ratio of angle subtended by image to angle subtended by object	Eq. 33.18	unitless
m	mass	amount of substance	Table 1.1, Eq. 13.1	kg
m	inertia	measure of object's resistance to change in its velocity	Eq. 4.2	kg
m	fringe order	number indexing bright interference fringes, counting from central, zeroth-order bright fringe	Section 34.2, Eq. 34.5	unitless
m_v	inertia	inertia of object moving at speed v relative to observer	Eq. 14.41	kg
N	number of objects	number of objects in sample	Eq. 1.3	unitless
N_A	Avogadro's number	number of particles in 1 mol of a substance	Eq. 1.2	unitless
n	number density	number of objects per unit volume	Eq. 1.3	m^{-3}

Symbol	Name of Quantity	Definition	Where Defined	SI units
n	windings per unit length	in a solenoid, number of windings per unit length	Eq. 28.4	unitless
n	index of refraction	ratio of speed of light in vacuum to speed of light in a medium	Eq. 33.1	unitless
n	fringe order	number indexing dark interference fringes, counting from central, zeroth-order bright fringe	Section 34.2, Eq. 34.7	unitless
O	origin	origin of coordinate system	Section 10.2	
o	object distance	distance from lens to object	Section 33.6, Eq. 33.16	m
P	power	time rate at which energy is transferred or converted	Eq. 9.30	W
P	pressure	force per unit area exerted by fluid	Eq. 18.1	Pa
P_{atm}	atmospheric pressure	average pressure in Earth's atmosphere at sea level	Eq. 18.3	Pa
P_{gauge}	gauge pressure	pressure measured as difference between absolute pressure and atmospheric pressure	Eq. 18.16	Pa
p	time-dependent power	time-dependent rate at which source delivers energy to load; $P(t)$	Eq. 32.49	W
$\vec{p}$	momentum	vector that is product of an object's inertia and velocity	Eq. 4.6	kg · m/s
$\vec{p}$	(electric) dipole moment	vector representing magnitude and direction of electric dipole, equal amounts of positive and negative charge separated by small distance	Eq. 23.9	C · m
$\vec{p}_{\text{ind}}$	induced dipole moment	dipole moment induced in material by external electric field	Eq. 23.24	C · m
p_x	x component of momentum	x component of momentum	Eq. 4.7	kg · m/s
Q	quality factor	for damped oscillation, number of cycles for energy of oscillator to decrease by factor $e^{-2\pi}$	Eq. 15.41	unitless
Q	volume flow rate	rate at which volume of fluid crosses section of tube	Eq. 18.25	m^3/s
Q	energy transferred thermally	energy transferred into system by thermal interactions	Eq. 20.1	J
Q_{in}	thermal input of energy	positive amount of energy transferred into system by thermal interactions	Sections 21.1, 21.5	J
Q_{out}	thermal output of energy	positive amount of energy transferred out of system by thermal interactions	Sections 21.1, 21.5	J
q	electrical charge	attribute responsible for electromagnetic interactions	Eq. 22.1	C
q_{enc}	enclosed charge	sum of all charge within a closed surface	Eq. 24.8	C
q_{p}	dipole charge	charge of positively charged pole of dipole	Section 23.6	C
R	radius	radius of an object	Eq. 11.47	m
R	resistance	ratio of applied potential difference to resulting current	Eqs. 29.4, 31.10	Ω
R_{eq}	equivalent resistance	resistance that could be used to replace combination of circuit elements	Eqs. 31.26, 31.33	Ω
r	radial coordinate	polar coordinate measuring distance from origin of coordinate system	Eq. 10.1	m
$\vec{r}$	position	vector for determining position	Eqs. 2.9, 10.4	m
$\hat{r}_{12}$	unit vector ("r hat")	unit vector pointing from tip of $\vec{r}_1$ to tip of $\vec{r}_2$	Eq. 22.6	unitless
$\vec{r}_{\text{AB}}$	relative position	position of observer B in reference frame of observer A	Eq. 6.3	m
$\vec{r}_{\text{Ae}}$	relative position	value observer in reference frame A records for position at which event e occurs	Eq. 6.3	m

Symbol	Name of Quantity	Definition	Where Defined	SI units
$\vec{r}_{\text{cm}}$	position of a system's center of mass	a fixed position in a system that is independent of choice of reference frame	Eq. 6.24	m
$\vec{r}_{\text{p}}$	dipole separation	position of positively charged particle relative to negatively charged particle in dipole	Section 23.6	m
$r_{\perp}$	lever arm distance *or* lever arm	perpendicular distance between rotation axis and line of action of a vector	Eq. 11.36	m
$\Delta\vec{r}$	displacement	vector from object's initial to final position	Eq. 2.8	m
$\Delta\vec{r}_F$	force displacement	displacement of point of application of a force	Eq. 9.7	m
S	entropy	logarithm of number of basic states	Eq. 19.4	unitless
S	intensity	intensity of electromagnetic wave	Eq. 30.36	W/m^2
$\vec{S}$	Poynting vector	vector representing flow of energy in combined electric and magnetic fields	Eq. 30.37	W/m^2
s	arc length	distance along circular path	Eq. 11.1	m
s^2	space-time interval	invariant measure of separation of events in space-time	Eq. 14.18	m^2
T	period	time interval needed for object in circular motion to complete one revolution	Eq. 11.20	s
T	absolute temperature	quantity related to rate of change of entropy with respect to thermal energy	Eq. 19.38	K
$\mathcal{T}$	tension	stress in object subject to opposing forces stretching the object	Section 8.6	N
t	instant in time	physical quantity that allows us to determine the sequence of related events	Table 1.1	s
t_{Ae}	instant in time	value observer A measures for instant at which event e occurs	Eq. 6.1	s
Δt	interval of time	difference between final and initial instants	Table 2.2	s
Δt_{proper}	proper time interval	time interval between two events occurring at same position	Section 14.1	s
Δt_v	interval of time	time interval between two events measured by observer moving at speed v relative to an observer for whom the events occur at the same position	Eq. 14.13	s
U	potential energy	energy stored in reversible changes to system's configuration state	Eq. 7.7	J
U^B	magnetic potential energy	potential energy stored in magnetic field	Eqs. 29.25, 29.30	J
U^E	electric potential energy	potential energy due to relative position of charged objects	Eq. 25.8	J
U^G	gravitational potential energy	potential energy due to relative position of gravitationally interacting objects	Eqs. 7.13, 13.14	J
u_B	energy density of magnetic field	energy per unit volume stored in magnetic field	Eq. 29.29	J/m^3
u_E	energy density of electric field	energy per unit volume stored in electric field	Eq. 26.6	J/m^3
V	volume	amount of space occupied by an object	Table 1.1	m^3
V_{AB}	potential difference	negative of electrostatic work per unit charge done on charged particle as it is moved from point A to point B	Eq. 25.15	V
V_{batt}	battery potential difference	magnitude of potential difference between terminals of battery	Eq. 25.19	V
V_C	amplitude of oscillating potential	maximum magnitude of potential across circuit element C	Section 32.1, Eq. 32.8	V
V_{disp}	displaced volume	volume of fluid displaced by submerged object	Eq. 18.12	m^3

Symbol	Name of Quantity	Definition	Where Defined	SI units
V_P	(electrostatic) potential	potential difference between conveniently chosen reference point of potential zero and point P	Eq. 25.30	V
V_{rms}	rms potential	root-mean-square potential difference	Eq. 32.55	V
V_{stop}	stopping potential	minimum potential difference required to stop flow of electrons from photoelectric effect	Eq. 34.34	V
$\mathcal{V}$	"volume" in velocity space	measure of range of velocities in three dimensions	Eq. 19.20	$(m/s)^3$
v	speed	magnitude of velocity	Table 1.1	m/s
$\vec{v}$	velocity	time rate of change in position	Eq. 2.23	m/s
$\vec{v}_{12}$	relative velocity	velocity of object 2 relative to object 1	Eq. 5.1	m/s
$\vec{v}_{AB}$	relative velocity	velocity of observer B in reference frame of observer A	Eq. 6.3	m/s
v_C	time-dependent potential	time-dependent potential across circuit element C; $V_C(t)$	Section 32.1, Eq. 32.8	V
$\vec{v}_{cm}$	velocity, center of mass	velocity of the center of mass of a system, equal to the velocity of the zero-momentum reference frame of the system	Eq. 6.26	m/s
$\vec{v}_d$	drift velocity	average velocity of electrons in conductor in presence of electric field	Eq. 31.3	m/s
v_{esc}	escape speed	minimum launch speed required for object to reach infinity	Eq. 13.23	m/s
v_r	radial component of velocity	for object moving along circular path, always zero	Eq. 11.18	m/s
v_{rms}	root-mean-square speed	square root of average of square of speed	Eq. 19.21	m/s
v_t	tangential component of velocity	for object in circular motion, rate at which arc length is swept out	Eq. 11.9	m/s
v_x	x component of velocity	component of velocity directed along x axis	Eq. 2.21	m/s
W	work	change in system's energy due to external forces exerted on system	Eqs. 9.1, 10.35	J
$W_{P\to Q}$	work	work done along path from P to Q	Eq. 13.12	J
W_{in}	mechanical input of energy	positive amount of mechanical work done on system	Section 21.1	J
W_{out}	mechanical output of energy	positive amount of mechanical work done by system	Section 21.1	J
W_q	electrostatic work	work done by electrostatic field on charged particle moving through field	Section 25.2, Eq. 25.17	J
X_C	capacitive reactance	ratio of potential difference amplitude to current amplitude for capacitor	Eq. 32.14	Ω
X_L	inductive reactance	ratio of potential difference amplitude to current amplitude for inductor	Eq. 32.26	Ω
x	position	position along x axis	Eq. 2.4	m
$x(t)$	position as function of time	position x at instant t	Section 2.3	m
Δx	x component of displacement	difference between final and initial positions along x axis	Eq. 2.4	m
Δx_F	force displacement	displacement of point of application of a force	Eq. 9.7	m
Z	impedance	(frequency-dependent) ratio of potential difference to current through circuit	Eq. 32.33	Ω
z	zero-momentum reference frame	reference frame in which system of interest has zero momentum	Eq. 6.23	

Math notation

Math notation	Name	Where introduced
$\equiv$	defined as	Eq. 1.3
$\approx$	approximately equal to	Section 1.9
Σ (sigma, upper case)	sum of	Eq. 3.25
$\int$	integral of	Eq. 3.27
$\parallel$	parallel	Section 10.2
$\perp$	perpendicular	Section 10.2
$\propto$	proportional to	Section 13.1
$\cdot$	scalar product of two vectors	Eq. 10.33
$\times$	vector product of two vectors	Eq. 12.35
$\frac{\partial f}{\partial x}$	partial derivative of f with respect to x	Eq. 16.47
$\vec{b}$	vector b	Eq. 2.2
$\lvert\vec{b}\rvert$ or b	magnitude of $\vec{b}$	Eq. 2.3
b_x	x component of $\vec{b}$	Eq. 2.2
$\vec{b}_x$	x component vector of $\vec{b}$	Eq. 10.5
$\hat{\imath}$	unit vector ("i hat")	Eq. 2.1
$\hat{r}_{12}$	unit vector ("r hat")	Eq. 22.6

Note concerning superscripts and subscripts

Superscripts are appended to forces and potential energies to indicate the type of force or energy. They may be found in the main list under F, for forces, and U, for potential energies. Uppercase superscripts are used for fundamental interactions.

Subscripts are used on many symbols to identify objects, reference frames, types (for example, of energy), and processes. Object identifiers may be numbers, letters, or groups of letters. Reference frames are indicated by capital letters. Object identifiers and reference frames can occur in pairs, indicating relative quantities. In this case, the main symbol describes a property of whatever is identified by the second subscript relative to that of the first. In the case of forces, the first subscript identifies the object that causes the force and the second identifies the object on which the force is exerted. Types and processes are identified in various ways; many are given in the main list. Here are some examples:

m_1	inertia of object 1
m_{ball}	inertia of ball
$\vec{v}_{\text{cm}}$	velocity of center of mass of system
$\vec{r}_{12}$	position of object 2 relative to object 1; $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1$
$\vec{p}_1$	momentum of object 1
$\vec{p}_{\text{Z2}}$	momentum of object 2 as measured in zero-momentum reference frame
$\vec{v}_{\text{AB}}$	velocity of observer B as measured in reference frame of observer A
$\vec{v}_{\text{Ao}}$	velocity of object o as measured in reference frame A
$\vec{r}_{\text{Ee}}$	position of event e as measured in Earth reference frame
$\vec{F}^{\text{c}}_{\text{pw}}$	contact force exerted by person on wall
$\vec{F}^{G}_{\text{Eb}}$	gravitational force exerted by Earth on ball
E_{th}	thermal energy
K_{conv}	convertible kinetic energy
P_{av}	average power
a_{c}	centripetal acceleration
$W_{\text{P}\to\text{Q}}$	work done along path from P to Q

Initial and final conditions are identified by subscripts i and f, following other identifiers. For example:

$\vec{p}_{1\text{i}}$	initial momentum of object 1
$\vec{p}_{\text{Zball,f}}$	final momentum of ball as measured in zero-momentum reference frame

Italic subscripts are used to identify components of vectors. These include x, y, z, r (radial), t (tangential), and ϑ (angular, with respect to given axis). They are also used to enumerate collections, for example, as indices of summation, and to indicate that a subscript refers to another variable. Here are some examples:

r_x	x component of position
a_t	tangential component of acceleration
L_ϑ	ϑ component of angular momentum
$p_{\text{Zball}\,y,\text{f}}$	final y component of momentum of ball as measured in zero-momentum reference frame
$\delta m_n r_n^2$	contribution to rotational inertia of extended object of small segment n, with inertia δm_n, at position r_n
c_P	specific heat capacity at constant pressure
W_q	electrostatic work

Appendix B

Mathematics Review

1 Algebra

Factors

$$ax + bx + cx = (a + b + c)x$$
$$(a + b)^2 = a^2 + 2ab + b^2$$
$$(a - b)^2 = a^2 - 2ab + b^2$$
$$(a + b)(a - b) = a^2 - b^2$$

Fractions

$$\left(\frac{a}{b}\right)\left(\frac{c}{d}\right) = \frac{ac}{bd}$$
$$\left(\frac{a/b}{c/d}\right) = \frac{a}{b} \div \frac{c}{d} = \frac{a}{b} \cdot \frac{d}{c} = \frac{ad}{bc}$$
$$\left(\frac{1}{1/a}\right) = a$$

Exponents

$$a^n = \underbrace{a \times a \times a \times \cdots \times a}_{n \text{ factors}}$$

Any real number can be used as an exponent:

$$a^{-x} = \frac{1}{a^x}$$
$$a^0 = 1$$
$$a^1 = a$$
$$a^{1/2} = \sqrt{a}$$
$$a^{1/n} = \sqrt[n]{a}$$
$$a^x a^y = a^{x+y}$$
$$\frac{a^x}{a^y} = a^{x-y}$$
$$(a^x)^y = a^{x \cdot y}$$
$$a^x b^x = (ab)^x$$
$$\frac{a^x}{b^x} = \left(\frac{a}{b}\right)^x$$

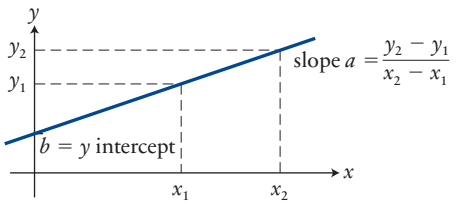
Logarithms

Logarithm is the inverse function of the exponential function:

$$y = a^x \Leftrightarrow \log_a y = \log_a a^x = x \quad \text{and} \quad x = \log_a (a^x) = a^{\log_a x}$$

The two most common values for the base a are 10 (the common logarithm base) and e (the natural logarithm base).

$$y = e^x \Leftrightarrow \log_e y = \ln y = \ln e^x = x \quad \text{and} \quad x = \ln e^x = e^{\ln x}$$



Logarithm rules (valid for any base):

$$\ln(ab) = \ln(a) + \ln(b)$$
$$\ln\left(\frac{a}{b}\right) = \ln(a) - \ln(b)$$
$$\ln(a^n) = n \ln(a)$$
$$\ln 1 = 0$$

The expression $\ln(a + b)$ cannot be simplified.

Linear equations

A linear equation has the form $y = ax + b$, where a and b are constants. A graph of y versus x is a straight line. The value of a equals the slope of the line, and the value of b equals the value of y when x equals zero.

If $a = 0$, the line is horizontal. If $a > 0$, the line rises as x increases. If $a < 0$, the line falls as x increases. For any two values of x, say x_1 and x_2, the slope a can be calculated as

$$a = \frac{y_2 - y_1}{x_2 - x_1}$$

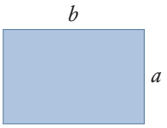
where y_1 and y_2 correspond to x_1 and x_2 (that is to say, $y_1 = ax_1 + b$ and $y_2 = ax_2 + b$).

Proportionality

If y is proportional to x (written $y \propto x$), then $y = ax$, where a is a constant. Proportionality is a subset of linearity. Because $y/x = a =$ constant for any corresponding x and y,

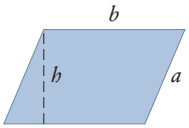
$$\frac{y_1}{x_1} = \frac{y_2}{x_2} \Leftrightarrow \frac{y_1}{y_2} = \frac{x_1}{x_2}.$$

Quadratic equation



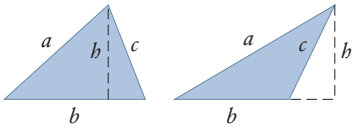
The equation $ax^2 + bx + c = 0$ (the quadratic equation) has two solutions (called *roots)* for x:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

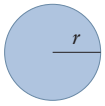


If $b^2 \geq 4ac$, the solutions are real numbers.

2 Geometry

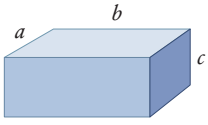


Area and circumference for two-dimensional shapes

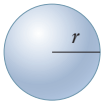


rectangle:
area $= ab$
circumference $= 2(a + b)$

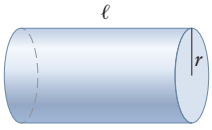
parallelogram:
area $= bh$
circumference $= 2(a + b)$



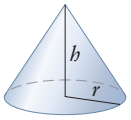
triangle:
area $= \frac{1}{2}bh$
circumference $= a + b + c$



circle:
area $= \pi r^2$
circumference $= 2\pi r$

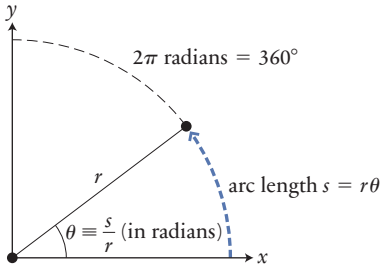


Volume and area for three-dimensional shapes



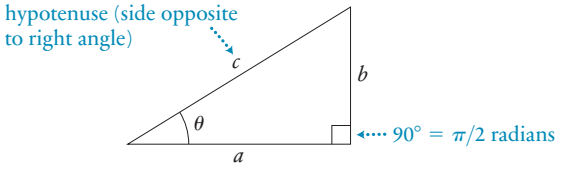
rectangular box:
volume $= abc$
area $= 2(a^2 + b^2 + c^2)$

sphere:
volume $= \frac{4}{3}\pi r^3$
area $= 4\pi r^2$



right circular cylinder:
volume $= \pi r^2 \ell$
area $= 2\pi r\ell + 2\pi r^2$

right circular cone:
volume $= \frac{1}{3}\pi r^2 h$
area $= \pi r^2 + \pi r\sqrt{r^2 + h^2}$



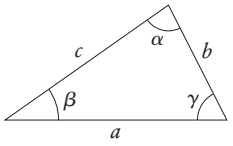
3 Trigonometry

Angle and arc length

Right triangles

A right triangle is a triangle in which one of the angles is a right angle:

Pythagorean theorem: $a^2 + b^2 = c^2 \Leftrightarrow c = \sqrt{a^2 + b^2}$
Trigonometric functions:



$$\sin\theta = \frac{b}{c} = \frac{\text{opposite side}}{\text{hypotenuse}}, \quad \theta = \sin^{-1}\left(\frac{b}{c}\right) = \arcsin\left(\frac{b}{c}\right)$$

$$\cos\theta = \frac{a}{c} = \frac{\text{adjacent side}}{\text{hypotenuse}}, \quad \theta = \cos^{-1}\left(\frac{a}{c}\right) = \arccos\left(\frac{a}{c}\right)$$

$$\tan\theta = \frac{b}{a} = \frac{\text{opposite side}}{\text{adjacent side}}, \quad \theta = \tan^{-1}\left(\frac{b}{a}\right) = \arctan\left(\frac{b}{a}\right)$$

General triangles

For any triangle, the following relationships hold:

$$\alpha + \beta + \gamma = 180° = \pi \text{ rad}$$

$$\text{Sine law: } \frac{\sin\alpha}{a} = \frac{\sin\beta}{b} = \frac{\sin\gamma}{c}$$

$$\text{Cosine law: } c^2 = a^2 + b^2 - 2ab\cos\gamma$$

Identities

$$\tan\theta = \frac{\sin\theta}{\cos\theta}$$

$$\cot\theta = \frac{1}{\tan\theta} = \frac{\cos\theta}{\sin\theta}$$

$$\csc\theta = \frac{1}{\sin\theta}$$

$$\sec\theta = \frac{1}{\cos\theta}$$

Periodicity

$$\cos(\alpha + 2\pi) = \cos\alpha$$
$$\tan(\alpha + \pi) = \sin\alpha$$

Angle addition

$$\sin(\alpha \pm \beta) = \sin\alpha\cos\beta \pm \cos\alpha\sin\beta$$
$$\cos(\alpha \pm \beta) = \cos\alpha\cos\beta \mp \sin\alpha\sin\beta$$

Double angles

$$\sin(2\alpha) = 2\sin\alpha\cos\alpha$$

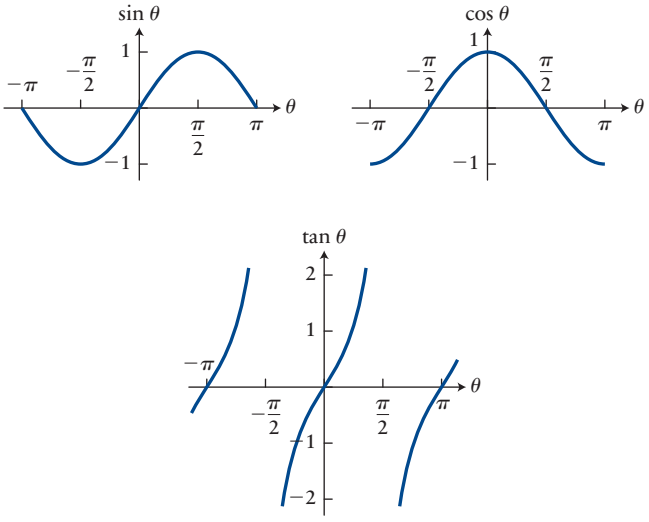
$$\cos(2\alpha) = \cos^2\alpha - \sin^2\alpha = 1 - 2\sin^2\alpha = 2\cos^2\alpha - 1$$

Other relations

$$\sin^2\alpha + \cos^2\alpha = 1$$

$$\sin(-\alpha) = -\sin\alpha$$

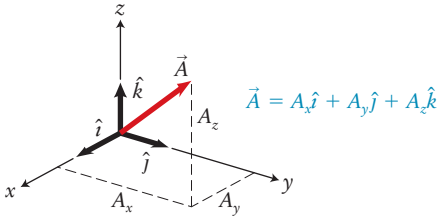
$$\cos(-\alpha) = \cos\alpha$$



$$\sin(\alpha \pm \pi) = -\sin\alpha$$

$$\cos(\alpha \pm \pi) = -\cos\alpha$$

$$\sin(\alpha \pm \pi/2) = \pm\cos\alpha$$



$$\cos(\alpha \pm \pi/2) = \mp\sin\alpha$$

The following graphs show sin θ, cos θ, and tan θ as functions of θ:

4 Vector algebra

A vector $\vec{A}$ in three-dimensional space can be written in terms of magnitudes A_x, A_y, and A_z of unit vectors $\hat{\imath}$, $\hat{\jmath}$, and $\hat{k}$, which have length 1 and lie along the x, y, and z axes:

Dot products between vectors produce scalars:

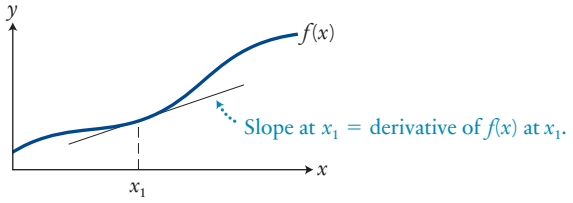
$$\vec{A}\cdot\vec{B} = A_xB_x + A_yB_y + A_zB_z = |A||B|\cos\theta$$

(θ is the angle between vectors $\vec{A}$ and $\vec{B}$)

Cross products between vectors produce vectors:

$$\vec{A}\times\vec{B} = (A_yB_z - A_zB_y)\hat{\imath} + (A_zB_x - A_xB_z)\hat{\jmath} + (A_xB_y - A_yB_x)\hat{k}$$

$$|\vec{A}\times\vec{B}| = |\vec{A}||\vec{B}|\sin\theta$$ (θ is the angle between vectors $\vec{A}$ and $\vec{B}$)



The direction of $\vec{A}\times\vec{B}$ is given by the right-hand rule (see Figure 12.44).

5 Calculus

In this section, x is a variable, and a and n are constants.

Derivatives

Geometrically, the derivative of a function $f(x)$ at $x = x_1$ is the slope of $f(x)$ at x_1:

Derivatives of common functions

$$\frac{d}{dx}a = 0$$

$$\frac{d}{dx}x^n = nx^{n-1}$$ (n need not be an integer)

$$\frac{d}{dx}\sin x = \cos x$$

$$\frac{d}{dx}\cos x = -\sin x$$

$$\frac{d}{dx}\tan x = \frac{1}{\cos^2 x}$$

$$\frac{d}{dx}e^{ax} = ae^{ax}$$

$$\frac{d}{dx}\ln(ax) = \frac{1}{x}$$

$$\frac{d}{dx}a^x = a^x\ln a$$

Derivatives of sums, products, and functions of functions

Constant times a function: $\frac{d}{dx}[a\cdot f(x)] = a\cdot\frac{d}{dx}f(x)$

Sum of functions: $\frac{d}{dx}[f(x) + g(x)] = \frac{d}{dx}f(x) + \frac{d}{dx}g(x)$

Product of functions:

$$\frac{d}{dx}[f(x)\cdot g(x)] = g(x)\frac{d}{dx}f(x) + f(x)\frac{d}{dx}g(x)$$

Quotient of functions: $\frac{d}{dx}\left[\frac{f(x)}{g(x)}\right] = \frac{g(x)\frac{d}{dx}f(x) - f(x)\frac{d}{dx}g(x)}{[g(x)]^2}$

Functions of functions (the chain rule): If f is a function of u, and u is a function of x, then

$$\frac{d[f(u)]}{du}\cdot\frac{d[u(x)]}{dx}=\frac{d[f(x)]}{dx}$$

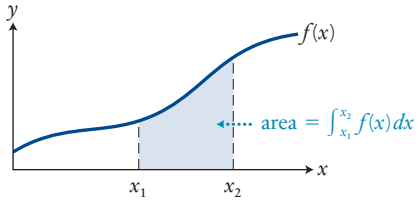
Second and higher derivatives The second derivative of a function f with respect to x is the derivative of the derivative:

$$\frac{d^2f(x)}{dx^2}=\frac{d}{dx}\left(\frac{d}{dx}f(x)\right)$$

Higher derivatives are defined similarly:

$$\frac{d^nf(x)}{dx^n}=\underbrace{\cdots\frac{d}{dx}\left(\frac{d}{dx}\left(\frac{d}{dx}f(x)\right)\right)}_{n\text{ uses of }\frac{d}{dx}}\quad\text{(where }n\text{ is a positive integer).}$$

Partial derivatives For functions of more than one variable, the partial derivative, written $\frac{\partial}{\partial x}$, is the derivative with respect to one variable; all other variables are treated as constants.

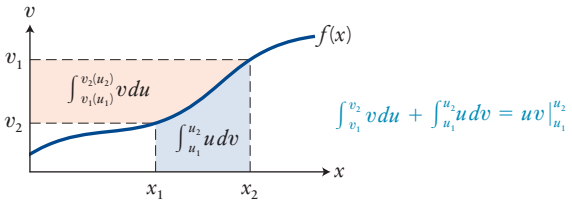


Integrals

Indefinite integrals Integration is the reverse of differentiation. An indefinite integral $\int f(x)dx$ is a function whose derivative is $f(x)$.

That is to say, $\frac{d}{dx}[\int f(x)dx]=f(x)$.

If $A(x)$ is an indefinite integral of $f(x)$, then so is $A(x)+C$, where C is any constant. Thus, it is customary when evaluating indefinite integrals to add a "constant of integration" C.



Definite integrals The definite integral of $f(x)$, written as $\int_{x_1}^{x_2}f(x)dx$, represents the sum of the area of contiguous rectangles that each intersect $f(x)$ at some point along one base and that each have another base coincident with the x axis over some part of the range between x_1 and x_2; the indefinite integral evaluates the sum in the limit of arbitrarily small rectangle bases. In other words, the indefinite integral gives the net area that lies under $f(x)$ but above the x axis between the boundaries x_1 and x_2.

If $A(x)$ is any indefinite integral of $f(x)$, then the definite integral is given by $\int_{x_1}^{x_2}f(x)dx=A(x_2)-A(x_1)\equiv A(x)|_{x_1}^{x_2}$. The constant of integration C does not affect the value of definite integrals and thus can be ignored (i.e., set to zero) during evaluation.

Integration by parts $\int_a^b udv$ is the area under the curve of $u(v)$. If $\int_a^b udv$ is difficult to evaluate directly, it is sometimes easier to express the area under the curve as the area within part of a rectangle minus the area under the curve of $v(u)$. In other words:

$$\int_a^b udv=uv|_a^b-\int_a^b vdu.$$

By choosing u and dv appropriately (both can be functions of x), this approach, called "integration by parts," can transform difficult integrals into easier ones.

Table of integrals In the following expressions, a and b are constants. An arbitrary constant of integration C can be added to the right-hand side.

$$\int x^ndx=\frac{1}{n+1}x^{n+1}\ (\text{for } n\neq -1)$$

$$\int x^{-1}dx=\ln|x|$$

$$\int\frac{1}{a^2+x^2}dx=\frac{1}{a}\tan^{-1}\frac{x}{a}$$

$$\int\frac{1}{(a^2+x^2)^2}dx=\frac{1}{2a^3}\tan^{-1}\frac{x}{a}+\frac{x}{2a^2(x^2+a^2)}$$

$$\int\frac{1}{\sqrt{\pm a^2+x^2}}dx=\ln|x+\sqrt{\pm a^2+x^2}|$$

$$\int\frac{1}{\sqrt{a^2-x^2}}dx=\sin^{-1}\frac{x}{|a|}=\tan^{-1}\frac{x}{\sqrt{a^2-x^2}}$$

$$\int\frac{x}{\sqrt{\pm a^2-x^2}}dx=-\sqrt{\pm a^2-x^2}$$

$$\int\frac{x}{\sqrt{\pm a^2+x^2}}dx=\sqrt{\pm a^2+x^2}$$

$$\int\frac{1}{(\pm a^2+x^2)^{3/2}}dx=\frac{\pm x}{a^2\sqrt{\pm a^2+x^2}}$$

$$\int\frac{x}{(a^2+x^2)^{3/2}}dx=-\frac{1}{\sqrt{a^2+x^2}}$$

$$\int\frac{1}{a+bx}dx=\frac{1}{b}\ln(a+bx)$$

$$\int\frac{1}{(a+bx)^2}dx=-\frac{1}{b(a+bx)}$$

$$\int\sin(ax)dx=-\frac{1}{a}\cos(ax)$$

$$\int \cos(ax)dx = \frac{1}{a}\sin(ax)$$

$$\int \tan(ax)dx = -\frac{1}{a}\ln(\cos ax)$$

$$\int \sin^2(ax)dx = \frac{x}{2} - \frac{\sin 2ax}{4a}$$

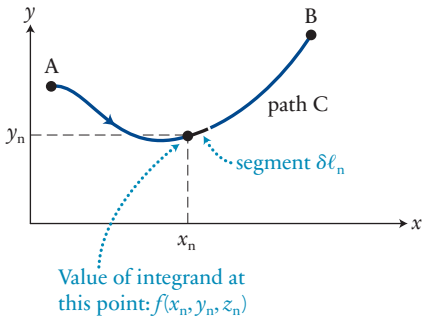
$$\int \cos^2(ax)dx = \frac{x}{2} + \frac{\sin 2ax}{4a}$$

$$\int x\sin(ax)dx = \frac{1}{a^2}\sin ax - \frac{1}{a}x\cos ax$$

$$\int x\cos(ax)dx = \frac{1}{a^2}\cos ax + \frac{1}{a}x\sin ax$$

$$\int e^{ax}dx = \frac{1}{a}e^{ax}$$

$$\int xe^{ax}dx = \frac{e^{ax}}{a^2}(ax-1)$$



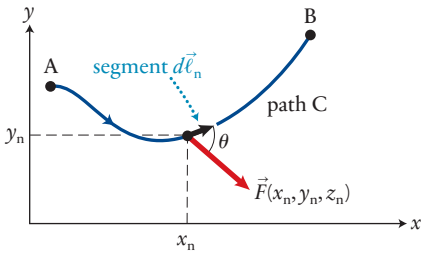
$$\int x^2e^{ax}dx = \frac{x^2e^{ax}}{a} - \frac{2}{a}\left[\frac{e^{ax}}{a^2}(ax-1)\right]$$

$$\int \ln ax\,dx = x\ln(ax) - x$$

$$\int_0^\infty x^n e^{-ax}dx = \frac{n!}{a^{n+1}}$$

$$\int_0^\infty e^{-ax^2}dx = \frac{1}{2}\sqrt{\frac{\pi}{a}}$$

Line integrals A *line integral* is an integral of a function that needs to be evaluated over a path (that is, a curve connecting two points in space). Consider, for example, the two-dimensional path C from point A to point B in the figure below. (The procedure described below is equally applicable in three dimensions.)



The path from A to B is *directed:* At any point the direction along the path away from A and toward B is forward (positive). Suppose we have a function $f(x, y, z)$ defined everywhere along the path. The function can be either a scalar or a vector; we will first discuss line integrals of scalar functions. We divide the path between A and B into small segments of length $\delta\ell_n$, each segment small enough that we can consider it essentially straight and small enough that the value of the function $f(x, y, z)$ can be considered constant over that segment. We then calculate the product $f(x_n, y_n, z_n)\delta\ell_n$ for each segment. The line integral of the function $f(x, y, z)$ along path C is then given by the sum of all those products along the path in the limit of infinitesimally small segments:

$$\int_C f(x, y, z)d\ell = \lim_{\delta\ell\to\infty}\sum_n f(x_n, y_n, z_n)\delta\ell_n.$$

To evaluate the integral on the right, we need to know the path C. Usually the path is specified in terms of the length parameter ℓ: $x = x(\ell)$, $y = y(\ell)$, $z = z(\ell)$. The line integral can then be written as an ordinary definite integral:

$$\int_C f(x, y, z)d\ell = \int_A^B f[x(\ell), y(\ell), z(\ell)]d\ell.$$

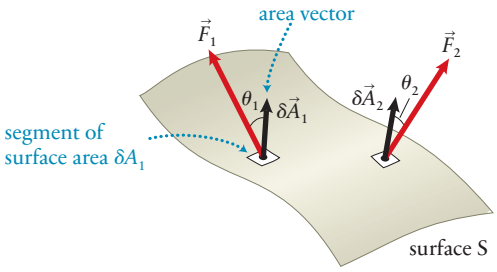
Next we consider the line integral of a vector function. We consider the same path C from A to B, but now we consider a vector function $\vec{F}(x, y, z)$. Instead of taking infinitesimally small scalar segments $d\ell_n$ along the path, we take small vector segments $d\vec{\ell}_n$ along the path of length $d\ell_n$ and whose direction is tangent to the path in the direction of the path from A to B:

At each point we calculate the scalar product $\vec{F}(x_n, y_n, z_n)\cdot d\vec{\ell}_n$ and then sum these products over path C to obtain the line integral.

$$\int_C \vec{F}(x, y, z)\cdot d\vec{\ell}.$$

By writing out the scalar product, $\vec{F}(x, y, z)\cdot d\vec{\ell} = F(x, y, z)\cdot\cos\theta\, d\ell$, we can reduce the line integral of a vector function to that of a scalar function:

$$\int_C \vec{F}(x, y, z)\cdot d\vec{\ell} = \int_C F(x, y, z)\cos\theta\, d\ell.$$



In other words, we need to compute the line integral of the component of the vector $\vec{F}(x, y, z)$ along the tangent to the path.

If the path is closed—that is, the path returns to the starting point—we indicate that by putting a circle through the integration sign:

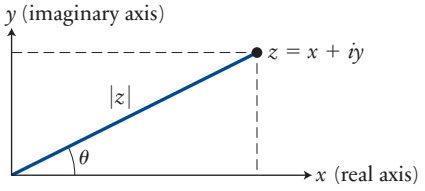
$$\oint_C \vec{F}(x, y, z)\cdot d\vec{\ell}.$$

Surface integrals A *surface integral* is an integral of a function that needs to be evaluated over a surface. As with line integrals, the integrand of a surface integral can be a scalar or a vector function. We will only discuss the more general case of a vector function here.

The surface over which the integration is to be taken can be either *closed* or *open*. A closed surface, such as the surface of a sphere, divides space into two parts—an inside and an outside—and to get from one part to the other one has to go through the surface. An open surface does not have this property: For the surface S shown in the figure below, for example, one can go from one side of the surface to the other without passing through it.

Consider a vector function $\vec{F}(x, y, z)$. To calculate the surface integral of this function over surface S, we begin by dividing the surface into small segments of surface area δA_n, each segment being small enough that we can consider it to be essentially flat and small enough so that the function $\vec{F}(x, y, z)$ can be considered constant over the segment. We then define an *area vector* $\delta\vec{A}_n$ whose magnitude is equal to the surface area δA_n of the segment and whose direction is normal to that segment. For each segment we then calculate the scalar product of the area vector and the value $\vec{F}_n$ of the vector function at that location: $\vec{F}_n(x_n, y_n, z_n) \cdot \delta\vec{A}_n$. The surface integral of the vector function over the surface S is then given by the sum of all those products for all the segments that make up the surface:

$$\int_S \vec{F}(x, y, z) \cdot d\vec{A} = \lim_{\delta\vec{A}_n \to \infty} \sum_n \vec{F}_n(x_n, y_n, z_n) \cdot \delta\vec{A}_n.$$



If the surface is closed, we indicate that by putting a circle through the integration sign:

$$\oint_S \vec{F}(x, y, z) \cdot d\vec{A}$$

6 Complex numbers

A complex number $z = x + iy$ is defined in terms of its real part x and its imaginary part y. Both x and y are real numbers. i is Euler's constant, defined by the property $i^2 = -1$.

Each complex number z has a "complex conjugate" z^* which has the same real part but an imaginary part with opposite sign: $z = x + iy \Leftrightarrow z^* = x - iy$.

The real and imaginary parts can be expressed in terms of the complex number and its conjugate:

$$x = \tfrac{1}{2}(z + z^*)$$

$$y = \tfrac{1}{2}i(z - z^*)$$

A complex number is like a two-dimensional vector in a plane with a real axis and an imaginary axis. Thus, z can be described by a magnitude or length $|z|$ and an angle θ formed with the real axis (called the "phase angle"):

$$z = |z|(\cos\theta + i\sin\theta), \text{ where } |z| = \sqrt{zz^*} \text{ and}$$

$$\theta = \tan^{-1}\frac{y}{x} = \tan^{-1}\frac{i(z - z^*)}{(z + z^*)}.$$

Euler's formula says that $e^{i\theta} = \cos\theta + i\sin\theta$, allowing complex numbers to be written in the form $z = |z|e^{i\theta}$. This is a convenient form for expressing complex numbers. For example, it is easy to raise a complex number z to a power n: $z^n = |z|^n e^{in\theta}$.

7 Useful approximations

Binomial expansion

$$(1 + x)^n = 1 + nx + \frac{n(n-1)}{2}x^2 + \cdots$$

If $x \ll 1$, then $(1 + x)^n \approx 1 + nx$

Trigonometric expansions

$$\sin\alpha = \alpha - \frac{\alpha^3}{3!} + \frac{\alpha^5}{5!} - \frac{\alpha^7}{7!} + \cdots \quad (\alpha \text{ in rad})$$

$$\cos\alpha = 1 - \frac{\alpha^2}{2!} + \frac{\alpha^4}{4!} - \frac{\alpha^6}{6!} + \cdots \quad (\alpha \text{ in rad})$$

$$\tan\alpha = \alpha + \frac{1}{3}\alpha^3 + \frac{2}{15}\alpha^5 + \frac{17}{315}\alpha^7 + \cdots \quad (\alpha \text{ in rad})$$

If $\alpha \ll 1$ rad, then $\sin\alpha \approx \alpha$, $\cos\alpha \approx 1$, and $\tan\alpha \approx \alpha$.

Other useful expansions

$$\frac{1}{1 - x} = 1 + x + x^2 + x^3 + \cdots \text{ for } -1 < x < 1$$

$$e^x = 1 + x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \frac{1}{24}x^4 + \cdots$$

$$\ln(1 + x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \frac{1}{4}x^4 + \cdots \text{ for } -1 < x < 1$$

$$\ln\left(\frac{1 + x}{1 - x}\right) = 2x + \frac{2}{3}x^3 + \frac{2}{5}x^5 - \frac{2}{7}x^7 + \cdots \text{ for } -1 < x < 1$$

Appendix D

Center of Mass of Extended Objects

We can apply the concept of center of mass to extended objects. Consider, for example, the object of inertia m in **Figure D.1**. If you imagine breaking down the object into many small segments of equal inertia δm, you can use Eq. 6.24 to compute the position of the center of mass:

$$x_{\text{cm}} = \frac{\delta m_1 x_1 + \delta m_2 x_2 + \cdots}{\delta m_1 + \delta m_2 + \cdots}, \tag{D.1}$$

where x_n is the position of segment δm_n. Because the sum of the inertias of all segments is equal to the inertia m of the extended object, $\delta m_1 + \delta m_2 + \cdots = m$, we can write Eq. D.1 as

$$x_{\text{cm}} = \frac{1}{m}(\delta m_1 x_1 + \delta m_2 x_2 + \cdots) = \frac{1}{m}\sum_n (\delta m_n x_n) \tag{D.2}$$

To evaluate this sum for the extended object, we take the limit of this expression as $\delta m \to 0$. In this limit, the sum becomes an integral:

$$x_{\text{cm}} = \frac{1}{m}\lim_{\delta m \to 0}\sum_n (\delta m_n x_n) \equiv \frac{1}{m}\int_{\text{object}} x\, dm. \tag{D.3}$$

To evaluate the integral we need to know how the inertia is distributed over the object. Let the *inertia per unit length* of the object be $\lambda \equiv dm/dx$. In general λ is a function of position—that is, the inertia per unit length need not be the same at different locations along the object—and so $\lambda = \lambda(x)$ and $dm = \lambda(x)dx$. Substituting this expression for dm into Eq. D.3, we obtain

$$x_{\text{cm}} = \frac{1}{m}\int_{\text{object}} x\lambda(x)dx. \tag{D.4}$$

In this expression, the limits of integration should be taken to be the positions of the left and right ends of the object (x_{L} and x_{R}, respectively).

For example, let the object in Figure D.1 have a uniformly distributed inertia so that $\lambda(x)$ has the same value (the inertia of the extended object divided by the length of the object) everywhere:

$$\lambda(x) = \frac{m}{x_{\text{R}} - x_{\text{L}}}. \tag{D.5}$$

Because $\lambda(x)$ does not depend on x, we can pull it out of the integral in Eq. D.4 and so, substituting Eq. D.5 into Eq. D.4, we get

$$x_{\text{cm}} = \frac{\lambda(x)}{m}\int_{x_{\text{L}}}^{x_{\text{R}}} x\, dx = \frac{1}{x_{\text{R}} - x_{\text{L}}}\int_{x_{\text{L}}}^{x_{\text{R}}} x\, dx = \frac{1}{x_{\text{R}} - x_{\text{L}}}\left[\tfrac{1}{2}x^2\right]_{x_{\text{L}}}^{x_{\text{R}}}$$

$$= \frac{x_{\text{R}}^2 - x_{\text{L}}^2}{2(x_{\text{R}} - x_{\text{L}})} = \frac{x_{\text{R}} + x_{\text{L}}}{2}. \tag{D.6}$$

In other words, the center of mass of the object is halfway between the ends of the object (at the center of the object), as we expect.

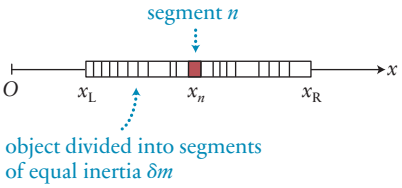

Figure D.1

Appendix E

Derivation of the Lorentz Transformation Equations

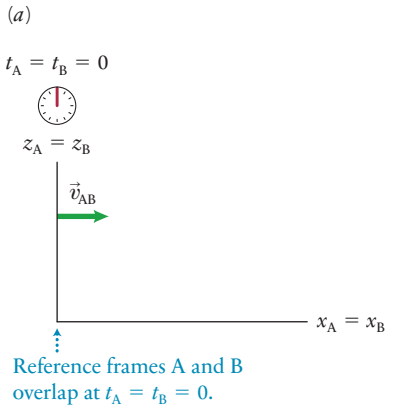

Figure E.1 Determining the space and time coordinates of an event from two reference frames that overlap at $t_A = t_B = 0$.

In this appendix we derive the Lorentz transformation equations (Eqs. 14.29–14.32), which relate position and time in two reference frames A and B. The origins of the reference frames coincide at $t_A = t_B = 0$, and the frames are moving at constant velocity $\vec{v}_{AB} = v_{ABx}\hat{i}$ in the x direction relative to each other (**Figure E.1*a***).

Consider an event e that occurs at instant t_{Ae} and position x_{Ae} in reference frame A (Figure E.1*b*).* Our goal is to express t_{Be} and x_{Be}, the instant and the position at which the event occurs in reference frame B, in terms of t_{Ae} and x_{Ae}:

$$t_{Be} = f(x_{Ae}, t_{Ae}) \tag{E.1}$$

$$x_{Be} = g(x_{Ae}, t_{Ae}). \tag{E.2}$$

To obtain these relationships, we consider the space-time interval (Eq. 14.18) between the event in Figure E.1*b* and the event in Figure E.1*a* (this event being the overlapping of the two origins). The spatial separation of these two events is $\Delta x_{Ae} = x_{Ae} - 0 = x_{Ae}$ in reference frame A and $\Delta x_{Be} = x_{Be} - 0 = x_{Be}$ in reference frame B. The temporal separations are $\Delta t_{Ae} = t_{Ae} - 0 = t_{Ae}$ and $\Delta t_{Be} = t_{Be} - 0 = t_{Be}$. Because the space-time interval is an invariant, we have

$$(c_0 t_{Be})^2 - (x_{Be})^2 = (c_0 t_{Ae})^2 - (x_{Ae})^2. \tag{E.3}$$

To satisfy Eq. E.3, the relationships expressed in Eqs. E.1 and E.2 must be linear:

$$t_{Be} = Dt_{Ae} + Ex_{Ae} \tag{E.4}$$

$$x_{Be} = Ft_{Ae} + Gx_{Ae}, \tag{E.5}$$

where D, E, F, and G are constants. To obtain relationships between these constants, consider the position of the origin of reference frame B at the instant illustrated in Figure E.1*b*. The origin of reference frame B moves at constant velocity $\vec{v}_{AB}$ relative to reference frame A, and so at t_{Ae} the position of B's origin in reference frame A is

$$x_{AB} = v_{ABx}t_{Ae}. \tag{E.6}$$

The position of B's origin in reference frame B is always zero, $x_{BB} = 0$.† According to Eq. E.5 we then have $x_{BB} = 0 = Ft_{Ae} + Gx_{AB}$, or substituting for x_{AB} from Eq. E.6, $0 = Ft_{Ae} + G(v_{ABx}t_{Ae})$. Therefore

$$F = -v_{ABx}G. \tag{E.7}$$

Conversely, the origin of reference frame A is located at $x_{BA} = -v_{ABx}t_{Be}$ in reference frame B, and so, with $x_{AA} = 0$, Eqs. E.4 and E.5 become

$$t_{Be} = Dt_{Ae} + 0 \tag{E.8}$$

$$-v_{ABx}t_{Be} = Ft_{Ae} + 0. \tag{E.9}$$

Solving Eqs. E.8 and E.9 for F gives $F = -v_{ABx}D$, and so, from Eq. E.7,

$$D = G. \tag{E.10}$$

*Remember our subscript format: The capital letter refers to the reference frame; the lowercase e is for "event." Thus the vector $\vec{r}_{Ae}$ represents observer **A**'s measurement of the position at which the event occurs.

†Do not be stymied by the unfamiliar subscript BB. It's the same format we've been using all along: The first B tells you the reference frame in which the measurement is made, and the second B tells you what's being measured—in this case, the position of the origin of reference frame B.

Equations E.4 and E.5 then become

$$t_{\mathrm{Be}} = Gt_{\mathrm{Ae}} + Ex_{\mathrm{Ae}} \tag{E.11}$$

$$x_{\mathrm{Be}} = -v_{\mathrm{ABx}}Gt_{\mathrm{Ae}} + Gx_{\mathrm{Ae}}. \tag{E.12}$$

Substituting Eqs. E.11 and E.12 into the left side of Eq. E.3 and using $v_{\mathrm{ABx}}^2 = v^2$ yields

$$c_0^2G^2\left(1 - \frac{v^2}{c_0^2}\right)t_{\mathrm{Ae}}^2 + (c_0^2EG + G^2v_{\mathrm{ABx}})2t_{\mathrm{Ae}}x_{\mathrm{Ae}} - (G^2 - c_0^2E^2)x_{\mathrm{Ae}}^2$$
$$= (c_0t_{\mathrm{Ae}})^2 - (x_{\mathrm{Ae}})^2. \tag{E.13}$$

and then gather all the $(t_{\mathrm{Ae}})^2$ terms, all the $x_{\mathrm{Ae}}\,t_{\mathrm{Ae}}$ terms, and all the $(t_{\mathrm{Ae}})^2$ terms:

$$\left[c_0^2G^2\left(1 - \frac{v^2}{c_0^2}\right) - c_0^2\right]t_{\mathrm{Ae}}^2 + 2(c_0^2EG + G^2v_{\mathrm{ABx}})\,x_{\mathrm{Ae}}t_{\mathrm{Ae}}$$
$$-(G^2 - c_0^2E^2 - 1)x_{\mathrm{Ae}}^2 = 0. \tag{E.14}$$

Because Eq. E.14 must hold for any value of t_{Ae} and x_{Ae}, the coefficient of each term must be zero. The coefficient of the t_{Ae}^2 term yields

$$c_0^2G^2\left(1 - \frac{v^2}{c_0^2}\right) = c_0^2. \tag{E.15}$$

Solving Eq. E.15 for G yields

$$G = \left(1 - \frac{v^2}{c_0^2}\right)^{-1/2} \equiv \gamma, \tag{E.16}$$

and so from Eq. E.7, $F = -v_{\mathrm{ABx}}G$, we see that $F = -\gamma v_{\mathrm{ABx}}$.

The coefficient of the $x_{\mathrm{Ae}}t_{\mathrm{Ae}}$ term in Eq. E.14 must also be zero. Substituting γ for G in that coefficient gives us

$$c_0^2E\gamma + \gamma^2v_{\mathrm{ABx}} = 0 \tag{E.17}$$

$$E = -\gamma v_{\mathrm{ABx}}/c_0^2. \tag{E.18}$$

Now we are ready to substitute for *D*, *E*, *F*, and *G* in Eqs. E.4 and E.5—*D* from Eq. E.10, *E* from Eq. E.18, *F* from Eq. E.7, and *G* from Eq. E.16:

$$t_{\mathrm{Be}} = \gamma\left(t_{\mathrm{Ae}} - \frac{1}{c_0^2}v_{\mathrm{ABx}}x_{\mathrm{Ae}}\right) \tag{E.19}$$

$$x_{\mathrm{Be}} = \gamma(x_{\mathrm{Ae}} - v_{\mathrm{ABx}}t_{\mathrm{Ae}}). \tag{E.20}$$

Because there is no length contraction in the directions perpendicular to the relative velocity $\vec{v}_{\mathrm{AB}}$ of the two reference frames, we have

$$y_{\mathrm{Be}} = y_{\mathrm{Ae}} \tag{E.21}$$

$$z_{\mathrm{Be}} = z_{\mathrm{Ae}}. \tag{E.22}$$

Equations E.19–E.22 are the Lorentz transformation equations we wanted to derive.

Velocities in two reference frames

We can use Eqs. E.19 and E.20 to derive Eq. 14.33, the relationship between the *x* components of the velocities of an object o measured in two reference frames A and B. Let the *x* component be $v_{\mathrm{Aox}} = dx_{\mathrm{Ao}}/dt_{\mathrm{A}}$ in reference frame A and $v_{\mathrm{Box}} = dx_{\mathrm{Bo}}/dt_{\mathrm{B}}$ in reference frame B. We begin by writing Eqs. E.19 and E.20 in differential form:

$$dt_{\mathrm{B}} = \gamma\left(dt_{\mathrm{A}} - \frac{v_{\mathrm{ABx}}}{c_0^2}dx_{\mathrm{Ao}}\right) \tag{E.23}$$

$$dx_{\mathrm{Bo}} = \gamma(dx_{\mathrm{Ao}} - v_{\mathrm{ABx}}\,dt_{\mathrm{A}}), \tag{E.24}$$

$$dy_{\mathrm{Bo}} = dy_{\mathrm{Ao}}, \tag{E.25}$$

$$dz_{\mathrm{Bo}} = dz_{\mathrm{Ao}}, \tag{E.26}$$

where we have replaced the subscript e by o because we are considering an object rather than an event. Dividing Eq. E.24 by Eq. E.23 yields an expression for the x component of the velocity in reference frame B:

$$v_{\mathrm{B}ox} = \frac{dx_{\mathrm{B}o}}{dt_{\mathrm{B}}} = \frac{\gamma(dx_{\mathrm{A}o} - v_{\mathrm{AB}x}\,dt_{\mathrm{A}})}{\gamma\left(dt_{\mathrm{A}} - \dfrac{v_{\mathrm{AB}x}}{c_0^2}dx_{\mathrm{A}o}\right)} = \frac{(dx_{\mathrm{A}o} - v_{\mathrm{AB}x}\,dt_{\mathrm{A}})}{\left(dt_{\mathrm{A}} - \dfrac{v_{\mathrm{AB}x}}{c_0^2}dx_{\mathrm{A}o}\right)}. \tag{E.27}$$

Finally, we divide the numerator and denominator of the rightmost term by dt_{A} to obtain Eq. 14.33:

$$v_{\mathrm{B}ox} = \frac{\left(\dfrac{dx_{\mathrm{A}o}}{dt_{\mathrm{A}}} - v_{\mathrm{AB}x}\right)}{\left(1 - \dfrac{v_{\mathrm{AB}x}}{c_0^2}\dfrac{dx_{\mathrm{A}o}}{dt_{\mathrm{A}}}\right)} = \frac{(v_{\mathrm{A}ox} - v_{\mathrm{AB}x})}{\left(1 - \dfrac{v_{\mathrm{AB}x}}{c_0^2}v_{\mathrm{A}ox}\right)}. \tag{E.28}$$

To find the y component of the velocity in reference frame B, we divide Eq. E.25 by Eq. E.23:

$$v_{\mathrm{B}oy} = \frac{dy_{\mathrm{B}o}}{dt_{\mathrm{B}}} = \frac{dy_{\mathrm{A}o}}{\gamma\left(dt_{\mathrm{A}} - \dfrac{v_{\mathrm{AB}x}}{c_0^2}dx_{\mathrm{A}o}\right)}. \tag{E.29}$$

Dividing numerator and denominator by dt_{A} then yields

$$v_{\mathrm{B}oy} = \frac{v_{\mathrm{A}oy}}{\gamma\left(1 - \dfrac{v_{\mathrm{AB}x}v_{\mathrm{A}ox}}{c_0^2}\right)}. \tag{E.30}$$

For the z component of the velocity we obtain a similar equation with y replaced by z:

$$v_{\mathrm{B}oz} = \frac{v_{\mathrm{A}oz}}{\gamma\left(1 - \dfrac{v_{\mathrm{AB}x}v_{\mathrm{A}ox}}{c_0^2}\right)}. \tag{E.31}$$

$$\Delta p_{sx} = +0.38\ \text{kg} \cdot \text{m/s} - 0$$

Solutions to Checkpoints

Chapter 1

1.1 A nickel and a quarter. If you had to think about this for more than a few seconds, you probably unknowingly assumed that *neither* coin could be a nickel. This is an example of a hidden assumption.

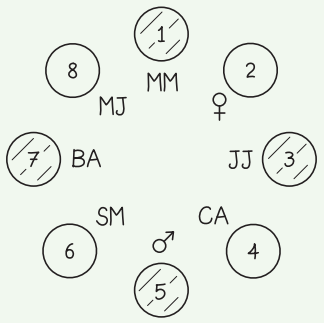
1.2 That the clock works with the new batteries does not necessarily mean the old batteries are dead. They could have been inserted incorrectly, or there could have been a bad contact that got fixed when the new batteries were inserted. That the clock does not work with the new batteries does not necessarily mean the clock is broken. Both the new and the old batteries could be inserted incorrectly, or both the new and the old batteries could be dead.

1.3 Two valuable goals are to become a better problem solver and to learn to apply the scientific method to any type of reasoning. Either skill is useful in any type of career. If you wrote "pass physics requirement" or "get into medical school," think again. With those goals, it is going to be very difficult for you to derive much satisfaction or benefit from this course.

Here are some interesting responses I have collected over the years: to become a responsible citizen of the world, to understand modern technology, to bridge the gap between the sciences and the arts/humanities, to sharpen my mind.

1.4 Likely answers are that something about the case or cap has changed. The case opening may have expanded due to the heat, or the cap may have acquired a dent that prevents it from fitting over the opening. If you answered something along these lines, you assumed symmetry with respect to translation in both time and space: If the cap fits at home, it ought to fit elsewhere now and anytime in the future.

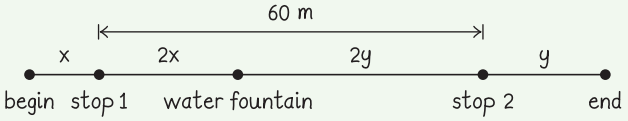
1.5 The distance from the North Pole to the equator is one-fourth of Earth's circumference c, which means $c = 4 \times (10{,}000{,}000\ \text{m}) = 40{,}000{,}000\ \text{m}$. Because $c = 2\pi R_E$, where R_E is Earth's radius, you have $R_E = c/2\pi = (40{,}000{,}000\ \text{m})/2\pi = 6{,}400{,}000\ \text{m}$.



1.6 The diameter of an atom is 10^{-10} m (see Figure 1.9); the diameter of an apple is about 10^{-1} m. Therefore the required magnification factor is $(10^{-1}\ \text{m})/(10^{-10}\ \text{m}) = 10^9$. With this magnification, the apple's diameter would be $10^9(10^{-1}\ \text{m}) = 10^8$ m, which is about 10 times Earth's diameter.

1.7 (*a*) (*i*) Somebody switches the power off; the light bulb burns out. (*ii*) Thunder; tractor trailer passing dorm; stomach growling; dorm starting to collapse. (*iii*) You spent all the money in your account; you forgot to deposit the money your parents gave you last week; the bank made a mistake. (*b*) No. All these causes occur before the event. (*c*) One emotion you almost certainly experience is anxiety. Such events tend to be unsettling—we want to know the causes of things we observe.

1.8 A typical physics class lasts about 1 h, which is 3600 s, or order of magnitude 10^4 s. The number of sequential chemical reactions is thus $(10^4\ \text{s})(1\ \text{reaction}/10^{-13}\ \text{s}) = 10^{17}$ (hundred million billion!) reactions.



1.9 Because Mike Masters imposes the most constraints, you begin by placing him in seat 1 (Figure S1.9). To satisfy the constraint of having men and women alternate, placing Mike here means the odd-numbered seats are for the men. Only two arrangements avoid putting Cyndi Ahlers next to Mike: Put her in 4 or in 6. If you put Cyndi in 4, Sylvia Masters has to go in 6 to avoid being next to her husband in 1. With Sylvia in 6, John Jones cannot be in 5 or 7, and so you have to put him in 3. Mary Jones then has to go in 8. The remaining empty seats—2, 5, and 7—leave you no choice: Bob Ahlers has to go in 7 because putting him in 5 would have him next to his wife in 4, and your spouse and you get 2 and 5. (Had you put Cyndi Ahlers in 6, you would have obtained the mirror image of the arrangement shown in Figure S1.9.)

Figure S1.9

1.10 90 m. If you call the distance from the west end of the corridor to stop 1 x, the distance from stop 1 to the fountain is $2x$ (Figure S1.10). If you call the distance from stop 2 to the fountain $2y$, the distance from stop 2 to the east end of the corridor is y. Because the distance between the two stops is 60 m, you know that $2x + 2y = 60$ m. From the figure, you see that the total corridor length L is $L = x + 2x + 2y + y = 3x + 3y$. The rest is algebra: $2x + 2y = 60$ m, $x = (30\ \text{m} - y)$, $L = 3(30\ \text{m} - y) + 3y = 90$ m.

Figure S1.10

1.11 (*a*) $\ell = 150$ Mm (megameters) or 0.15 Gm (gigameters). (*b*) $t = 12$ ps (picoseconds). (*c*) 1.2 Mm/s. (*d*) 2.3 Mg.

1.12 The ratio on the left has inches in the numerator and millimeters in the denominator, meaning that the inches don't cancel out. In general, when converting from a given unit to a desired unit, you need to use a ratio that has the desired unit in the numerator and the given unit in the denominator.

1.13 (*a*) In 1 mol you have 6.022×10^{23} atoms, and when you pack this number of atoms into a cube, each side of the cube contains $\sqrt[3]{6.022 \times 10^{23}}$ atoms $= 8.445 \times 10^7$ atoms. The diameter of each atom is 10^{-10} m (see Figure 1.9), and so the length of each side of the cube is $(8.445 \times 10^7\ \text{atoms})(10^{-10}\ \text{m/atom}) = 8.4 \times 10^{-3}$ m, which is about one-third of an inch. (*b*) Because 1 mol of carbon has a mass of 12×10^{-3} kg, Eq. 1.4 gives $V = m/\rho = (12 \times 10^{-3}\ \text{kg})/(2.2 \times 10^3\ \text{kg/m}^3) = 5.5 \times 10^{-6}\ \text{m}^3$. If you assume this value to be a cube, then the cube root of V gives the length of a side, 1.8×10^{-2} m, about twice the length for each side calculated in part *a*.

1.14 (*a*) The circumference is $2\pi R = 2\pi(27.3\ \text{mm}) = 172$ mm. You are allowed to report three significant digits because the radius R has three (the 2 in $2\pi R$ has an infinite number of significant digits, and π has as many as your calculator has digits). (*b*) $a + b + c = 12.3 + 3.241 + 55.74 = 71.3$ (12.3 has the fewest decimal places (one), and so the sum must be rounded to one decimal place). (*c*) $f = (4.00)^2/7 = 2.29$; $g = (3.00)^2/7 = 1.29$; $f + g = (4.00)^2/7 + (3.00)^2/7 = 3.57$. Note that this result is not equal to the sum of the rounded values for f and g: $2.29 + 1.29 = 3.58$. Never use a rounded intermediate answer in a calculation!

1.15 Many answers are possible. One translation strategy would be to reason that water is like milk, and you know from experience that a quart of milk weighs about 2 lb. From Appendix C, you know that 1 qt $= 0.946 \times 10^{-3}\ \text{m}^3 \approx 10^{-3}\ \text{m}^3$ and that 2 lb $= 0.907$ kg ≈ 1 kg. Using Eq. 1.4, you thus obtain for the density of milk (and of water) $(1\ \text{kg})/(10^{-3}\ \text{m}^3) = 10^3\ \text{kg/m}^3$.

One division strategy would be to estimate the mass and the volume of a glass of water and then use Eq. 1.4 to obtain the density. A glass of water is about 2 in. across and 4 in. tall, so $V \approx \pi[(1\ \text{in.})(2.54 \times 10^{-2}\ \text{m/in.})]^2(4\ \text{in.})(2.54 \times 10^{-2}\ \text{m/in.}) = 2 \times 10^{-4}\ \text{m}^3$. Such a glass weighs about 0.25 lb, and so $m \approx (0.25\ \text{lb})(0.45\ \text{kg/lb}) = 0.11$ kg. Substituting V and m into Eq. 1.4 yields $\rho = m/V \approx (0.11\ \text{kg})/(2 \times 10^{-4}\ \text{m}^3) = 5.5 \times 10^2\ \text{kg/m}^3$. The order of magnitude of both estimates is $10^3\ \text{kg/m}^3$ because $5.5 \times 10^2\ \text{kg/m}^3$ rounds to $10 \times 10^2\ \text{kg/m}^3 = 10^3\ \text{kg/m}^3$, which is the same answer we obtained before.

1.16 If we ignore the oceans, which constitute only a small layer at Earth's surface, the planet is mostly rock, which has a mass density higher than that of water—say, five times higher. As discussed in Section 1.9, the mass density of water is $1000\ \text{kg/m}^3$, meaning that rock should have a mass density of about $5 \times 10^3\ \text{kg/m}^3$. From Checkpoint 1.5 (which you worked out, didn't you?), you know that the Earth's radius is 6.4×10^6 m. Taking Earth to be a sphere, you obtain for its volume $V = \frac{4}{3}\pi R_E^3 = 1.1 \times 10^{21}\ \text{m}^3$. Rearranging Eq. 1.4 to $m = \rho V$ gives you $m = (5 \times 10^3\ \text{kg/m}^3)(1.1 \times 10^{21}\ \text{m}^3) = 5 \times 10^{24}$ kg, with order of magnitude 10^{25} kg. (The current best measurement of Earth's mass is 5.9736×10^{24} kg.)

Chapter 2

2.1 (*a*) See Table 2.1. (*b*) See Figure 2.2.

2.2 (*a*) Staying the same distance from the left edge in five sequential frames means I have stopped and am standing in one spot as time passes and the camera continues to roll. (*b*) I am again in the same spot in two frames, but now the frames are not sequential, and the data points in between are not aligned, telling you that in the time that passed between frames 7 and 14, I walked away from the spot and then came back to it. (*c*) Two vertically aligned points would mean that in one frame (which means one instant in time), I was at two different distances from the origin, something that could never happen.

2.3 (*a*) My image is 4.5 mm tall in the film clip. Estimating my height to be 1.8 m (6 ft), you get that 4.5 mm in the photograph corresponds to 1.8 m in the real world. So 1 mm in the photograph corresponds to (1 mm in photo)(1.8 m in real world)/(4.5 mm in photo) = 0.40 m in the real world. (*b*) In frame 1, I am 2.5 mm from the left edge of the frame; in frame 10, 12.0 mm. So the distance traveled between frames 1 and 10 is (12.0 mm in photo) − (2.5 mm in photo) = 9.5 mm in photo. This corresponds to an actual distance of (9.5 mm in photo) · (0.40 m in real world)/(1 mm in photo) = 3.8 m.

2.4 (*a*) +3.4 m in Figure 2.3; +2.4 m in Figure 2.4. (*b*) +3.4 m − (+1.0 m) = +2.4 m; +2.4 m − 0 = +2.4 m.

2.5 (*a*) Because your final position is the same as your initial position, the x component of your displacement is zero. (*b*) Your

distance traveled is 4 m. (*c*) No. In general the *distance traveled* and the *x component of the displacement* are two different quantities.

2.6 (*a*) A vertical line drawn from the first $x = +4.0$ m point down to the horizontal axis tells you that I was at that position at 1.7 s. The vertical line for the $x = +1$ m position is already drawn: It is the vertical axis. Therefore the length of time I took to travel this distance was $(1.7\text{ s}) - (0) = 1.7$ s. (*b*) Vertical lines through the curve at $x = +2.0$ m and $x = +3.0$ m intersect the time axis at 0.6 s and 1.2 s, and so I traveled this distance in $(1.2\text{ s}) - (0.6\text{ s}) = 0.6$ s. (*c*) At 0.8 s. (*d*) I was at $x = +2.5$ m for *zero* time (not even a split second, an infinitesimally small amount of time!) because it takes no time to move over a *point*. If this surprises you, look at your answers to parts *a* and *b*: To move from +1.0 m to +4.0 m took 1.7 s; from +2.0 m to +3.0 m it took 0.6 s. As we make the interval smaller and smaller, the time it takes to move over that interval gets smaller. If we consider just the point at +2.5 m, the distance shrinks to zero, and so does the time it takes to cross the point.

2.7 (*a*) Normal: $3.50\text{ m} - 1.00\text{ m} = 2.50$ m; slow: $2.25\text{ m} - 1.00\text{ m} = 1.25$ m (half the distance, as one would expect). (*b*) Normal: $(2.50\text{ m})/(1.50\text{ s}) = 1.67$ m/s; slow: $(1.25\text{ m})/(1.50\text{ s}) = 0.83$ m/s (note units of meter per second). (*c*) Normal: $1.50\text{ s} - 0.60\text{ s} = 0.90$ s; slow: $3.00\text{ s} - 1.20\text{ s} = 1.80$ s (twice as long, as you expect). (*d*) Normal: $(1.50\text{ m})/(0.90\text{ s}) = 1.67$ m/s; slow: $(1.50\text{ m})/(1.80\text{ s}) = 0.83$ m/s (same as the values you calculated in part *b*).

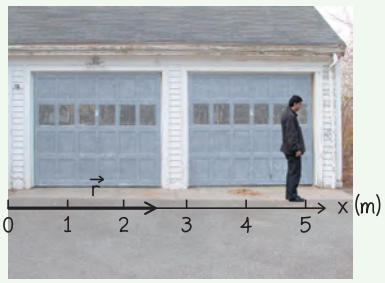
2.8 (*a*) At $t = 1.3$ s. (*b*) $(3.4\text{ m} - 1.0\text{ m})/(1.3\text{ s}) = 1.8$ m/s.

2.9 (*a*) The average speed is

$$\frac{\text{distance traveled}}{\text{time taken}} = \frac{0.5\text{ km}}{6.0\text{ min}} \times \frac{1000\text{ m}}{1.0\text{ km}} \times \frac{1.0\text{ min}}{60\text{ s}} = 1.4\text{ m/s}.$$

(*b*) The average speed is

$$\frac{\text{distance traveled}}{\text{time taken}} = \frac{0.5\text{ km}}{2.0\text{ min}} \times \frac{1000\text{ m}}{1.0\text{ km}} \times \frac{1.0\text{ min}}{60\text{ s}} = 4.2\text{ m/s}.$$



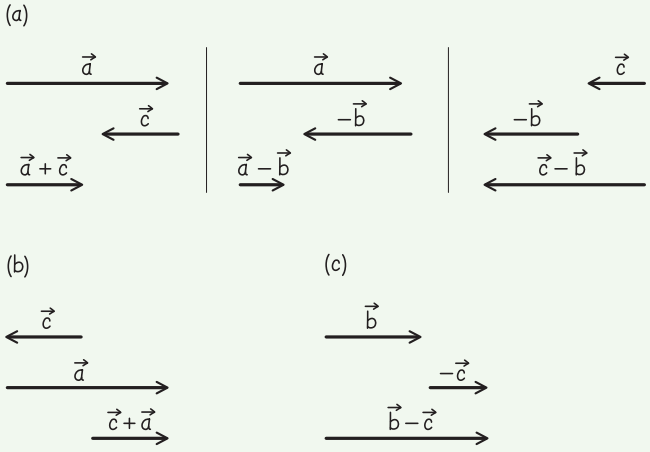
(*c*) $(1.4\text{ m/s} + 4.2\text{ m/s})/2 = 2.8$ m/s. This is not equal to the answer worked out in Example 2.3 because average speed is obtained not by averaging speeds over different segments of a trip but by dividing the distance traveled by the duration of the entire trip.

2.10 (*a*) Negative. The *x* component of the displacement is $-2.3\text{ m} - (-1.2\text{ m}) = -1.1$ m. Because the *x* component of the displacement is negative, the *x* component of the average velocity is negative. (*b*) Negative again. The *x* component of the displacement is $-1.2\text{ m} - (+1.2\text{ m}) = -2.4$ m, and so the *x* component of the average velocity is negative as well. (*c*) Yes. In both cases, the object moves in the direction of decreasing *x* and so must have a negative *x* component of the average velocity.

2.11 (*i*) and (*iv*) are scalars because no direction is required in order to specify these quantities completely; (*ii*) and (*iii*) are vectors because direction is required to specify them completely.

2.12 (*a*) Because my feet in Figure 2.18 are at $x = +4.8$ m, the *x* coordinate of the vector pointing from the origin to my feet is $x = +4.8$ m. (*b*) The vector $\vec{r}$ is obtained by multiplying the unit vector by +4.8 m: $\vec{r} = (+4.8\text{ m})\vec{\imath}$. (*c*) It represents my position in the frame shown in Figure 2.18. (*d*) Yes. It is a vector that is 2.5 m long and points to the right (Figure S2.12). This vector could represent my position at an earlier instant, or it could be a vector representing the position of the right edge of the left garage door.

Figure S2 .12



2.13 (*a*) $\Delta x = x_f - x_i = +4.8\text{ m} - (+2.2\text{ m}) = +2.6$ m. (*b*) $\Delta\vec{r} = (+2.6\text{ m})\vec{\imath}$.

2.14 (*a*) Positive. If the object is initially at $x_i = -2$ m and moves to $x_f = -1$ m, then the *x* component of the displacement is $\Delta x = -1\text{ m} - (-2\text{ m}) = +1$ m. (*b*) No. Imagine any case where the object moves from a negative value of *x* to a positive value, and the displacement is again positive. Whenever positive *x* values are to the right of the origin, the *x* component of any displacement to the right is positive, regardless of the initial and final locations.

2.15 (*a*) See Figure S2.15*a*. (*b*) Yes, because addition is commutative: $\vec{a} + \vec{c} = \vec{c} + \vec{a}$; see Figure S2.15*b*. (*c*) No, because subtraction is not commutative: $\vec{a} - \vec{c} \neq \vec{c} - \vec{a}$; see Figure S2.15*c*.

Figure S2.15

2.16 (*a*) The time interval between frames 6 and 17 is $\Delta t = t_f - t_i = 5.33\text{ s} - 1.67\text{ s} = 3.66$ s; the distance traveled is 2.0 m (from $x = +3.8$ m to $x = +4.8$ m and back). Average speed: $(2.0\text{ m})/(3.66\text{ s}) = 0.55$ m/s; *x* component of average velocity: $\Delta x = x_f - x_i = +3.8\text{ m} - (+3.8\text{ m}) = 0$, and so

$$v_{x,\text{av}} = \frac{\Delta x}{\Delta t} = \frac{0}{\Delta t} = 0.$$

Average velocity: $\vec{v}_{\text{av}} = v_{x,\text{av}}\vec{\imath} = (0)\vec{\imath} = \vec{0}$.

(*b*) The time interval between frames 1 and 17 is $\Delta t = t_f - t_i = 5.33\text{ s} - 0 = 5.33$ s; the distance traveled is 4.8 m (3.8 m from $x = +1.0$ m to $x = +4.8$ m and then 1.0 m back to $x = +3.8$). Average speed: $(4.8\text{ m})/(5.33\text{ s}) = 0.90$ m/s; *x* component of average velocity: $\Delta x = x_f - x_i = +3.8\text{ m} - (+1.0\text{ m}) = +2.8$ m, and so

$$v_{x,\text{av}} = \frac{\Delta x}{\Delta t} = \frac{+2.8\text{ m}}{5.33\text{ s}} = +0.53\text{ m/s}.$$

Average velocity: $\vec{v}_{\text{av}} = v_{x,\text{av}}\vec{\imath} = (+0.53\text{ m/s})\vec{\imath}$.

2.17 From Figure 2.30 you see that, at $t = 2.0$ s, the object is at $x = +2.8$ m. Substituting $t_i = 2.0$ s, $x_i = +2.8$ m, and $v_x = +0.60$ m/s into Eq. 2.19 yields

$$\begin{aligned} x_f &= +2.8 \text{ m} + (+0.60 \text{ m/s})(t_f - 2.0 \text{ s}) \\ &= +2.8 \text{ m} + (+0.60 \text{ m/s})t_f - (+0.60 \text{ m/s})(2.0 \text{ s}) \\ &= +2.8 \text{ m} + (+0.60 \text{ m/s})t_f - 1.2 \text{ m} \\ &= +1.6 \text{ m} + (+0.60 \text{ m/s})t_f, \end{aligned}$$

which is identical to the result in Example 2.10.

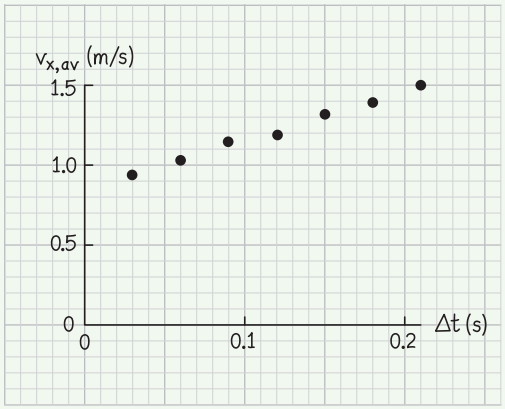
2.18 (*a*) $x_2 = 0$, $x_9 = +0.314$ m;

$$t_2 = 2 \text{ intervals} \times \frac{0.0300 \text{ s}}{\text{interval}} = 0.0600 \text{ s}$$

$$t_9 = 9 \text{ intervals} \times \frac{0.0300 \text{ s}}{\text{interval}} = 0.2700 \text{ s}$$

$$v_{x,\text{av}} = \frac{\Delta x}{\Delta t} = \frac{+0.314 \text{ m}}{0.210 \text{ s}} = +1.50 \text{ m/s}.$$

(*b*) $x_8 = +0.250$ m, $t_8 = 0.240$ s, so



$$v_{x,\text{av}} = \frac{\Delta x}{\Delta t} = \frac{+0.250 \text{ m}}{0.180 \text{ s}} = +1.39 \text{ m/s}.$$

(*c*) See Table S2.18. (*d*) Decreases. Because the ball speeds up as it falls, averaging over a shorter time interval involves lower velocities, and therefore the average decreases (see also Figure 2.32). (*e*) See Figure S2.18. (*f*) Note that extrapolating the data to $\Delta t = 0$ does not yield a zero average velocity. This makes sense: The ball's velocity is nonzero before and after passing position 2, and so neither the average value nor the instantaneous value can be zero at position 2.

Table S2.18 Average velocities

Position	Δx (m)	Δt (s)	$\Delta x/\Delta t$ (m/s)
7	+0.197	0.1500	+1.31
6	+0.143	0.1200	+1.19
5	+0.102	0.0900	+1.13
4	+0.061	0.0600	+1.02
3	+0.028	0.0300	+0.93
2	0	0	–

Figure S2.18

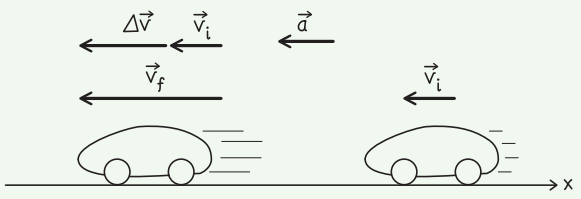
2.19 (*a*) Because the derivative with respect to time of a constant is zero, you have, from Eq. 2.22, $v_x = dx/dt = 0$. If the position is constant, then its x coordinate is also constant, and so Δx is always zero. Therefore $\Delta x/\Delta t = 0$ for any finite time interval Δt. Substituting $\Delta x/\Delta t = 0$ into Eq. 2.21 yields $v_x = 0$ because the limit of zero is zero. (*b*) If $x = ct$, then $v_x = dx/dt = d(ct)/dt = c\,dt/dt = c$. Over a finite time interval Δt, you have $x_i = ct_i$ and $x_f = c(t_i + \Delta t)$. Therefore $\Delta x = c(t_i + \Delta t) - ct_i = c\Delta t$, and so $\Delta x/\Delta t = c$. Because c does not depend on Δt, the limit in Eq. 2.21 has no effect and so $v_x = c$. This result makes sense because the relationship $x = ct$ means x changes by a constant amount c each second. Therefore the object travels the same distance in equal time intervals, and so its velocity must be constant.

Chapter 3

3.1 (*a*) The x component of the average acceleration is the change in the x component of the velocity divided by the time interval during which that change took place:

$$\frac{+5.0 \text{ m/s} - 0}{1.0 \text{ s}} = +5.0 \text{ m/s}^2.$$

(*b*)
$$\frac{+10 \text{ m/s} - (+5.0 \text{ m/s})}{2.0 \text{ s}} = +2.5 \text{ m/s}^2.$$



(*c*)
$$\frac{+10 \text{ m/s} - 0}{3.0 \text{ s}} = +3.3 \text{ m/s}^2.$$

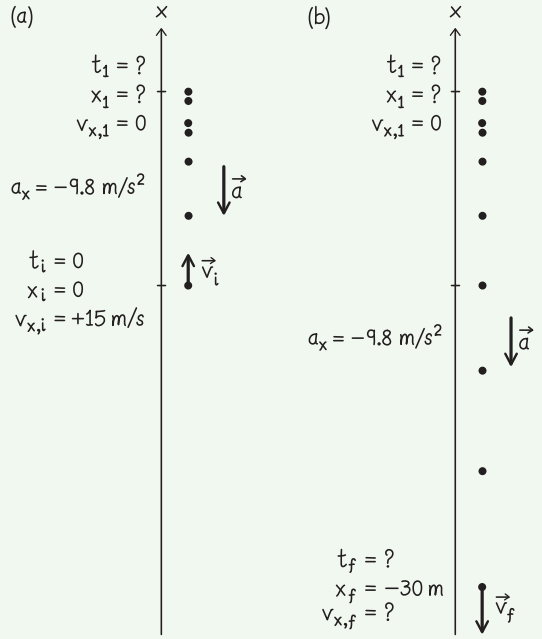
3.2 (*a*) The minus signs on the two v_x values tell you that the car is traveling in the negative x direction. (*b*) $\Delta v_x = v_{x,f} - v_{x,i} = -2$ m/s $-$ $(-10$ m/s$) = +8$ m/s; because Δv_x is positive, the vector $\Delta\vec{v}$ points in the positive x direction. (*c*) $\vec{a}$ always points in the same direction as $\Delta\vec{v}$ and so points in the positive x direction. Consequently the x component of the acceleration is positive. (*d*) The acceleration points in the direction opposite the direction of the velocity, and so the car is slowing down.

3.3 (*a*) For both graphs, x decreases with time, which means both velocities are in the negative x direction, and so the x components of the velocities are negative. (*b*) The speeds are increasing in part *a* (more distance covered in equal time intervals as the $x(t)$ curve bends down; decreasing in part *b* as the curve bends up. (*c*) From part *a* you know that the velocity is always in the negative x direction; from part *b* you know that the speed is increasing in *a* and decreasing in *b*. Combining these results, you see that $\Delta\vec{v}$ points in the negative x direction in *a* and in the positive x direction in *b*, and so Δv_x is negative in *a* and positive in *b*. (*d*) The x components are negative in *a* and positive in *b* ($\vec{a}$ always points in the same direction as $\Delta\vec{v}$, and so the algebraic signs of Δv_x and a_x are the same).

3.4 (*a*) The car is moving in the negative x direction, and so $\vec{v}$ must point in that direction. To increase the car's speed, $\Delta\vec{v}$ must point in the negative x direction (Figure S3.4). Because $\vec{a}$ and $\Delta\vec{v}$ always point in the same direction, $\vec{a}$ also points in the negative x direction. (*b*) The figure shows a car slowing down in the negative x direction. Motion in the negative x direction implies a negative slope of the $x(t)$ curve, which eliminates the two graphs in Figure 3.2. Because the car slows down, it should cover increasingly smaller distances (smaller Δx for a given Δt at later instants t). This is so for Figure 3.3*b*.

Figure S3.4

3.5 When the book and the paper are held side by side, the book falls faster. When the paper is on top of the book, they fall at the same rate. The difference is due to air resistance, which slows down the light piece of paper but not the heavier book. When the paper is on top of the book, the paper is shielded from the flow of air and so feels no air resistance.



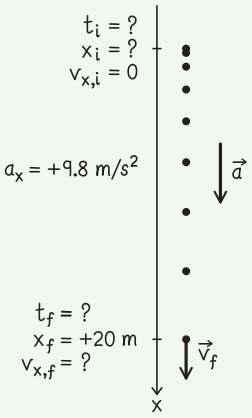
3.6 In Figure 3.6*b* you can see that Δx goes from -2.2 mm at $n = 2$ to -7.0 mm at $n = 10$: The displacement increases from one exposure to the next as n increases—the ball is accelerating. Because the magnitude of the displacement is increasing with time, the magnitude of the velocity must also be increasing.

3.7 (*a*) The speed increases because the object covers greater and greater distances in equal time intervals. (*b*) The x component of the velocity is negative because the motion is in the negative x direction. From part *a* you know that the magnitude of the velocity increases, and so the x component of the velocity becomes increasingly negative—it *decreases*. (*c*) Because the object speeds up in the negative x direction, the acceleration points in the negative x direction and so a_x is negative.

3.8 The ball's speed is about 20 m/s after 1 s and 30 m/s after 2 s. All your throwing has done is change the initial speed from zero (the initial speed if the ball is released from rest) to 10 m/s. Once the ball leaves your hand at this initial speed, the only thing affecting its motion is the acceleration due to gravity, which increases the speed at the rate of about 10 m/s^2.

3.9 See Figure S3.9. Because the rock reverses its motion, the motion diagram is split into two parts: one for the upward motion and the other for the downward motion. If you take up as the positive direction, the x component of the rock's acceleration is $a_x = -9.8$ m/s^2. With the origin chosen to be at the top of the cliff, the initial conditions are $t_i = 0$, $x_i = 0$, and $v_{x,i} = +15$ m/s. At the top of its trajectory, the rock reverses direction, and so the velocity is zero at that position. You do not know its position or the instant at which it reaches the top, and so your diagram must show $t_1 = ?$, $x_1 = ?$, and $v_{x,1} = 0$. The final conditions at the instant the rock reaches the water are $t_f = ?$, $x_f = -30$ m, and $v_{x,f} = ?$

Figure S3.9



3.10 From the motion diagram in Figure 3.11 you have $t_i = 0$, $x_i = 0$, and $v_{x,i} = 0$. Substituting these values into Eq. 3.9 gives $x_f = \frac{1}{2}a_x t_f^2$ or, solving for t_f: $t_f = \sqrt{2x_f/a_x}$. Substituting the values for x_f and a_x, you get $t_f = \sqrt{2(300\text{ m})/(9.8\text{ m/s}^2)} = 7.8$ s. Equation 3.10 then yields $v_{x,f} = v_{x,i} + a_x t_f = 0 + (9.8\text{ m/s}^2)(7.8\text{ s}) = 77$ m/s. (Alternatively, you can substitute the values for a_x and Δx into Eq. 3.13 to obtain the same result.)

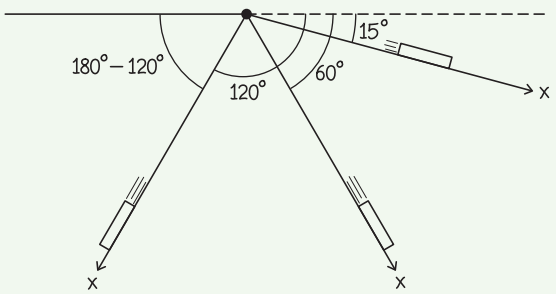
3.11 Figure S3.11 shows the motion diagram for the new choice of x axis. The initial conditions are as before; the final conditions are $t_f = ?$, $x_f = +h$, and $v_{x,f} = ?$. The acceleration is now positive ($a_x = +g$) because it points in the same direction as the x axis, and so Eq. 3.9 is

$$h = 0 + 0 + \tfrac{1}{2}gt_f^2,$$

which yields the same result as before for t_f. The x component of the final velocity is $v_{x,f} = +gt_f$. This x component of the velocity is equal in magnitude to the velocity in Example 3.5 but opposite in sign (because the axis has been inverted).

Figure S3.11

3.12 Applying Eq. 3.10 to the downward part of the motion, with $v_{x,i} = 0$, $a_x = -g$, and $t = v_{x,i}/g$, you get



$$v_{x,f} = 0 - g\frac{v_{x,i}}{g} = -v_{x,i}.$$

The stone hits the ground at the same speed it had when it was launched.

3.13 Figure S3.13 shows that any angle $180° > \theta > 90°$ gives the same result you would get for an angle of $180° - \theta$. All that matters is the angle the incline makes with the floor; once you go beyond 90°, the cart faces the other way, but that is immaterial. (Compare, for example, the 60° angle with $180° - 60° = 120°$.) Note that Eq. 3.20 properly accounts for this fact because $\sin\theta = \sin(180° - \theta)$. For example,

$$a_{120°} = g\sin(120°) = g\sin(180° - 120°) = a_{60°}.$$

Figure S3.13

3.14 The first derivative, dropping the subscript f on t_f because it represents an (arbitrary) instant, is

$$\frac{dx_f}{dt} = \frac{d}{dt}\left(x_i + v_{x,i}t + \tfrac{1}{2}a_x t^2\right) = 0 + v_{x,i} + a_x t.$$

The expression on the right side is the x component of the velocity of an object moving at constant acceleration (Eq. 3.10). The second derivative yields the x component of the (constant) acceleration:

$$\frac{d^2x_f}{dt^2} = \frac{d}{dt}\frac{dx_f}{dt} = \frac{d}{dt}(v_{x,i} + a_x t) = 0 + a_x.$$

Chapter 4

4.1 (*a*) Yes, because each of the $v_x(t)$ curves is a straight line (constant slope = constant acceleration). (*b*) The concrete, because the magnitude of the acceleration is largest when the magnitude of Δv_x for a given time interval is largest—that is, when the slope of the line is the steepest.

4.2 (*a*) $\Delta v_{1x} = v_{1x,f} - v_{1x,i} = +0.63\ \text{m/s} - (+0.14\ \text{m/s}) = +0.49\ \text{m/s}$. (*b*) $\Delta v_{2x} = v_{2x,f} - v_{2x,i} = +0.14\ \text{m/s} - (+0.63\ \text{m/s}) = -0.49\ \text{m/s}$. (*c*) The changes are equal in magnitude but opposite in sign, meaning that the velocity of one increases and the velocity of the other decreases.

4.3 No. The magnitude of the change in the x component of the velocity of the standard cart is always half that of the half cart. If you lower $v_{sx,i}$, the only thing that happens is that the velocity-versus-time graph shrinks in the vertical direction; the x component of the velocity of the standard cart still ends up being positive. If you increase $v_{sx,i}$, the graph expands in the vertical direction and again the x component of the final velocity of the cart is positive.

4.4 $\Delta v_{ux} = v_{ux,f} - v_{ux,i} = +0.21\ \text{m/s} - (0\ \text{m/s}) = +0.21\ \text{m/s}$; $\Delta v_{sx} = v_{sx,f} - v_{sx,i} = -0.21\ \text{m/s} - (+0.42\ \text{m/s}) = -0.63\ \text{m/s}$. Therefore $\Delta v_{ux}/\Delta v_{sx} = (+0.21\ \text{m/s})/(-0.63\ \text{m/s}) = -1/3$.

4.5 $\Delta v_{mx} = v_{mx,f} - v_{mx,i} = +0.07\ \text{m/s} - (0\ \text{m/s}) = +0.07\ \text{m/s}$; $\Delta v_{px} = v_{px,f} - v_{px,i} = -0.20\ \text{m/s} - (+0.27\ \text{m/s}) = -0.47\ \text{m/s}$; $\Delta v_{px}/\Delta v_{mx} = -6.7$.

4.6 Greater. Δv_{ux} is smaller than Δv_{sx}, which tells you that the cart of unknown inertia puts up more resistance to a change in its velocity and hence has more inertia.

4.7 (*a*) Extensive. The inertia of a double cart is equal to the sum of the inertias of the individual carts. (*b*) Intensive. The velocity of a double cart is equal to the velocity of each of the individual carts. (*c*) Extensive. The product of inertia and velocity of a double cart is equal to the double inertia times the velocity of the assembly: $2m_s v_d$; the sum of the product of inertia and velocity of each individual cart is equal to two times the single inertia times the velocity of the assembly: $2m_s v_d$. In general, the product of an extensive and an intensive quantity is extensive.

4.8 (*a*) Extensive. If I separate an amount of money into two piles, then the sum of the amounts of money in each pile equals the original sum of money. (*b*) Not extensive. The sum of the temperatures in each half of a room is not equal to the temperature of the entire room. (*c*) Not extensive. The sum of the humidities in each half of a greenhouse is not equal to the humidity of the entire greenhouse. (*d*) Extensive. The volume of a bathtub is equal to the sum of the volumes of each half of the bathtub.

4.9 The x component of the change in momentum of the standard cart is positive, so the change in momentum $\Delta\vec{p}_s$ points in the positive x direction. The x component of the change in momentum of the red cart is negative and so $\Delta\vec{p}_r$ points in the negative x direction.

4.10 (*a*) Nonzero. The puck's velocity decreases, so its momentum changes. (*b*) Zero. The cart's velocity is constant. (*c*) Nonzero. The collision changes the cart's velocity. (*d*) Zero, see Eq. 4.9. (*e*) Nonzero. The cart's velocity changes.

4.11 (*a*) No. If you push with your legs against the sled, you are interacting with the sled and so you are not isolated. (*b*) Ignoring any interaction between sled and ice, however, you and the sled form an isolated system.

4.12 (*a*) The magnitude of the changes in momentum is $0.061\ \text{kg}\cdot\text{m/s}$, so the collision transfers $0.061\ \text{kg}\cdot\text{m/s}$. (*b*) Cart 1 gains that amount (Δp_{1x} is positive); cart 2 loses that same amount. So, momentum is transferred from cart 2 to cart 1.

4.13 (*a*) The magnitude of the impulse delivered to cart 1 is equal to the magnitude of the momentum change of cart 1, which we calculated in Checkpoint 4.13: $J = 0.061\ \text{kg}\cdot\text{m/s}$. (*b*) The impulse points in the same direction as the momentum change (in the positive x direction), so $\vec{J} = (+0.061\ \text{kg}\cdot\text{m/s})\hat{i}$. (*c*) No. While momentum is conserved, the momentum of a system or object can change due to transfer of momentum.

4.14 (*a*) No, because the inertias are not equal: $\Delta v_{1x} = +0.17\ \text{m/s} - 0 = +0.17\ \text{m/s}$; $\Delta v_{2x} = -0.17\ \text{m/s} - (+0.34\ \text{m/s}) = -0.51\ \text{m/s}$. (*b*) $m_1/m_2 = (0.36\ \text{kg})/(0.12\ \text{kg}) = 3$; $\Delta v_{2x}/\Delta v_{1x} = (-0.51\ \text{m/s})/(0.17\ \text{m/s}) = -3$. (*c*) $p_{1x,i} = m_1 v_{1x,i} = (0.36\ \text{kg})(0) = 0$; $p_{2x,i} = (0.12\ \text{kg})(+0.34\ \text{m/s}) = +0.041\ \text{kg}\cdot\text{m/s}$; $p_{1x,f} = (0.36\ \text{kg})(+0.17\ \text{m/s}) = +0.061\ \text{kg}\cdot\text{m/s}$; $p_{2x,f} = (0.12\ \text{kg})(-0.17\ \text{m/s}) = -0.020\ \text{kg}\cdot\text{m/s}$. (*d*) $p_{1x,i} + p_{2x,i} = 0\ \text{kg}\cdot\text{m/s} + (+0.041\ \text{kg}\cdot\text{m/s}) = +0.041\ \text{kg}\cdot\text{m/s}$. (*e*) $p_{1x,f} + p_{2x,f} = +0.061\ \text{kg}\cdot\text{m/s} + (-0.020\ \text{kg}\cdot\text{m/s}) = +0.041\ \text{kg}\cdot\text{m/s}$. (*f*) Yes. $\Delta p_{1x} = +0.061\ \text{kg}\cdot\text{m/s} - 0 = +0.061\ \text{kg}\cdot\text{m/s}$; $\Delta p_{2x} = -0.020\ \text{kg}\cdot\text{m/s} - (+0.041\ \text{kg}\cdot\text{m/s}) = -0.061\ \text{kg}\cdot\text{m/s}$. This is so because the momentum of the system does not change.

4.15 (*a*) Yes. Just as we do for the carts in Figure 4.3, we can ignore the interaction between the carts and the low-friction track, and so the two carts constitute an isolated system. (*b*) For an isolated system, the momentum law tells us that the momentum of the system cannot change.

4.16 There are two ways to solve this problem. The hard way is to apply the law of conservation of momentum to each collision separately. The easy way is to look at the momentum of the system at only two instants: before the first collision and after the final one. The system's momentum before the first collision is $mv_{x,i}$, where m is the inertia of a single railroad car. After all the cars collide, they move together at the same final speed $v_{x,f}$. The system's final momentum is therefore $4mv_{x,f}$. Because momentum is conserved, the final momentum must equal the initial momentum. Therefore $4mv_{x,f} = mv_{x,i}$, and thus $v_{x,f} = \frac{1}{4}v_{x,i}$. The speed of the four-car train is one-quarter the initial speed of the first car.

Chapter 5

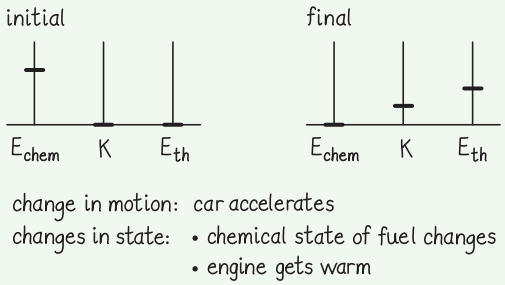
5.1 No. The relative speed $|\vec{v}_2 - \vec{v}_1|$ takes into account the directions of $\vec{v}_1$ and $\vec{v}_2$, but the difference in speeds $v_2 - v_1$ doesn't. For example, if $v_{1x} = +2\ \text{m/s}$ and $v_{2x} = -2\ \text{m/s}$, then $v_{12} = |v_{2x} - v_{1x}| = 4\ \text{m/s}$ but $v_2 - v_1 = 2\ \text{m/s} - 2\ \text{m/s} = 0$.

5.2 (*a*) Totally inelastic, because after the collision the relative speed is zero. (*b*) Elastic, because there is no change in the relative speed. (*c*) Whether or not momentum is constant depends only on whether the system is isolated, not on the type of collision. In part *a*, the system (ball + glove) is not isolated because the glove interacts with something outside the system (the outfielder). Thus the sum of the momenta is not constant. In part *b*, the system (two balls) is isolated because, if we ignore friction, neither ball interacts

with any object external to the system. Therefore the sum of the momenta is constant.

5.3 Yes. Consider an object that is moving at speed v and consists of two pieces having inertias m_1 and m_2. The kinetic energy of the object, $\frac{1}{2}(m_1 + m_2)v^2$, is equal to the sum of the kinetic energies of its two parts, $\frac{1}{2}m_1v^2 + \frac{1}{2}m_2v^2$.

5.4 Denote the x component of the initial velocity of the moving cart $v_{x,\mathrm{i}}$ and the x component of the final velocity of the combined carts $v_{x,\mathrm{f}}$. Conservation of momentum requires that the two carts have a final momentum equal to the initial momentum, and so $mv_{x,\mathrm{i}} = 2mv_{x,\mathrm{f}}$. Thus $v_{x,\mathrm{f}} = \frac{1}{2}v_{x,\mathrm{i}}$. The initial kinetic energy is $\frac{1}{2}mv_{x,\mathrm{i}}^2$; the final kinetic energy is $\frac{1}{2}(2m)v_{x,\mathrm{f}}^2 = m\left(\frac{1}{2}v_{x,\mathrm{i}}\right)^2 = \frac{1}{4}mv_{x,\mathrm{i}}^2$. This is half the initial kinetic energy.



5.5 Increase. The system has some kinetic energy before the collision but zero kinetic energy after. This decrease in kinetic energy is accompanied by a change in the state of the dough (it changes shape). This change in state represents a change in the internal energy of the dough. If the sum of the internal and kinetic energies of the system is to remain constant, the internal energy must increase.

5.6 You could throw something against the cart, push it with your hand, blow against it, or ignite an explosive next to it. Changes in state or motion: The motion of the thrown object changes when it collides with the cart. To push or blow, you have to move your muscles, which causes chemical reactions that change your chemical state. The ignition causes the chemical state of the explosive to change.

5.7 (*a*) No. The momentum of the system is zero before the spring expands and nonzero afterward. (*b*) No, because $\Delta p \neq 0$. There is an external interaction with the post that holds the left end of the spring fixed. Without this interaction, the expanding spring would not cause the cart to move.

5.8 See Figure S5.8. The car engine heats up, and so part of the chemical energy is converted to thermal energy. The sum of the changes ΔK and ΔE_{th} is equal in magnitude to the change ΔE_{chem}.

Figure S5.8

5.9 (*a*) No. Changing the magnitude of an object's momentum means changing the object's speed, and this automatically means changing its kinetic energy. (*b*) Yes. If the change in kinetic energy is compensated by a change in the internal energy of the object, its energy remains unchanged. (*c*) Yes, for both parts. With a system of objects, it is possible to keep the kinetic energy constant while changing the magnitude of the momentum. Imagine two identical carts on a low-friction track moving away from each other in opposite directions at speed v. The momentum of the system is zero, and the kinetic energy of the system is mv^2. If the velocity of one of the two carts is reversed by some interaction, the system's kinetic energy remains unchanged but the momentum of the system becomes $2mv$. For the energy of the system, use the same reasoning you used to answer part *b*.

5.10 For a single object, if mv_x and mv_x^2 remain constant, then the product of these two quantities must also remain constant: $(mv_x)(mv_x^2) = m^2v_x^3 =$ constant. Because m does not change for a single, isolated object, $m^2v_x^3/m = mv_x^3$ must also be constant. Therefore mv_x^3 indeed remains constant for a single object.

In an elastic collision between two objects of identical inertia m with velocities v_{1x} and v_{2x}, the system's momentum, $mv_{1x} + mv_{2x}$, remains constant. The system's kinetic energy is also constant, and so $mv_{1x}^2 + mv_{2x}^2$ is constant. The product of these two must also be constant: $m^2v_{1x}^3 + m^2v_{1x}^2v_{2x} + m^2v_{1x}v_{2x}^2 + m^2v_{2x}^3 = m(mv_{1x}^3 + mv_{2x}^3) + mv_{1x}v_{2x}(mv_{1x} + mv_{2x}) =$ constant. From this we see that $(mv_{1x}^3 + mv_{2x}^3)$ is constant if the second term, $mv_{1x}v_{2x}(mv_{1x} + mv_{2x})$, is constant. The part in parentheses is the system's momentum and is constant. The inertia m is also constant, so all we need to know is whether or not $v_{1x}v_{2x}$ is constant. Suppose $v_{1x,\mathrm{i}}$ changes by Δv_{1x}. Conservation of momentum then requires $v_{2x,\mathrm{i}}$ to change by $-\Delta v_{1x}$. So the product of the final velocities becomes $(v_{1x,\mathrm{i}} + \Delta v_{1x})(v_{2x,\mathrm{i}} - \Delta v_{1x}) = v_{1x,\mathrm{i}}v_{2x,\mathrm{i}} + \Delta v_{1x}(v_{2x,\mathrm{i}} - v_{1x,\mathrm{i}}) - (\Delta v_{1x})^2$. This can be equal to the product of the initial velocities, $v_{1x,\mathrm{i}}v_{2x,\mathrm{i}}$, only if the change in velocity Δv_{1x} is equal to $v_{2x,\mathrm{i}} - v_{1x,\mathrm{i}}$. This can indeed happen but, in general, need *not* be so. In general, therefore, mv_x^3 is not unchanged in an elastic collision.

5.11 No. If one object is initially at rest, then the other object must be moving in order for the collision to occur, and so the initial momentum of the system is nonzero. Because the system is isolated, its momentum is unchanged, and so the system's final momentum, too, is nonzero. Therefore the combination of the two objects has a nonzero velocity after the collision, which means the kinetic energy cannot be zero.

5.12 From Eq. 5.12 you know that $v = \sqrt{2K/m}$. Substituting 1.2×10^8 J for the kinetic energy K and 1200 kg for the inertia m gives $v = 4.5 \times 10^2$ m/s, which is more than 1000 mph! (Apparently it is not possible to convert all of the energy in gasoline to kinetic energy! You'll see why in Chapter 21.)

5.13 No. Cart 1 gets twice as much energy as cart 2: $K_{1\mathrm{f}} = \frac{1}{2}m_1v_{1\mathrm{f}}^2 = \frac{1}{2}(0.25\ \mathrm{kg})(2.0\ \mathrm{m/s})^2 = 0.50$ J, and $K_{2\mathrm{f}} = \frac{1}{2}m_2v_{2\mathrm{f}}^2 = \frac{1}{2}(0.50\ \mathrm{kg}) \cdot (1.0\ \mathrm{m/s})^2 = 0.25$ J. The reason is that the system's final momentum needs to be zero, and so $v_{1\mathrm{f}}$ must be $2v_{2\mathrm{f}}$. Because $m_2 = 2m_1$, you have $K_{2\mathrm{f}} = \frac{1}{2}m_2v_{2\mathrm{f}}^2 = \frac{1}{2}(2m_1)\left(\frac{1}{2}v_{1\mathrm{f}}\right)^2 = \frac{1}{4}m_1v_{1\mathrm{f}}^2 = \frac{1}{2}K_{1\mathrm{f}}$.

Chapter 6

6.1 Because $\vec{v}_{\mathrm{Eo}} = \vec{v}_{\mathrm{EM}} + \vec{v}_{\mathrm{Mo}}$, you can write $v_{\mathrm{Mo}x} = v_{\mathrm{Eo}x} - v_{\mathrm{EM}x}$. With $v_{\mathrm{EM}x} = -3.0$ mm/frame, you have $v_{\mathrm{M1}x} = 0 - (-3.0\ \mathrm{mm/frame}) = +3.0$ mm/frame and $v_{\mathrm{M2}x} = (3.6\ \mathrm{mm/frame}) - (-3.0\ \mathrm{mm/frame}) = +6.6$ mm/frame.

6.2 (*a*) There is no change in the state of either cart, and so the internal energy of either cart is not changing. From observer E's point of view, both velocities are constant and so both kinetic energies are constant. Observer M reaches the same conclusion: Both carts are moving at constant velocity and so their kinetic energies are constant. The observers agree that the energy of each cart is constant. (*b*) and (*c*) No state change or motion change in the environment surrounding each isolated system causes any state change or motion change inside the system, and so each system is closed.

6.3 (*a*) There is no change in the state of either cart and so no change in the internal energy. For observer E, cart 1 accelerates, and so its kinetic energy K and energy E increase; the velocity of cart 2 is constant, and so its kinetic energy K and energy E are constant. For observer M, cart 1 is at rest, and so its kinetic energy K and energy E are constant; cart 2 accelerates, and so its kinetic energy K and energy E are increasing. (*b*) For observer E, a change in state in the spring is responsible for the cart's acceleration, and so the system is not closed. For observer M, changes in both state and motion occur in the environment, but the expansion of the spring cannot account for the change in the kinetic energy of the entire environment (the universe minus cart 1), which means that the energy changes don't add to zero and so the system is

not closed. (*c*) For observer E, there are no changes in state or motion in the environment that are responsible for any changes in state or motion inside the system, and so the system is closed. For observer M, there are no changes in state or motion in the environment, and so it is closed. (*d*) For observer E, the cart 1 system is not closed and its energy increases; the cart 2 system is closed, and its energy is constant. The conservation of energy law holds for both systems. For observer M, the cart 1 system is not closed, and its energy remains constant; the cart 2 system is closed, and its energy is increasing. Neither observation agrees with the law of conservation of energy.

6.4 (*a*) $v_{\mathrm{Ec}x,\mathrm{i}} = +0.40$ m/s, $v_{\mathrm{Ec}x,\mathrm{f}} = +0.80$ m/s, $\Delta K = K_{\mathrm{Ec,f}} - K_{\mathrm{Ec,i}} = \frac{1}{2}(0.12\ \mathrm{kg})(0.80\ \mathrm{m/s})^2 - \frac{1}{2}(0.12\ \mathrm{kg})(0.40\ \mathrm{m/s})^2 = 29$ mJ.
(*b*) $v_{\mathrm{Mc}x,\mathrm{i}} = -0.20$ m/s, $v_{\mathrm{Mc}x,\mathrm{f}} = +0.20$ m/s,
$\Delta K = \frac{1}{2}(0.12\ \mathrm{kg})(0.20\ \mathrm{m/s})^2 - \frac{1}{2}(0.12\ \mathrm{kg})(-0.20\ \mathrm{m/s})^2 = 0$.
(*c*) $v_{\mathrm{Mc}x,\mathrm{i}} = -0.40$ m/s, $v_{\mathrm{Mc}x,\mathrm{f}} = 0$,
$\Delta K = 0 - \frac{1}{2}(0.12\ \mathrm{kg})(-0.40\ \mathrm{m/s})^2 = 10$ mJ.

6.5 Because the momentum of the isolated system is not changing: $m_1 v_{\mathrm{E1}x,\mathrm{i}} + m_2 v_{\mathrm{E2}x,\mathrm{i}} = (m_1 + m_2) v_{\mathrm{E}x,\mathrm{f}}$, and so $v_{\mathrm{E}x,\mathrm{f}} = (m_1 v_{\mathrm{E1}x,\mathrm{i}} + m_2 v_{\mathrm{E2}x,\mathrm{i}})/(m_1 + m_2) = +0.20$ m/s. In the moving reference frame, $v_{\mathrm{M}x,\mathrm{f}} = +0.40$ m/s. See Table S6.5.

Table S6.5 Conversion of kinetic energy

Cart	Inertia (kg)	v_x (m/s) before	v_x (m/s) after	Δv_x	K (10^{-3} J) before	K (10^{-3} J) after	ΔK
Earth reference frame							
1	0.36	0	+0.20	+0.20	0	7.2	+7.2
2	0.12	+0.80	+0.20	−0.60	38.4	2.4	−36
						$\Delta K =$	−29
Reference frame moving at −0.20 m/s relative to Earth							
1	0.36	+0.20	+0.40	+0.20	7.2	28.8	+21.6
2	0.12	+1.0	+0.40	−0.60	60	9.6	−50.4
						$\Delta K =$	−29

6.6 Because the laws of the universe are the same in all inertial reference frames, the coefficient of restitution must also be the same. Another way of seeing this: Relative velocities do not depend on the velocity of the reference frame (Figure 6.11), and so $e = v_{12\mathrm{f}}/v_{12\mathrm{i}}$ is also independent of the reference frame.

6.7 Less. In the Earth reference frame, $K_{\mathrm{E,i}} = 0 + \frac{1}{2}(0.12\ \mathrm{kg}) \cdot (0.80\ \mathrm{m/s})^2 = 38$ mJ. In the zero-momentum reference frame, $K_{\mathrm{Z,i}} = \frac{1}{2}(0.36\ \mathrm{kg})(0.20\ \mathrm{m/s})^2 + \frac{1}{2}(0.12\ \mathrm{kg})(0.60\ \mathrm{m/s})^2 = 29$ mJ.

6.8 (*a*) If the jogger stays in place, he must be moving at the same speed as the belt but in the opposite direction. Therefore $v_{\mathrm{Bj}x} = -2.0$ m/s, and so $r_{\mathrm{Bj}x} = v_{\mathrm{Bj}x}\, t = (-2.0\ \mathrm{m/s})(10\ \mathrm{s}) = -20$ m. (*b*) Equation 6.3 yields $r_{\mathrm{Ej}x} = r_{\mathrm{EB}x} + r_{\mathrm{Bj}x}$. The position of the belt relative to Earth is $r_{\mathrm{EB}x} = v_{\mathrm{EB}x}\Delta t$, and the position of the jogger relative to the belt is $r_{\mathrm{Bj}x} = v_{\mathrm{Bj}x}\Delta t$. Because $v_{\mathrm{Bj}x} = -v_{\mathrm{EB}x}$, you find that $r_{\mathrm{Ej}x} = r_{\mathrm{EB}x} + r_{\mathrm{Bj}x} = v_{\mathrm{EB}x}\Delta t + v_{\mathrm{Bj}x}\Delta t = 0$.

6.9 If you define northward as the positive x direction, you have $v_{\mathrm{TP}x} = +1.2$ m/s, $v_{\mathrm{ET}x} = +3.1$ m/s, and $v_{\mathrm{Ps}x} = -0.5$ m/s. For the velocity of the spider relative to Earth, subscript cancellation gives $v_{\mathrm{Es}x} = v_{\mathrm{EP}x} + v_{\mathrm{Ps}x}$. For the velocity of the passenger relative to Earth, $v_{\mathrm{EP}x} = v_{\mathrm{ET}x} + v_{\mathrm{TP}x}$, and so $v_{\mathrm{Es}x} = (v_{\mathrm{ET}x} + v_{\mathrm{TP}x}) + v_{\mathrm{Ps}x} = (+3.1\ \mathrm{m/s}) + (+1.2\ \mathrm{m/s}) + (-0.5\ \mathrm{m/s}) = +3.8$ m/s. An observer standing by the side of the tracks sees the spider moving at 3.8 m/s northward.

6.10 (*a*) Substituting $m_1 = 3m_2 = 3m$ into Eq. 1 of Example 6.7 yields $x_{\mathrm{A}\mathrm{cm}} = (3mx_{\mathrm{A1}} + mx_{\mathrm{A2}})/(3m + m) = (3x_{\mathrm{A1}} + x_{\mathrm{A2}})/4$, one-quarter of the way from x_{A1} to x_{A2}. (*b*) $x_{\mathrm{A}\mathrm{cm}} = (m_1 x_{\mathrm{A1}} + m_2 x_{\mathrm{A2}} + m_3 x_{\mathrm{A3}})/(m_1 + m_2 + m_3)$. Substituting $m_1 = m_3 = 3m_2 = 3m$ and $x_{\mathrm{A}\mathrm{cm}} = x_{\mathrm{A2}}$ gives $x_{\mathrm{A2}} = (3mx_{\mathrm{A1}} + mx_{\mathrm{A2}} + 3mx_{\mathrm{A3}})/(3m + m + 3m) = (3x_{\mathrm{A1}} + x_{\mathrm{A2}} + 3x_{\mathrm{A3}})/7$. Then $x_{\mathrm{A3}} = 2x_{\mathrm{A2}} - x_{\mathrm{A1}}$.

6.11 (*a*) Because $m_1 = 3m_2$, Eq. 6.26 gives: before the collision $v_{\mathrm{cm}x} = [(m_1)(0) + (m_2)(+0.80\ \mathrm{m/s})]/(m_1 + m_2) = +0.20$ m/s; after the collision $v_{\mathrm{cm}x} = [(3m_2)(+0.40\ \mathrm{m/s}) + m_2(-0.40\ \mathrm{m/s})]/(3m_2 + m_2) = +0.20$ m/s. This is the x component of the velocity where the two $v_x(t)$ curves intersect. (*b*) Yes. When two objects collide, the object that initially has greater velocity always ends up with less velocity after the collision (and vice versa). Therefore there always has to be a location at which the two objects have the same velocity. At that location $v_{1x} = v_{2x} = v_x$, and so

$$v_{\mathrm{cm}x} = (m_1 v_x + m_2 v_x)/(m_1 + m_2)$$
$$= v_x(m_1 + m_2)/(m_1 + m_2) = v_x.$$

(*c*) From Eqs. 6.23 and 6.26, $v_{\mathrm{EZ}x} = v_{\mathrm{cm}x} = +0.20$ m/s. From Eq. 6.8, $v_{\mathrm{E1}x,\mathrm{i}} = v_{\mathrm{EZ}x} + v_{\mathrm{Z1}x,\mathrm{i}}$, and so $v_{\mathrm{Z1}x,\mathrm{i}} = v_{\mathrm{E1}x,\mathrm{i}} - v_{\mathrm{EZ}x} = 0 - (+0.20\ \mathrm{m/s}) = -0.20$ m/s, $v_{\mathrm{Z2}x,\mathrm{i}} = +0.6$ m/s, $v_{\mathrm{Z1}x,\mathrm{f}} = +0.2$ m/s, and $v_{\mathrm{Z2}x,\mathrm{f}} = -0.6$ m/s. Then $p_{\mathrm{Z}x,\mathrm{i}} = (3m_2)(-0.20\ \mathrm{m/s}) + (m_2)(+0.60\ \mathrm{m/s}) = 0$ and $p_{\mathrm{Z}x,\mathrm{f}} = (3m_2)(+0.20\ \mathrm{m/s}) + (m_2) \cdot (-0.60\ \mathrm{m/s}) = 0$.

6.12

$$K_{\mathrm{conv}} = \left(\tfrac{1}{2}m_1 v_1^2 + \tfrac{1}{2}m_2 v_2^2\right) - \tfrac{1}{2}(m_1 + m_2)v_{\mathrm{cm}}^2$$
$$= \left(\tfrac{1}{2}m_1 v_1^2 + \tfrac{1}{2}m_2 v_2^2\right) - \frac{1}{2}\frac{(m_1 v_{1x} + m_2 v_{2x})^2}{m_1 + m_2}$$
$$= \left(\tfrac{1}{2}m_1 v_1^2 + \tfrac{1}{2}m_2 v_2^2\right) - \frac{1}{2}\frac{(m_1^2 v_1^2 + 2m_1 m_2 v_{1x} v_{2x} + m_2^2 v_2^2)}{m_1 + m_2}$$
$$= \frac{1}{2}\frac{(m_1 v_1^2 + m_2 v_2^2)(m_1 + m_2) - (m_1^2 v_1^2 + 2m_1 m_2 v_{1x} v_{2x} + m_2^2 v_2^2)}{m_1 + m_2}$$
$$= \frac{1}{2}\frac{(m_1 m_2 v_1^2 + m_1 m_2 v_2^2) - 2m_1 m_2 v_{1x} v_{2x}}{m_1 + m_2}$$
$$= \frac{1}{2}\frac{m_1 m_2 (v_1^2 - 2v_{1x}v_{2x} + v_2^2)}{m_1 + m_2} = \frac{1}{2}\left(\frac{m_1 m_2}{m_1 + m_2}\right)(v_{2x} - v_{1x})^2$$
$$= \frac{1}{2}\left(\frac{m_1 m_2}{m_1 + m_2}\right)v_{12}^2$$

6.13 (*a*) Because $\mu = m(0.5m)/(m + 0.5m) = m/3$, $K_{\mathrm{conv}} = \frac{1}{2}(m/3)\, v^2$. Because $K_{\mathrm{i}} = \frac{1}{2}mv^2$, the fraction that is convertible is $K_{\mathrm{conv}}/K_{\mathrm{i}} = 1/3$. (*b*) If it were converted, the momentum of the isolated two-object system would change.

6.14 (*a*) $v_{12\mathrm{i}} = |0 - (+4.0\ \mathrm{m/s})| = 4.0$ m/s and $v_{12\mathrm{f}} = |(+1.5\ \mathrm{m/s}) - (-0.50\ \mathrm{m/s})| = 2.0$ m/s, so $e = (2.0\ \mathrm{m/s})/(4.0\ \mathrm{m/s}) = 0.50$.
(*b*) See Table S6.14.

Table S6.14 Conversion of kinetic energy

Object	inertia (kg)	Velocity (m/s) before	Velocity (m/s) after	Δv_x	Kinetic energy (J) before	Kinetic energy (J) after	ΔK

						$\Delta K =$	−4.5

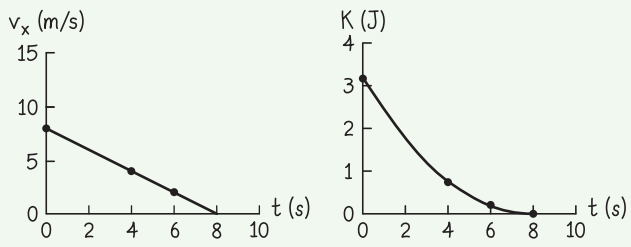
Chapter 7

7.1 (*a*) The other object is Earth; this is an attractive interaction because it makes the ball and Earth accelerate toward each other. (*b*) Repulsive, because the interaction causes the two objects to accelerate away from each other.

7.2 (*a*) At $t = 30$ ms, the velocity-versus-time graph shows $v_{1x} = 0$ and $v_{2x} = +0.55$ m/s, so $p_{1x} = (0.12\text{ kg})(0) = 0$ and $p_{2x} = (0.24\text{ kg})(+0.55\text{ m/s}) = +0.13\text{ kg}\cdot\text{m/s}$. At $t = 60$ ms, $v_{1x} = 0.37$ m/s and $v_{2x} = 0.37$ m/s, so $p_{1x} = (0.12\text{ kg})(+0.37\text{ m/s}) = +0.044\text{ kg}\cdot\text{m/s}$ and $p_{2x} = (0.24\text{ kg})(+0.37\text{ m/s}) = +0.089\text{ kg}\cdot\text{m/s}$. At $t = 90$ ms, $v_{1x} = +0.73$ m/s and $v_{2x} = +0.18$ m/s, so $p_{1x} = +0.088\text{ kg}\cdot\text{m/s}$ and $p_{2x} = +0.043\text{ kg}\cdot\text{m/s}$. (*b*) At 30 ms, $p_x = p_{1x} + p_{2x} = 0 + (+0.13\text{ kg}\cdot\text{m/s}) = +0.13\text{ kg}\cdot\text{m/s}$. At 60 ms, $p_x = (+0.044\text{ kg}\cdot\text{m/s}) + (+0.089\text{ kg}\cdot\text{m/s}) = +0.13\text{ kg}\cdot\text{m/s}$. At 90 ms, $p_x = (+0.088\text{ kg}\cdot\text{m/s}) + (+0.043\text{ kg}\cdot\text{m/s}) = +0.13\text{ kg}\cdot\text{m/s}$.



7.3 (*a*) With the velocity values from Checkpoint 7.2 and the formula $K = \frac{1}{2}mv^2$, the kinetic energies are: at $t = 30$ ms, $K_1 = 0$ and $K_2 = 0.036$ J; at $t = 60$ m/s, $K_1 = 0.0082$ J and $K_2 = 0.016$ J; at $t = 90$ ms, $K_1 = 0.032$ J and $K_2 = 0.0039$ J. (*b*) At 30 ms, $K = 0.036$ J; at 60 ms, $K = 0.025$ J; at 90 ms, $K = 0.036$ J.

7.4 (*a*) Zero, because the ball's speed is zero. (*b*) The momentum of the ball is constant only when the ball is isolated—in other words, when it is not interacting with anything. Ignoring the gravitational interaction with Earth because that interaction is much, much weaker than the ball-wall interaction, you can say that the ball is not interacting with anything before and after the collision, and so its momentum remains constant during these intervals. The ball interacts with the wall during the collision, and so now momentum is not constant for the system made up of only the ball; momentum is constant, however, for the system made up of ball plus wall.

7.5 As the spring is compressed, the kinetic energy of the cart is converted to potential energy in the deformed spring. Because the sum of the kinetic and potential energies must not change, any loss in kinetic energy must be made up by a gain in potential energy. Initially, all the energy of the system is kinetic and equal to $\frac{1}{2}mv_i^2$, where m is the inertia of the cart. In the middle drawing, the kinetic energy is zero, and so the potential energy is $\frac{1}{2}mv_i^2$.

7.6 (*a*) Let the direction in which the puck moves be the $+x$ direction. The x component of the puck's initial velocity is then $v_x = +8.0$ m/s, and the x component of its acceleration is $a_x = -1.0\text{ m/s}^2$. With that acceleration, the puck's speed is reduced by 1.0 m/s each second. So, after 4 s, the speed is half of its original value. Because kinetic energy depends on v^2, the puck's kinetic energy is reduced to one-quarter of its original value after 4 s. After 6 s, the speed is one-quarter of its original value and the kinetic energy is one-sixteenth. Based on these data, your sketches should look like Figure S7.6. (*b*) The kinetic energy is converted to thermal energy (both puck and ice get warmer).

Figure S7.6

7.7 It should be classified as incoherent configuration energy. Chemical energy is associated with changes in the arrangement of atoms in molecules and so is configuration energy. In a chemical reaction, the orientation of the molecules and the kinetic energy given to the products are random, and so chemical energy is incoherent. It is not possible to make all products move in one direction and extract (coherent) kinetic energy. (The same arguments hold for nuclear energy, the form of incoherent configuration energy that corresponds to changes in nuclear configuration.)

7.8 Both of you, because the term *conserve* means one thing when used by physicists and another thing when used by environmentalists. To physicists, energy is always conserved, which means it is neither created out of nothing nor destroyed. When you leave the lights on, electrical energy is converted to light energy and thermal energy (lamps get hot). The sum of those forms of energy is equal to the electrical energy consumed by the lights. To environmentalists, *conserving energy* means reducing or eliminating the use of source energy. When you turn off the lights, less source energy (oil, gas, coal, or nuclear fuel) needs to be converted to electrical energy. The phrase *conserving energy* has nothing to do with the law of conservation of energy, and because Earth's supply of source energy is limited, you are right to turn off the lights.

7.9 (*a*) Elastic potential energy in the spring is converted to kinetic energy in the ball and in the spring as the spring expands. The interaction is nondissipative because it can run in reverse: The ball compresses the spring. (*b*) The ball gains speed as it changes its position relative to the ground, which means potential energy is converted to kinetic energy. The interaction is nondissipative because it can run in reverse: The ball is launched up. (*c*) Kinetic energy is converted to thermal energy: The bicycle slows down because of friction, which irreversibly dissipates the kinetic energy. The interaction is dissipative because the reverse motion—the bicycle accelerates backward without the pedals moving—is not possible. (*d*) Chemical energy in the gasoline is converted to kinetic energy (and thermal energy). The conversion is irreversible and therefore the interaction is dissipative. (If you played this situation in reverse, you would see a car slowing down backward. This is possible, but close inspection would reveal details that are not possible: The driver pressing the gas pedal instead of the brake pedal and fuel being added to the tank.)

7.10 (*a*) When you throw a ball, your momentum increases in the direction opposite the direction of the ball's momentum because the momentum of the isolated system comprising you and the ball must be constant. The throwing corresponds to an explosive separation ($e > 1$). The catching corresponds to a totally inelastic collision ($e = 0$). So, when your friend catches the ball, her momentum increases in the direction in which the ball was originally moving (away from you). (Normally these momentum changes aren't noticeable because of the friction between feet and ground, which is why this checkpoint has you standing on ice.) (*b*) The thrower moves back ("recoils") in the direction opposite the direction of the thrown ball (away from the catcher). The catcher recoils in the direction in which the ball was originally moving (away from the thrower). Therefore, each throw or catch increases the momentum of each of you in the direction away from the other, meaning that the interaction is repulsive. The ball serves as the carrier—the "gauge particle"—of the interaction. (*c*) Improbable as it may seem, there actually is a mechanical model for an attractive interaction based on an exchange of particles. Imagine two people standing within arm's reach of each other and extending their arms toward each other without touching. Person A holds a ball and throws it back toward himself; person B catches it before it hits person A, and throws it back toward herself. Repeat as needed. This is perhaps not easy to implement, but the throwing back and forth does result in an attraction.

7.11 (*a*) Once the vehicles lock together, they have identical velocities, the center-of-mass velocity. If you take the x component of the car's initial velocity as positive, you get from Eq. 6.26 $v_{\text{cm}x} = [(1000\text{ kg})(+25\text{ m/s}) + (2000\text{ kg})(-25\text{ m/s})]/[1000\text{ kg} + 2000\text{ kg}] = -8.3$ m/s. Therefore $\Delta v_c = (-8.3\text{ m/s}) - (+25\text{ m/s}) = -33$ m/s and $\Delta v_v = (-8.3\text{ m/s}) - (-25\text{ m/s}) = +17$ m/s. Because it has

less inertia, the car has the larger change in velocity. Because both velocity changes occur during the same time interval, the acceleration is greater for the car, in agreement with Eq. 7.6. (*b*) $a_{cx,av} = (-33\text{ m/s})/(0.20\text{ s}) = -1.7\times10^2\text{ m/s}^2$ and $a_{cx,av} = (+17\text{ m/s})/(0.20\text{ s}) = +83\text{ m/s}^2$. The ratio is not exactly -2 because of the rounding of the velocity changes in part *a*.

7.12

$$\begin{aligned}\Delta K_E &= \tfrac{1}{2}m_E v_{E,f}^2 - \tfrac{1}{2}m_E v_{E,i}^2 = \tfrac{1}{2}m_E(v_{E,f}^2 - v_{E,i}^2)\\ &= \tfrac{1}{2}m_E[(v_{Ex,i} + \Delta v_{Ex})^2 - v_{E,i}^2]\\ &= m_E v_{E,i}\Delta v_{Ex} + \tfrac{1}{2}m_E(\Delta v_{Ex})^2.\end{aligned}$$

Rearranging terms and substituting Δp_{Ex} for $m_E\Delta v_{Ex}$, you get

$$\begin{aligned}\Delta K_E &= v_{Ex,i}(m_E\Delta v_{Ex}) + \tfrac{1}{2}\frac{(m_E\Delta v_{Ex})^2}{m_E}\\ &= v_{Ex,i}\Delta p_{Ex} + \frac{(\Delta p_{Ex})^2}{2m_E}.\end{aligned}$$

The first term on the right of the final equals sign is zero because in the reference frame of Earth, $v_{Ex,i} = 0$. The second term to the right of the final equals sign is negligibly small compared to the corresponding term for the cart because the numerators are the same (conservation of momentum requires that $\Delta p_E = -\Delta p_c$) and $m_E \gg m_c$. Therefore $\Delta K_E \approx 0$, and the only change in kinetic energy in the Earth-cart system must be that of the cart.

7.13

$$\begin{aligned}\Delta U_{12} &= U(x_2) - U(x_1)\\ \Delta U_{21} &= U(x_1) - U(x_2) = -\Delta U_{12}\\ \Delta U_{1\to2\to1} &= \Delta U_{12} + \Delta U_{21}\\ &= [U(x_2) - U(x_1)] + [U(x_1) - U(x_2)]\\ &= 0.\end{aligned}$$

The potential energy change as an object moves in one direction has a sign, and the potential energy change when the object moves back to its original position has the opposite sign and the same magnitude. Thus the change in potential energy along a round trip is zero. This statement, trivial as it may seem, is another hallmark of potential energy. No other form of energy has this property.

7.14 As the ball moves upward, it slows down, reducing its kinetic energy. Because the Earth-ball system is closed, the gravitational potential energy of the system must therefore increase as the ball moves upward. The slowing down of the upward-moving ball means that the acceleration points down—the direction in which the gravitational potential energy of the Earth-ball system decreases. When the ball moves downward, it is again accelerated downward, its kinetic energy increases, and its potential energy decreases.

7.15 (*a*) It increases (see Checkpoint 7.14). (*b*) $\Delta U^G = (3.4\text{ kg})\cdot(9.8\text{ m/s}^2)(1.0\text{ m}) = 33\text{ J}$. (*c*) Your arm muscles burn up some chemical energy as you raise the book.

7.16 No. Even though you may hear people say that the quantity expressed by Eq. 7.21 is "the gravitational potential energy of the ball," it is incorrect to do so. It is not the ball by itself that possesses the potential energy. The gravitational potential energy is a property of the configuration of the Earth-ball system. Put another way, the ball by itself is not a closed system—it does not fall by itself. Consequently, the energy of the ball by itself is not constant.

7.17 With $e = 0$, Eq. 7.26 gives $\Delta E_{th} = \frac{1}{2}\mu v_{12,i}^2$. The reduced inertia is $\mu = (1000\text{ kg})(2000\text{ kg})/(1000\text{ kg} + 2000\text{ kg}) = 667\text{ kg}$, and the initial relative speed is $v_{12,i} = 50\text{ m/s}$. Thus $\Delta E_{th} = \frac{1}{2}(667\text{ kg})(50\text{ m/s})^2 = 8.3\times10^5\text{ J}$.

Chapter 8

8.1 Because the crate's velocity is constant, its momentum is also constant. So the change in its momentum is zero, and therefore the rate of change in its momentum is also zero. Surprised? Read on.

8.2 (*a*) As you set the crate in motion, the acceleration and the change in momentum point in the direction of travel. Because the vector sum of the forces exerted on the crate is equal to the time rate of change in its momentum, the vector sum points in the direction of travel. This makes sense: To make the crate move faster in a certain direction, you must push it in that direction. (*b*) When the crate is slowing down, all the signs are reversed: The acceleration points opposite the direction of travel, and so the change in momentum and the vector sum of the forces point opposite the direction of travel. Again, this makes sense because in order to stop the crate, you have to exert a force in the direction opposite its direction of travel. (*c*) When the crate is at rest—whether you are pushing against it or not—the vector sum of the forces exerted on it is zero, and so there is no direction involved.

8.3 (*a*) Because both collisions have the same initial and final velocities, it suffices to look at just one. To see whether the momentum of the two-cart system is constant, we calculate the change in momentum of each cart:

$$\Delta v_{1x} = v_{1x,f} - v_{1x,i} = (+0.80\text{ m/s}) - 0 = +0.80\text{ m/s}$$

$$\Delta v_{2x} = v_{2x,f} - v_{2x,i} = (+0.20\text{ m/s}) - (+0.60\text{ m/s}) = -0.40\text{ m/s}$$

$$\Delta p_{1x} = m_1\Delta v_{1x} = (0.12\text{ kg})(+0.80\text{ m/s}) = +0.096\text{ kg}\cdot\text{m/s}$$

$$\Delta p_{2x} = m_2\Delta v_{2x} = (0.24\text{ kg})(-0.40\text{ m/s}) = -0.096\text{ kg}\cdot\text{m/s}.$$

The total change in momentum is therefore zero, $\Delta p_{1x} + \Delta p_{2x} = 0$, and so the momentum of the system does not change. (*b*) Whether or not the collision is elastic can be determined by looking at the relative speeds. Before the collision $v_{12i} = |v_{1x,i} - v_{2x,i}| = |0 - (+0.60\text{ m/s})| = 0.60\text{ m/s}$; after the collision $v_{12f} = |v_{1x,f} - v_{2x,f}| = |(+0.80\text{ m/s}) - (+0.20\text{ m/s})| = 0.60\text{ m/s}$. Therefore the relative speed is the same before and after the collision, $v_{12i} = v_{12f}$, and so $e \equiv v_{12f}/v_{12i} = 1$, and the collisions are indeed elastic. (You can obtain the same result by verifying that the kinetic energy of the two-cart system doesn't change.)

8.4 Yes. Because two colliding objects can be considered isolated, the momentum of the system remains unchanged regardless of the type of interaction. Therefore the changes in the momentum of the objects are equal in magnitude but opposite in direction, $\Delta\vec{p}_1 = -\Delta\vec{p}_2$, and so the objects exert equal forces on each other in opposite directions.

8.5 (*a*) The two magnitudes are equal. If that surprises you—how can something so small exert a force on something so large?—remember that any change in the book's momentum must be made up by an equal change of opposite sign in Earth's momentum, because the Earth-book system is isolated. (*b*) Yes. The fact that the book exerts a force $\vec{F}_{\text{by book on Earth}} = \Delta p_E/\Delta t$ means Earth's momentum must be changing. Its velocity must therefore be changing, and so it is accelerating. Because its inertia is so great, however, the acceleration is negligible: The Earth-book system is isolated and so $\Delta\vec{p}_E + \Delta\vec{p}_b = m_E\Delta\vec{v}_E + m_b\Delta\vec{v}_b = \vec{0}$, so that

$$\Delta\vec{v}_E = \frac{m_b}{m_E}\Delta\vec{v}_b \approx \vec{0},$$

which means that Earth's acceleration during this interaction is vanishingly small.

8.6 (*a*) Because the collision is totally inelastic, the final velocities are the same: $v_{bx,f} = v_{mx,f}$. Because the mosquito-bus system is isolated, the final momentum of the system must be the same as the initial momentum. The x component of the initial momentum is

$$\begin{aligned}p_{x,i} &= m_m v_{mx,i} + m_b v_{bx,i} = m_m(0) + m_b v_{bx,i}\\ &= 0 + (10^4\text{ kg})(+25\text{ m/s}) = +2.5\times10^5\text{ kg}\cdot\text{m/s}.\end{aligned}$$

The x component of the final momentum is

$$p_{x,f} = m_m v_{mx,f} + m_b v_{bx,f} = (m_m + m_b)v_{x,f},$$

where $v_{x,f}$ is the x component of the common final velocity. Substituting inertia values gives

$$p_{x,f} = (10^{-4}\text{ kg} + 10^{4}\text{ kg})v_{x,f} = p_{x,i} = +2.5 \times 10^{5}\text{ kg}\cdot\text{m/s}$$

or, solving for $v_{x,f}$,

$$v_{x,f} = +25\text{ m/s}.$$

It looks like the velocity of the bus hasn't changed at all. If you pretend that all the numerical values given are exact and keep more significant digits, however, you find that $v_{bx,f} = +24.99999975$ m/s, which means the bus velocity changes by a minuscule amount: $\Delta v_{bx} = -0.00000025$ m/s (no one in the bus notices!). The x component of the change in the mosquito's velocity is $\Delta v_{mx} = +25$ m/s.

(b) The x component of the change in the average acceleration of the bus is

$$a_{bx} = \Delta v_{bx}/\Delta t = (-0.00000025\text{ m/s})/(0.005\text{ s}) = -0.00005\text{ m/s}^2.$$

That of the mosquito is

$$a_{mx} = \Delta v_{mx}/\Delta t = (+25\text{ m/s})/(0.005\text{ s}) = +5000\text{ m/s}^2!$$

(c) The x component of the momentum changes are

$$\Delta p_{bx} = m_b \Delta v_{bx} = (10{,}000\text{ kg})(-0.00000025\text{ m/s}) = -0.0025\text{ kg}\cdot\text{m/s}$$

and

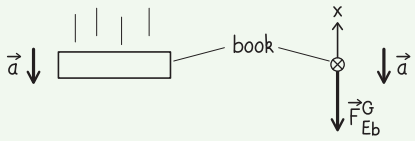
$$\Delta p_{mx} = m_m \Delta v_{mx} = (10^{-4}\text{ kg})(+25\text{ m/s}) = +0.0025\text{ kg}\cdot\text{m/s}.$$

Notice that these changes in momentum are equal in magnitude and opposite in direction, so that the momentum of the isolated system doesn't change.

(d), (e)

$$(F_{\text{by bus on mos}})_x = \Delta p_{mx}/\Delta t = (+0.0025\text{ kg}\cdot\text{m/s})/(0.005\text{ s}) = +0.5\text{ kg}\cdot\text{m/s}^2$$

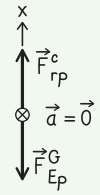
$$(F_{\text{by mos on bus}})_x = \Delta p_{bx}/\Delta t = (-0.0025\text{ kg}\cdot\text{m/s})/(0.005\text{ s}) = -0.5\text{ kg}\cdot\text{m/s}^2.$$



These two forces are equal in magnitude. Because of the large difference in inertia, however, the effect of this force on the bus is negligible, while on the mosquito the effect is enormous.

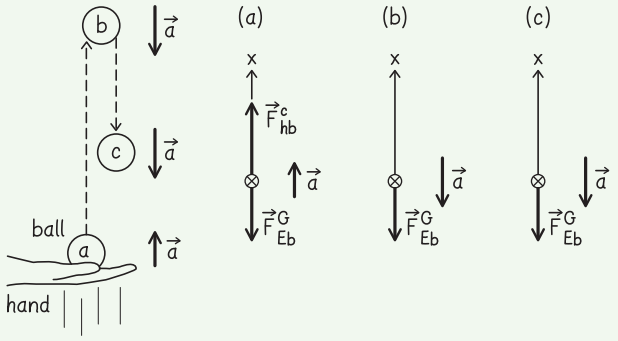
8.7 *Contact forces*: The only object in direct contact with the first magnet is the table, and so the table exerts a contact force on the magnet. There is no contact force with the other magnet because the two are not touching. Presumably the first magnet is also in contact with the surrounding air, and so there may also be a contact force exerted by the air on the magnet (in practice this force is negligible as long as the relative velocity of the magnet and the air is not too large). *Field forces*: Both gravitational and magnetic forces occur in this problem. There is a gravitational force exerted by Earth on the magnet and a magnetic force exerted by the second magnet. In principle, there is also a gravitational interaction between the two magnets and between the magnets and the table, but the forces due to these interactions are so small that we can safely ignore them.

8.8 No. Although the two forces are equal in magnitude and exerted in opposite directions, just as the two forces in an interaction pair are, they originate from different interactions and therefore are not part of the same interaction pair. The two forces in an interaction pair are exerted on different objects, whereas the two forces mentioned in this checkpoint are exerted on the same object (the book).



8.9 See Figure S8.9. During free fall, there is no contact force between the book and any other object. The only force exerted on the book is the gravitational force exerted by Earth (we ignore air resistance).

Figure S8.9



8.10 See Figure S8.10. The person is subject to one contact force: an upward force exerted by the ring (this is what keeps the person suspended). In addition, there is a downward gravitational force exerted by Earth.

Figure S8.10

8.11 (a) See Figure S8.11a. As you accelerate the ball upward, the force exerted by your hand on the ball is larger than the force of gravity exerted by Earth on the ball. (b) See Figure S8.11b. Once the ball is released, the only force exerted on it is that exerted by Earth (ignoring air resistance). (c) The forces exerted on the ball are the same on all parts of the trajectory. Therefore your drawing for part c should look exactly like your drawing for part b. Although the direction of the ball's velocity reverses during flight, the force exerted by Earth always points downward.

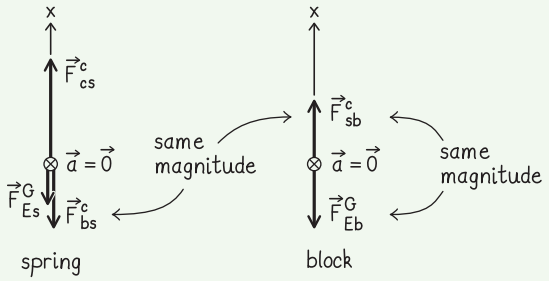


Figure S8.11

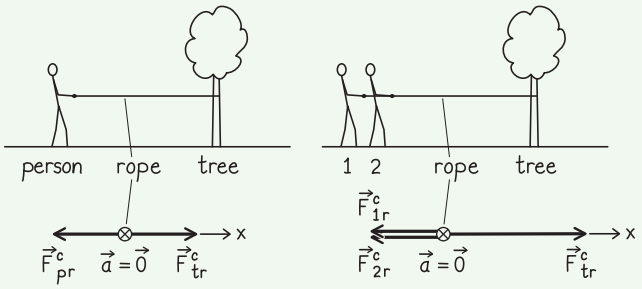
8.12 Figure S8.12 on the next page shows the free-body diagrams for the spring and the brick. The problem asks about the force exerted by the spring on the ceiling $\vec{F}^c_{sc}$, a force that forms an interaction pair with the force exerted by the ceiling on the spring. The brick is subject to a downward gravitational force exerted by Earth and an upward contact force exerted by the spring. Because the brick is at rest, we know that these two forces are equal in magnitude. The spring is subject to a downward gravitational force, a downward contact force exerted by the brick, and an upward contact force exerted by the ceiling. Because the spring is at rest we know that the forces must add up to zero and so the force exerted by the spring on the ceiling is equal to the combined gravitational forces exerted by



Earth on the spring and the brick. (This result makes sense because the ceiling has to support both of them.)

Figure S8.12

8.13 Figure S8.13 shows the free-body diagram for the rope. The tree now must exert a force of magnitude $2F$ to balance the forces exerted by the two people. This means a force of magnitude $2F$ is exerted on both ends of the rope, and so the tension is $\mathcal{T} = 2F$—twice as large as when the two people pulled on opposite ends.

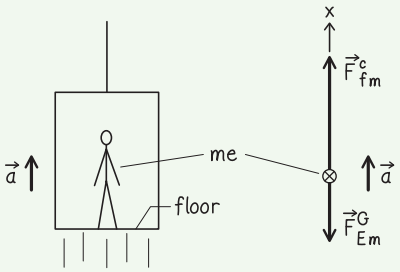
Figure S8.13

8.14 (*a*) The force you exert on your friend gives her a constant acceleration given by Eq. 8.7, where m is the inertia of your friend and her skates. Estimating m to be 60 kg (adjust for your own estimate), you have $a = (200\text{ N})/(60\text{ kg}) = 3.3\text{ m/s}^2$. Her displacement in the 2.0s is $\Delta x = \frac{1}{2}a_x(\Delta t)^2 = \frac{1}{2}(+3.3\text{ m/s}^2)(2.0\text{ s})^2 = +6.7\text{ m}$. (*b*) When a person jumps off a wall, he is in free fall, and so the magnitude of his acceleration is 9.8 m/s^2. (*c*) When you put the person's inertia at 60 kg (adjust to your liking), the magnitude of the force exerted by Earth on the person is $F^G_{Ep} = (60\text{ kg})(9.8\text{ m/s}^2) = 5.9\times10^2\text{ N}$.

8.15 The two forces in an interaction pair are exerted on different objects and so never cancel when you consider the forces exerted on a single object. For example, if you push on a crate, the force you exert on the crate accelerates the crate. The other force in the interaction pair is a force exerted by the crate *on you*, not on the crate. The effect of this force exerted by the crate is to slow you down, not to cancel the force you exert on the crate.

8.16 (*a*) If you answered $m_E g$, think again! Does Earth have an upward acceleration g whenever you drop an object from a certain height? No; Earth doesn't budge. From the reciprocity of forces, however, you know that the gravitational force exerted by Earth on an object is equal in magnitude to the force exerted by the object on Earth. So the correct answer is $m_1 g$. (*b*) The effect this force has on Earth's acceleration is entirely negligible because of the enormous inertia of Earth (compare Checkpoint 8.6):

$$a_E = \frac{m_1}{m_E}g \approx 0.$$



If you are wondering how it is possible that the force exerted by Earth on an object and the force exerted by the object on Earth both depend on the inertia of the object only, then you are very perceptive. I shall explain this when we discuss gravity in Chapter 13.

8.17 (*a*) See Figure S8.17. Note that the $\vec{F}^G_{Em}$ vector arrow is shorter than the $\vec{F}^c_{fm}$ arrow. You drew your diagram that way, right? (*b*) Because the elevator is accelerating upward, so are you. Therefore the vector sum of all the forces acting on you must point upward. This means that the contact force exerted by the floor of the elevator on you is larger than the downward gravitational force exerted on you. From Eq. 8.8,

$$\Sigma F_x = ma_x = F^c_{fmx} + F^G_{Emx}$$
$$F^c_{fmx} = ma_x - F^G_{Emx} = ma_x - (-mg) = m(a_x + g).$$

For an inertia $m = 60$ kg (substitute your own inertia), this yields a force of $(60\text{ kg})[(+1\text{ m/s}^2) + (9.8\text{ m/s}^2)] = 6.5\times10^2\text{ N}$.

Figure S8.17

8.18 (*a*) Stiffer. If k is large, a small displacement $x - x_0$ requires a large force (Eq. 8.18). A spring that compresses only a little under a large load is stiff. (*b*) Steel. Steel compresses less (small Δx) than foam rubber (larger Δx) under equal loads. So the spring constant for steel is larger than that for foam rubber.

8.19 (*a*) Smaller. Both objects have acceleration g, but the feather has much less inertia than the brick. The magnitude of the gravitational force is $F^G_{Eo} = mg$ (Eq. 8.17), and so the gravitational force exerted on the feather is smaller than that exerted on the brick. (*b*) The momentum is the same for both. The change in an object's momentum caused by a constant force—in other words, the impulse delivered to the object—is $\vec{F}\,\Delta t$. Because the same force is exerted on both objects for the same amount of time, $\Delta\vec{p}$ is the same for both. However the magnitude of $\Delta\vec{v}_{\text{feather}}$ is much larger than the magnitude of $\Delta\vec{v}_{\text{brick}}$ because of the difference in inertia.

8.20 (*a*) For a single object, the center-of-mass acceleration is equal to the particle's acceleration, $\vec{a}_{cm} = \vec{a}$, because the position of the center of mass coincides with the position x of the particle: $x_{cm} \equiv mx/m = x$ (Eq. 6.24). Finally for a single object there are no internal forces, so all forces are external and so $\Sigma\vec{F}_{ext} = \Sigma\vec{F}$. Consequently, Eqs. 8.46 and 8.47 are equivalent for a system made up of only one object. (*b*) Consider the motion of the system over a time interval $\Delta t = t_f - t_i$. If the center of mass initially moves at velocity $\vec{v}_{cm,i}$ at time t_i, then at the end of the time interval it has velocity

$$\vec{v}_{cm,f} = \vec{v}_{cm,i} + \vec{a}_{cm}\Delta t.$$

The change in the total momentum of the many-object system is thus

$$\Delta\vec{p} = \vec{p}_f - \vec{p}_i = m(\vec{v}_{cm,f} - \vec{v}_{cm,i})$$
$$= m(\vec{v}_{cm,i} + \vec{a}_{cm}\Delta t - \vec{v}_{cm,i}) = m\vec{a}_{cm}\Delta t.$$

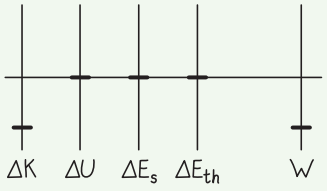
After substituting Eq. 8.44 for the vector sum of the forces exerted on the system, you have your result:

$$\Delta\vec{p} = (\Sigma\vec{F}_{ext})\,\Delta t.$$

Chapter 9

9.1 (*a*) External, because the force is exerted from outside the system. (*b*) No, no, and no. Because the wall is hard, heavy, and anchored to the ground, it neither moves nor changes shape at a macroscopic scale. Because there is no friction involved, the wall's temperature does not change. (*c*) No. Its kinetic energy doesn't change because it doesn't accelerate; its potential energy doesn't change because it doesn't change shape or deform; its thermal energy doesn't change because it doesn't heat up. (*d*) No. The energy of the wall remains the same, and so there is no transfer of energy from you to the wall, which means you do no work on the wall no matter how hard you push.

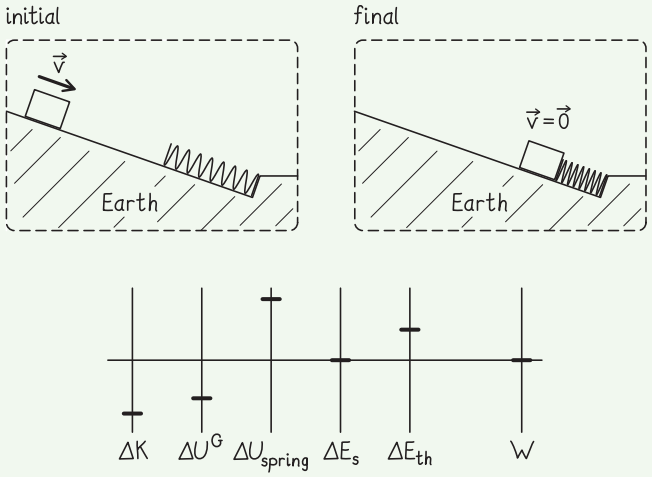
9.2 Both forces do work on the ball because for both the point of application is at the ball, and this point moves as you launch the ball.



9.3 (*a*) As the ball moves upward, its kinetic energy decreases and its internal energy doesn't change. So the change in the ball's energy (the sum of the kinetic and internal energies) is negative. This means the work done on the ball is negative. (*b*) The ball's kinetic energy now increases, causing a positive change in energy, and so the work done on the ball is positive.

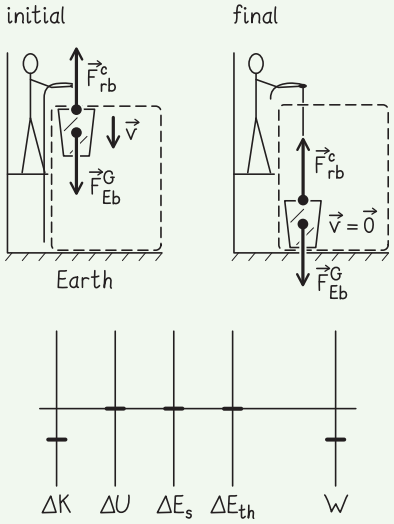
9.4 The directions of the force and the force displacement are consistent with the answers obtained by analyzing energy changes. In part *a* the only force exerted on the ball (the gravitational force) is downward, but the displacement is upward, and so the work done on the ball is negative. In part *b* both vectors are directed downward, and so the work done on the ball is positive.

9.5 (*a*) Yes. There are no changes in motion or state in the environment. (*b*) Positive. As the block compresses the spring, the force exerted by the block on the spring is directed toward the wall and the point of application of that force moves toward the wall. Force and force displacement pointing in the same direction means positive work. (Also, the energy of the system increases as the spring is compressed, and so the work done on it must be positive.) (*c*) Zero. The point of contact between wall and spring is not moving, and so the force displacement is zero, meaning that the work done by the wall on the system is also zero. (Indeed, the system comprising spring and block is closed, as we concluded in part *a*.)



9.6 See Figure S9.6. The cart's kinetic energy decreases to zero, and there are no changes in the other forms of energy. The decrease in kinetic energy is the result of negative work done by the person on the cart. The force exerted by the person is directed to the left, and the force displacement is directed to the right, which is a second way of telling you that the work done by the person on the cart is negative.

Figure S9.6



9.7 See Figure S9.7. As the block comes to rest against the compressed spring, the block's kinetic energy decreases, so you must draw the kinetic energy bar below the baseline. The system has two changes in potential energy: a change in gravitational potential energy ΔU^G due to the change in the block-Earth configuration and a change in elastic potential energy ΔU_{spring} due to the compression of the spring. You should draw two potential energy bars, one for each kind. The gravitational potential energy decreases, and the potential energy of the spring increases. The thermal energy increases because of friction. The lengths of the bars add up to zero because the system is closed, so $W = 0$.

Figure S9.7

9.8 See Figure S9.8. The only energy in the system that changes is the kinetic energy, which decreases to zero. The work done on the system must therefore be negative. This negative work is the sum of the work done by the rope on the system and the work done by Earth on the system. The work done by the rope on the system is negative (force upward, force displacement downward), and the work done by Earth on the system is positive (force and force displacement both downward). The work done on the system is negative because, in order for the system to slow down, the magnitude of the force exerted by the rope must be larger than that exerted by Earth.

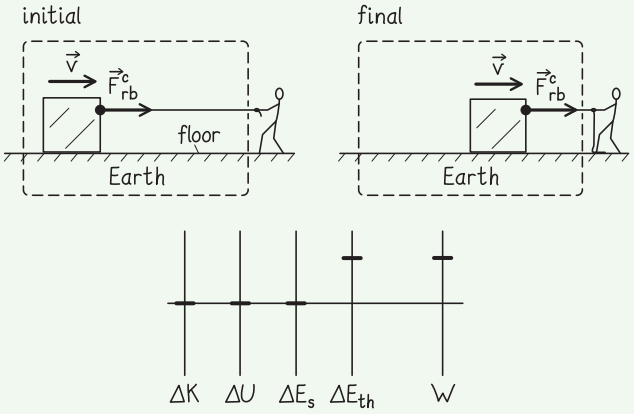


Figure S9.8

9.9 (*a*) See Figure S9.9 on the next page. The kinetic energy remains unchanged, but energy is dissipated because of the friction between box and floor. No changes occur in potential energy. The changes in thermal energy can be attributed to work done on the system. The person exerts external forces both on the box (via the rope) and on the floor (via his feet). Only the force displacement of the force exerted on the box is nonzero. Because the force displacement and the force point in the same direction, the work done by the person on the system is positive. (*b*) Because the system now includes the person/rope, the system is closed, which means no work is done on it and the W bar in the energy diagram is blank. As in the system chosen in part *a*, you have $\Delta K = 0$, $\Delta U = 0$, and $\Delta E_{\text{th}} > 0$ (friction

between box and floor increases E_{th} for the system). With the person/rope included as part of the system, the source energy bar must be filled in and it must be negative because muscle energy is used up as the person pulls.

Figure S9.9

9.10 The x component of the impulse delivered by the (constant) gravitational force is given by Eq. 8.25, $\Delta p_x = F^G_{\text{Eb}x}\Delta t = -m_b g \Delta t$. Because the acceleration is constant, $\Delta v_x/\Delta t = a_{x,\text{av}} = -g$, you can say that $\Delta t = -\Delta v_x/g$ and thus

$$\Delta p_x = -m_b g(-\Delta v_x/g) = m_b \Delta v_x = m_b(v_{x,f} - v_{x,i}).$$

9.11 Because Δx_F is larger than Δx_{cm} (see Figure 9.19), W in Eq. 9.16 is larger than ΔK_{cm} in Eq. 9.14. Because $\Delta E = W$, this means that ΔE is larger than ΔK_{cm}. This makes sense because only part of the work done on the system goes into changing K_{cm}. Another part goes into increasing the internal energy of the system. $W = \Delta E$ accounts for both the change in K_{cm} and the change in internal energy.

9.12 For a single particle, the position of the center of mass is the position of the particle (Eq. 6.24):

$$x_{cm} \equiv \frac{mx}{m} = x,$$

so the force displacement is equal to the displacement of the center of mass: $\Delta x_{cm} = \Delta x_F$. The center-of-mass translational kinetic energy is simply the particle's kinetic energy:

$$K_{cm} = \tfrac{1}{2}mv_{cm}^2 = \tfrac{1}{2}mv^2.$$

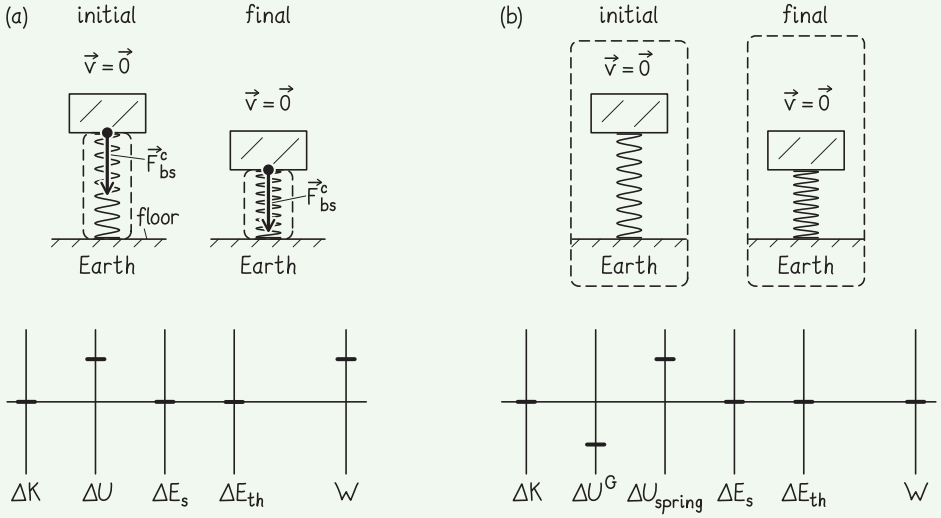
Therefore Eq. 9.14 becomes

$$\Delta K = (\Sigma F_x)\Delta x_F.$$

Because a particle has only kinetic energy, Eqs. 9.1 and 9.2 give $\Delta K = \Delta E = \Delta W$, so $\Delta W = (\Sigma F_x)\Delta x_F$, which is Eq. 9.9, the work equation for a single particle.

Now for reducing Eq. 9.18 to Eq. 9.9. Equation 9.18 is for a many-particle system. Because you want to use this equation for a single-particle system, there is only one particle experiencing the (external) force and so only one force displacement. That means you can take the factor Δx_{Fn} out of the summation in Eq. 9.18 and drop the subscript n. The equation is then identical to Eq. 9.9.

9.13 If the force is constant—in other words, if $F_x(x) = F_x$—it can be pulled out of the integral:



$$W = \int_{x_i}^{x_f} F_x(x)\,dx = F_x\int_{x_i}^{x_f} dx = F_x(x_f - x_i) = F_x\Delta x,$$

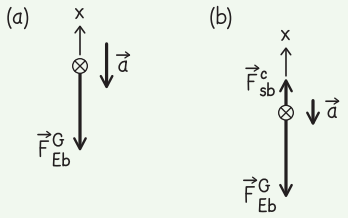
which is identical to Eq. 9.8.

9.14 See Figure S9.14. (*a*) This system is not closed, and the brick exerts a force on the system that has a nonzero force displacement. As it moves downward, the brick does positive work on the spring. This work ends up as elastic potential energy of the spring. (The force exerted by the floor on the spring does no work on the spring.) (*b*) The system is closed, so no work is done on it. In addition, none of the four types of energy changes! The increase in the elastic potential energy of the spring is accompanied by a decrease in the gravitational potential energy of the brick. To show this, you should draw two separate potential energy bars.

9.15 mg is the magnitude of the constant force of gravity exerted by Earth *on the brick*, not a force exerted on the spring. The contact force between brick and spring is a variable force described by Hooke's law.

Figure S9.14

If you find it surprising that the brick doesn't push down on the spring with the same force as Earth pulls down on the brick, look at the free-body diagrams for the brick in Figure S9.15. At the instant it is released just above the uncompressed spring, the brick is subject to only the downward force of gravity; the spring exerts no upward force as long as it is not compressed (Figure S9.15*a*). Consequently the x component of the brick's initial acceleration is $a_x = -g$. As the brick moves downward, the upward force exerted by the spring on it increases according to Hooke's law (Eq. 8.20, $F^{c}_{sbx} = -k(x - x_o)$. In this problem you are dealing with the situation represented by the free-body diagram in Figure S9.15*b*. At the instant represented in Figure S9.15*b*, $\vec{F}^{c}_{sb}$ is nonzero but still smaller in magnitude than F^{G}_{Eb} (because the brick has not yet come to rest against the compressed spring):



$$F^{c}_{bs} < F^{G}_{Eb} = mg.$$

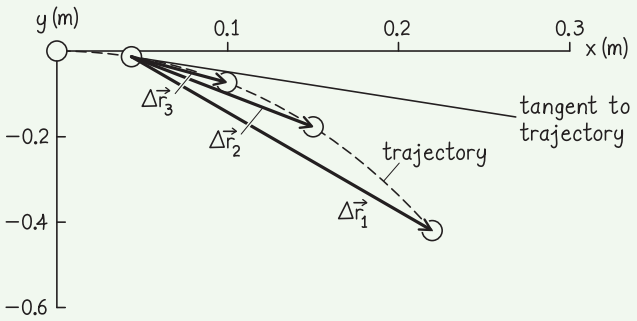
Answering this checkpoint requires knowing $\vec{F}^{c}_{bs}$, which forms an interaction pair with $\vec{F}^{c}_{sb}$: $\vec{F}^{c}_{bs} = -\vec{F}^{c}_{sb}$, so

$$F^{c}_{bs} < F^{G}_{Eb} = mg.$$

The difference between the two force magnitudes F^{c}_{bs} and mg is what makes the brick accelerate downward. (If you wonder where I get these brain twisters, the answer is simple: As I wrote the example, I was wondering about this question myself.)

Figure S9.15

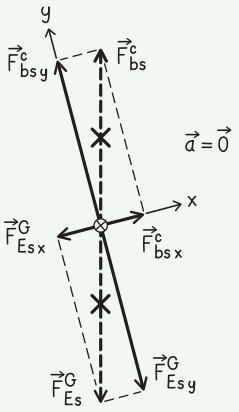
9.16 Although $\Delta x_{cm} = 0$ when the block comes to rest at its starting position, the distance it travels is nonzero: $d_{path} = 2(0.50\text{ m}) = 1.0\text{ m}$. All of the block's kinetic energy is converted to thermal energy, and so $\Delta E_{th} = K_i = \frac{1}{2}mv^2 = \frac{1}{2}(0.50\text{ kg})(1.0\text{ m/s})^2 = 0.25\text{ J}$. From Eq. 9.28, you get $F^{f}_{sb} = \Delta E_{th}/d_{path} = (0.25\text{ J})/(1.0\text{ m}) = 0.25\text{ N}$.



9.17 (*a*) Car: $(1.4 \times 10^8\text{ J})/(1800\text{ s}) = 78\text{ kW}$; plane: $(1.4 \times 10^8\text{ J})/(1\text{ s}) = 140\text{ MW}$. (*b*) Equation 7.19 tells you that, to raise the load, the gravitational potential energy of the load-Earth system must be increased by $\Delta U^G = (10\text{ kg})(10\text{ m/s}^2)(50\text{ m}) = 5000\text{ J}$. The athlete can deliver $500\text{ W} = 500\text{ J/s}$ and so takes $(5000\text{ J})/(500\text{ J/s}) = 10\text{ s}$. (*c*) $W_{\text{by engine}} = W_{\text{by athlete}}$ because the work done on the load does not depend on the rate at which it is done. In both cases, the work done on the load is equal to the change in the gravitational potential energy of the load-Earth system.

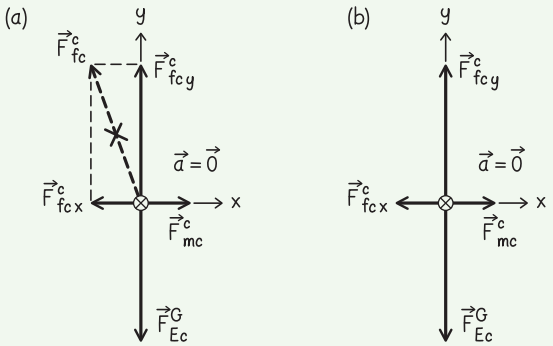
Chapter 10

10.1 (*a*) If your first reaction to this question was "In which reference frame?," you got the point! Before release, the ball is moving along with the cart, and so its initial velocity in the reference frame of the cart is zero. In the Earth reference frame, the ball's initial velocity is equal to that of the cart. (*b*) The speed is the magnitude of the velocity, which is the rate at which the displacement changes. Because of the cart's horizontal displacement, the ball's displacement from one frame of the film clip to the next is always greater in the Earth reference frame than in the cart's reference frame (see Figure 10.4). Therefore the ball's speed is higher in the Earth reference frame.



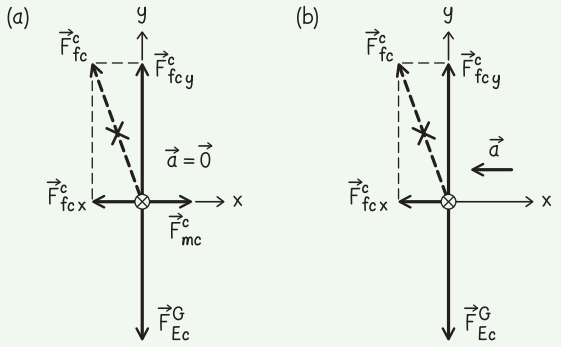
10.2 The ball's instantaneous velocity is the displacement over an infinitesimally small time interval. As Figure S10.2 shows, $\Delta\vec{r}$ approaches the tangent to the ball's trajectory as we make Δt smaller; $\vec{v}$ is thus tangent to the trajectory. Because of the downward curvature of the trajectory, $\vec{v}$ points above $\Delta\vec{r}$.

Figure S10.2



10.3 The suitcase is subject to a downward gravitational force and an upward contact force exerted by the belt. Because the suitcase's velocity is constant, its acceleration is zero, and so the vector sum of these forces must be zero. The two forces must therefore be equal in magnitude (Figure S10.3).

Figure S10.3



10.4 The cabinet participates in three interactions—with you, with the floor, and with Earth—and so is subject to three forces: a horizontal force due to your push $\vec{F}^{c}_{mc}$, a contact force $\vec{F}^{c}_{fc}$ exerted by the floor, and a downward force of gravity $\vec{F}^{G}_{Ec}$. Because the cabinet remains at rest, the vector sum of these forces must be zero. You know that your force is strictly horizontal and the gravitational force is strictly vertical. With these two forces being exerted on the cabinet, the only way for the vector sum of the forces exerted on the cabinet to be zero is for $\vec{F}^{c}_{fc}$ to have both a horizontal component $\vec{F}^{c}_{fcx}$ and a vertical component $\vec{F}^{c}_{fcy}$. The horizontal component of $\vec{F}^{c}_{fc}$ is therefore equal in magnitude to $\vec{F}^{c}_{mc}$, and the vertical component is equal in magnitude to $\vec{F}^{G}_{Ec}$. The free-body diagram for the file cabinet is shown in Figure S10.4*a*. (Alternatively, you can draw the two components of the contact force exerted by the floor as two separate forces, as shown in Figure S10.4*b*.)

Figure S10.4

10.5 (*a*) The cabinet is subject to the same three forces as in Checkpoint 10.4. Because it moves at constant speed, the vector sum of these forces is still zero, and so the free-body diagram is as shown in Figure S10.5*a*. (*b*) The instant you stop pushing, $\vec{F}^{\text{c}}_{\text{mc}}$ disappears but $\vec{F}^{\text{c}}_{\text{fc}\,y}$ and $\vec{F}^{G}_{\text{Ec}}$ must be as before because there is no vertical motion. You know that the cabinet comes to rest when you stop pushing, and so there must be a horizontal force that slows it *after* you stop pushing. This force is $\vec{F}^{\text{c}}_{\text{fc}\,x}$. The free-body diagram for the cabinet is shown in Figure S10.5*b*. Once the cabinet is at rest, $\vec{F}^{\text{c}}_{\text{fc}\,x}$ vanishes.

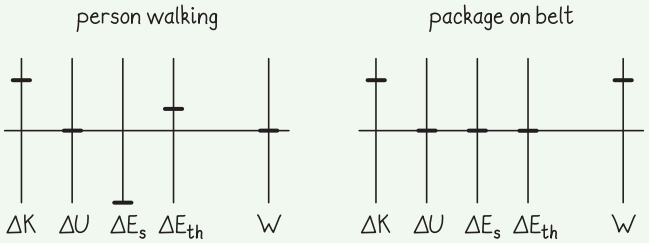


Figure S10.5

10.6 The motion of the two surfaces in contact relative to each other determines the type of friction: static friction between two surfaces not moving relative to each other and kinetic friction between two surfaces moving relative to each other. (*a*) Static, (*b*) kinetic, (*c*) kinetic, (*d*) kinetic, (*e*) static (as long as you are not slipping, your feet are at rest relative to the incline each time you put them on the ground while walking).

10.7 As the person accelerates, her kinetic energy increases. As you've just seen, this increase in kinetic energy is not due to work done on her by the force of static friction. The forces in the vertical direction add up to zero and so do no work either, so the work done on her is zero. What causes her to accelerate is that chemical energy in her muscles is converted to kinetic energy (and some of it is dissipated to thermal energy). So E_{th} increases and E_{s} decreases; the heights of the bars add up to zero (Figure S10.7). For the package, only its kinetic energy increases. Its shape and temperature remain the same, and so its internal energy does not change. The increase in kinetic energy is entirely due to work done by the conveyor belt on the package. The point of application of the force of friction exerted by the belt surface on the package is displaced in the direction of the force, so the work done on the package is positive, as Figure S10.7 shows.

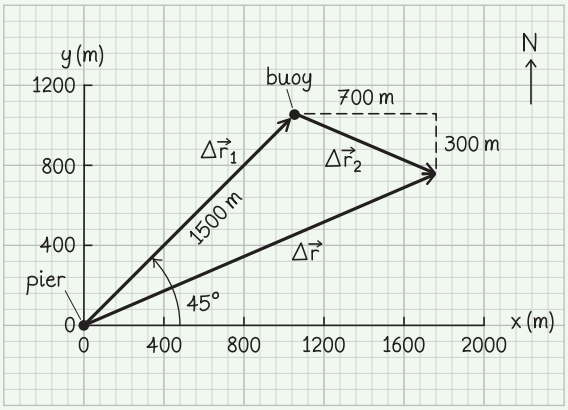
Figure S10.7

10.8 Your final displacement $\Delta\vec{r}$ is the sum of the displacements $\Delta\vec{r}_1$ and $\Delta\vec{r}_2$ in Figure S10.8. You know the length and angular coordinate of $\Delta\vec{r}_1$ and the x and y components of $\Delta\vec{r}_2$. To add the two vectors, you must first determine the x and y components of $\Delta\vec{r}_1$:

$$\Delta x_1 = \Delta r \cos\theta = (1500\text{ m})(\cos 45°) = 1060\text{ m}$$

$$\Delta y_1 = \Delta r \sin\theta = (1500\text{ m})(\sin 45°) = 1060\text{ m}.$$

Adding the components of $\Delta\vec{r}_1$ and $\Delta\vec{r}_2$ gives



$$\Delta x = \Delta x_1 + \Delta x_2 = 1060\text{ m} + 700\text{ m} = 1760\text{ m}$$

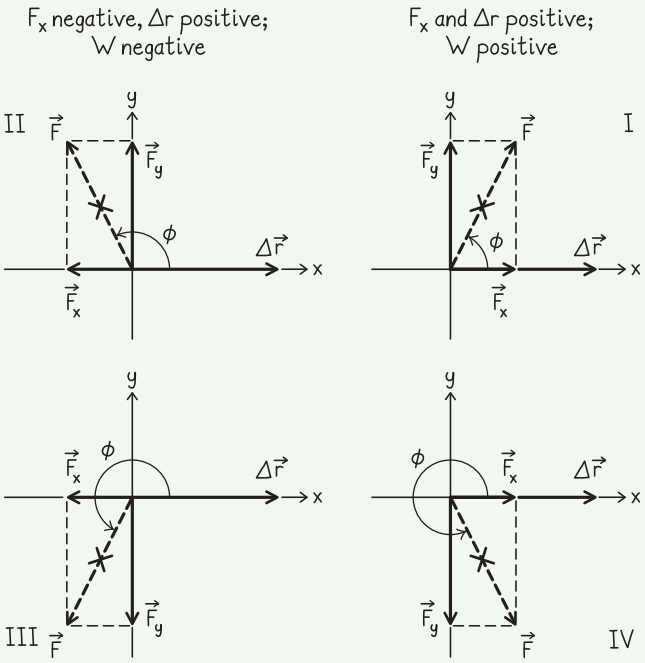
$$\Delta y = \Delta y_1 + \Delta y_2 = 1060\text{ m} - 300\text{ m} = 760\text{ m}.$$

The distance to the pier is thus

$$|\Delta\vec{r}| = \sqrt{\Delta x^2 + \Delta y^2} = 1.92 \times 10^3\text{ m}.$$

Figure S10.8

10.9 (*a*) According to Eqs. 10.3: $v_{x,\text{i}} = v_{\text{i}}\cos\theta$ and $v_{y,\text{i}} = v_{\text{i}}\sin\theta$. Substituting these values into the expressions we obtained in Examples 10.5 and 10.6 yields



$$x_{\text{f}} = \frac{2v_{\text{i}}^2 \sin\theta\cos\theta}{g} \quad \text{and} \quad y_{\text{top}} = \tfrac{1}{2}\frac{v_{\text{i}}^2 \sin^2\theta}{g}.$$

(*b*) For a given launch speed v_{i}, y_{top} has its greatest value when $\sin^2\theta$ is maximal. This occurs when $\theta = 90°$, which makes sense because all of the projectile's speed goes into the upward motion when the projectile is launched straight up. (*c*) The greatest value of x_{f} is obtained when $\sin\theta\cos\theta = \frac{1}{2}\sin 2\theta$ is maximum. This occurs when $2\theta = 90°$ or $\theta = 45°$.

10.10 To answer this question, we need to compare the system's final and initial kinetic energies. Let the inertia of puck 1 be m; the inertia of puck 2 is then $2m$. The system's initial kinetic energy is $\frac{1}{2}m(1.8\text{ m/s})^2 + \frac{1}{2}\cdot 2m(0.2\text{ m/s})^2 = \frac{1}{2}m(3.3\text{ m}^2/\text{s}^2)$. The final kinetic energy is $\frac{1}{2}m(0.8\text{ m/s})^2 + \frac{1}{2}\cdot 2m(1.0\text{ m/s})^2 = \frac{1}{2}m(2.6\text{ m}^2/\text{s}^2)$. Because the system's final kinetic energy is not equal to the initial kinetic energy, the collision is not elastic.

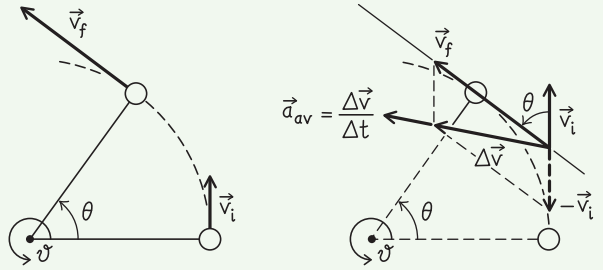
10.11 To determine the sign of W, you need to know the sign of the scalar product for various relative positions of $\vec{F}$ and $\Delta\vec{r}$. To do so we choose a coordinate system that has its x axis aligned with $\Delta\vec{r}$ and then we place $\vec{F}$ in different positions (Figure S10.11). The scalar product is $F|\Delta\vec{r}|\cos\phi$, which can be written as $|\Delta\vec{r}|F\cos\phi = |\Delta\vec{r}|F_x$ and which is the product of the magnitude of $\Delta\vec{r}$ and the x component of $\vec{F}$. Because $|\Delta\vec{r}|$ is always positive, the sign of the scalar product is determined by the algebraic sign of F_x. As you can see in Figure S10.11, F_x is positive when $\vec{F}$ is in quadrants I and IV and negative when $\vec{F}$ is in quadrants II and III. So W is positive when $0 < \phi < 90°$ or $270° < \phi < 360°$. For any other angle, F_x and W are negative. According to Section 9.2, W is positive when $\vec{F}$ and $\Delta\vec{r}$ point in the same direction and negative when they point in opposite directions. So Eq. 10.40 is in complete agreement with our earlier definition of when work is positive and when it is negative.

Figure S10.11

10.12 (*a*) That the brick slides more easily on ice tells you that the force of friction is smaller in the brick-ice case than in the brick-wood case, and so μ_s is smaller for the brick on ice. (*b*) Substituting $\mu_s = 1$ into Eq. 10.46 gives $(F^s_{sr})_{max} = F^c_{sr}$ for the maximum force of static friction exerted by the surface on the runner. This is the maximum horizontal force the surface can exert on the runner. Because the runner is not accelerating up or down, the magnitude of the normal force must be equal to the magnitude of the force of gravity, and so $F^c_{sr} = F^G_{Er} = mg$, where m is the runner's inertia. Substituting this value into the equation of motion $\Sigma F_x = ma_x$ shows that the maximum acceleration is $a_x = +g$.

10.13 (*a*) If $\mu_s = 1$, then $\theta_{max} = 45°$ according to Eq. 10.53. (*b*) All objects start sliding well before this angle is reached, telling you that generally $\mu_s < 1$.

10.14 (*a*) The free-body diagram for the bricks is given in Figure 10.42. At the point where the bricks begin to slide, $F^G_{Eb\,x}$ is equal to the maximum value of F^s_{sb}, and so $F^G_{Eb\,x} + (F^s_{sb})_{max} = 0$. Because both $F^G_{Eb\,x}$ and $(F^s_{sb})_{max}$ are proportional to the inertia m of the bricks, the angle at which $F^G_{Eb\,x} + (F^s_{sb})_{max} = 0$ is independent of m. The single and double bricks therefore begin sliding at the same instant. (You can also see this directly from Eq. 10.53, which shows that θ_{max} is independent of m.) (*b*) Once the bricks begin to slide, kinetic friction replaces static friction. So the vector sum of the forces exerted on the bricks in the x direction is $\Sigma F_x = F^G_{Eb\,x} + F^k_{sb} = -mg \sin\theta + F^k_{sb}$. Using Eqs. 10.43 and 10.55, you can write this as $\Sigma F_x = -\mu_s F^c_{sb} + \mu_k F^c_{sb} = (\mu_k - \mu_s)F^c_{sb}$. The x component of the acceleration of the bricks is thus given by



$$ma_x = \mu_k mg \cos\theta - mg \sin\theta$$

and is independent of inertia: $a_x = \mu_k g \cos\theta - g \sin\theta$. The single and double brick therefore both slide down with the same acceleration. These results can also be justified as follows: In parts *a* and *b* all forces exerted on the double brick are twice as large, but the double brick, having twice the inertia, requires twice as large a force to reach the same acceleration. Consequently there cannot be any difference between the accelerations.

Chapter 11

11.1 If $|\vec{v}_f| > |\vec{v}_i|$, the vector $\vec{v}_f$ has a greater magnitude than the vector $\vec{v}_i$. As a result, the change in velocity $\Delta\vec{v}$ and $\vec{a}_{av}$ now point not toward the center of the circle but more in the direction of motion, as shown in Figure S11.1 (compare with Figure 11.8*b*).

Figure S11.1

11.2 The centripetal acceleration is the same for both cubes, and so the force required to keep cube 1 going in a circle must be twice as large as the force required for cube 2. The maximum force of static friction, however, also scales with m—$(F^s_{tc})_{max} = \mu_s F^n_{tc} = \mu_s mg$—and so both cubes begin sliding at the same instant.

11.3 (*a*) Yes. In order to generate a vector sum of forces that points toward the center of the trajectory, the contact force exerted by the road surface on the bicycle (and that exerted by the bicycle on its rider) must be at an angle with the vertical. This can happen only when the bicycle leans into the curve. (*b*) No. The vertical component of $\vec{F}^c_{sb}$ is what prevents the bucket from falling to the ground: $F^c_{sb\,z} + F^G_{Eb} = 0$. If the rope is horizontal, then so is $\vec{F}^c_{sb}$ and consequently $F^c_{sb\,z} = 0$. Without this vertical component, the bucket cannot stay in the air.

11.4 (*a*) 3. The largest rotational inertia is obtained when the inertia of the pencil is as far as possible from the axis. For axis 3, half of the pencil is farther from the axis as for axis 2. (*b*) 1. For this axis all the inertia of the pencil is close to the axis.

11.5 (*a*) In 1.5 s the object covers an arc length of 4.5 m. Thus $\vartheta = (4.5\text{ m})/(2.0\text{ m}) = 2.3$. (*b*) The perimeter of the circle is $2\pi(2.0\text{ m})$. At 3.0 m/s, it therefore takes the object $2\pi(2.0\text{ m})/(3.0\text{ m/s}) = 4.2$ s to complete one revolution. (*c*) In 1.0 s the object moves through an arc of 3.0 m, and so the change in rotational coordinate in 1.0 s is $(3.0\text{ m})/(2.0\text{ m}) = 1.5$. The object begins at a polar angle of 90°, which corresponds to a rotational coordinate of $(90°)(2\pi\text{ rad}/360°)/(1\text{ rad}) = \pi/2$. So the final rotational coordinate is $\pi/2 + 1.5 = 3.1$.

11.6 The faster you go, the larger the inward force required to make you go around the curve. When the maximum force $(F^s_{sp})_{max}$ is reached, $\tan\theta_{max} = \mu_s$ (Eq. 11.53) and Eq. 1 in Example 11.4 becomes

$$\mu_s\, mg = m\frac{v^2}{r}$$

$$v = \sqrt{\mu_s gr} = 6.6\text{ m/s},$$

where I have used the value $\mu_s \approx 1$ for the coefficient of static friction between skates and road.

11.7 (*a*) The speeds of B and C are equal, but the circumference of C's trajectory is twice as large, and so it takes C twice as long to complete one revolution. Therefore the ratio of the rotational velocities is 2. (*b*) Because of the r^2 dependence of rotational inertia (see Eq. 11.30), C's rotational inertia is four times as large as B's. Therefore the ratio of the rotational inertias is $\frac{1}{4}$.

11.8 Yes. Using Eq. 11.31, you can write for the final rotational kinetic energy:

$$\tfrac{1}{2}I_f\omega_f^2 = \tfrac{1}{2}(I_f\omega_f)\omega_f = \tfrac{1}{2}(I_i\omega_i)\omega_f > \tfrac{1}{2}(I_i\omega_i)\omega_i = \tfrac{1}{2}I_i\omega_i^2.$$

Because his arms' centripetal acceleration must increase as he pulls them in, the force required to pull them in increases, requiring physical effort. Thus internal chemical energy in his body is converted to kinetic energy.

11.9 (*a*) Suppose the dumbbell has rotational velocity ω, with each puck moving at speed $v = r\omega = (l/2)\omega$. The kinetic energy of the dumbbell is equal to the sum of the kinetic energies of the two pucks:

$$K = 2\left(\tfrac{1}{2}mv^2\right) = mv^2.$$

Substituting the Eq. 11.11 value for v, you get

$$K = m\left(\tfrac{1}{2}l\omega\right)^2 = \tfrac{1}{4}ml^2\omega^2.$$

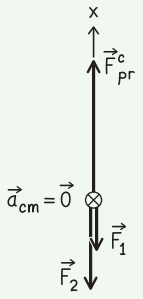
Knowing from Eq. 11.31 that $K = \frac{1}{2}I\omega^2$, you can say that

$$\tfrac{1}{4}ml^2\omega^2 = \tfrac{1}{2}I\omega^2.$$

Solve this expression for I and you see that, indeed, $I = \frac{1}{2}ml^2$. (*b*) No. The dumbbell rotates but has no momentum. Its axis is fixed to the table, so it cannot have any translational motion. Even though v is nonzero for each puck, $v_{\text{dumbbell}} = 0$ and therefore $p_{\text{dumbbell}} = 0$. Because the axis exerts a force on the dumbbell, the puck-dumbbell system is not isolated, and so it is not necessary for its momentum to be constant.

11.10 When the axis is at the end, you should choose the origin at that end, and so the integration boundaries in Example 11.9 become $x = 0$ and $x = l$. Therefore,

$$I = \frac{m}{l}\int_0^l x^2dx = \frac{m}{l}\left[\frac{x^3}{3}\right]_0^l = \tfrac{1}{3}ml^2.$$



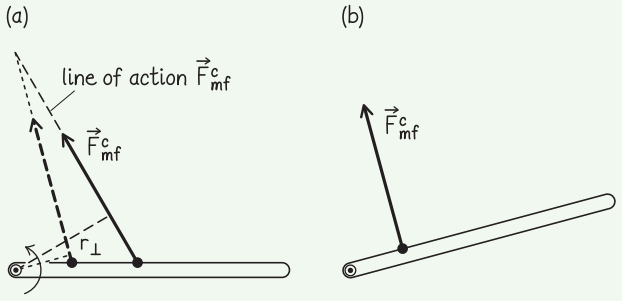
11.11 No, because drilling a hole removes material and its contribution to the rotational inertia, without changing the contribution of the remaining material: $I_{\text{solid}} = I_{\text{removed}} + I_{\text{remaining}} > I_{\text{remaining}}$. The m's in the two expressions for the rotational inertia are not the same: $m_{\text{hollow}} = \rho\pi l(R_{\text{outer}}^2 - R_{\text{inner}}^2)$, while $m_{\text{solid}} = \rho\pi lR_{\text{outer}}^2$. Substituting m_{hollow} into the expression for the rotational inertia of the hollow cylinder gives $I_{\text{hollow}} = \frac{1}{2}m_{\text{hollow}}(R_{\text{outer}}^2 + R_{\text{inner}}^2) = \frac{1}{2}\rho\pi l(R_{\text{outer}}^2 - R_{\text{inner}}^2)(R_{\text{outer}}^2 + R_{\text{inner}}^2) = \frac{1}{2}\rho\pi l(R_{\text{outer}}^4 - R_{\text{inner}}^4)$, which is *less* than $I_{\text{solid}} = \frac{1}{2}m_{\text{solid}}R_{\text{outer}}^2 = \frac{1}{2}\rho\pi lR_{\text{outer}}^4$.

11.12 About an axis through the center of mass. I is larger about any other axis because the term md^2 in Eq. 11.53 is always positive.

Chapter 12

12.1 (*a*) The rod is subject to four forces: the force of gravity $\vec{F}_{\text{Er}}^{G}$ (which we can ignore because the inertia of the rod is negligible compared to m_1 and m_2), the downward contact forces $\vec{F}_1$ and $\vec{F}_2$ exerted by the two objects, and an upward force $\vec{F}_{\text{pr}}^{\text{c}}$ exerted by the pivot that holds the rod in place. Because the rod remains at rest, the vector sum of these forces must be zero, and so the upward force must be equal in magnitude to the sum of the downward forces (Figure S12.1). (*b*) The rod is still subject to the same forces. The rod is pinned down at the pivot, so it cannot accelerate. Therefore $\vec{a}_{\text{cm}} = \vec{0}$ as before, and the free-body diagram is unchanged. (The rod rotates to one side, pulling object 1 up and lowering object 2, but this is not reflected in the free-body diagram.) (*c*) $r_1/r_2 = m_2/m_1$. (*d*) The rod rotates so that the end where object 1 was shoots up and the end holding object 2 falls down. (*e*) The rod rotates so that the end of the rod where the object of inertia $2m_1$ is suspended goes down and object 2 is pulled up. (*f*) The end of the rod where object 1 is suspended goes down. (*g*) The difference is the speed at which the rod rotates into a vertical position: fast in part *e* and slowly in part *f*.

Figure S12.1



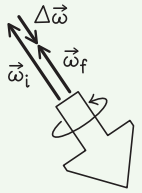
12.2 The seesaw remains at rest because the child causes a torque on the seesaw that is equal in magnitude to the torque you cause but tends to rotate the seesaw in the opposite direction.

12.3 (*a*) Because the torques caused by $\vec{F}_1$ and $\vec{F}_2$ cancel each other, the only way to prevent the rod from rotating is to make the torque caused by $\vec{F}_3$ zero. This can be achieved by aligning $\vec{F}_3$ along the long axis of the rod, either straight toward or straight away from the pivot. (*b*) The torque caused by $\vec{F}_1$ is $+r_{1\perp}F_1$; the torque caused by $\vec{F}_2$ is $-r_{2\perp}F_2 = -2r_{1\perp}F_2$. The lever arm distance of $\vec{F}_3$ is $r_{3\perp} = 3r_{1\perp}$, and so the torque caused by $\vec{F}_3$ is $+r_{3\perp}F_3 = +3r_{1\perp}F_1$ because $F_3 = F_1$. The sum of the torques is thus $+r_{1\perp}F_1 - 2r_{1\perp}F_2 + 3r_{1\perp}F_1$. Setting this sum to zero, I get $F_2 = 2F_1$. So, to balance the rod, you must increase the magnitude of $\vec{F}_2$ by a factor of 4.

12.4 If we neglect the very small effect of air resistance, the rotation of the wrench is steady. As you can verify by launching a stick or any other object, the object rotates in the same direction when it comes down. This shows that the rotational and translational motions are not coupled. The upward motion slows down because of the force of gravity, but this force does not affect the rotational motion because it does not cause a torque about the center of mass.

12.5 (*a*) The torque becomes greater because the lever arm distance of the force increases. See Figure S12.5*a*. (*b*) As the arm is raised, $\vec{F}_{\text{mf}}^{\text{c}}$ becomes more perpendicular to the forearm. See Figure S12.5*b*. This means that the torque caused by $\vec{F}_{\text{mf}}^{\text{c}}$ increases, and so the capacity to lift objects increases.

Figure S12.5



12.6 The acceleration of the center of mass is the same regardless of where the force is exerted. The acceleration of the center of mass of a system of particles is *always* given by $\sum\vec{F}_{\text{ext}} = m\vec{a}_{\text{cm}}$. See Section 8.12.

12.7 (*a*) Because the rotation slows down, the length of $\vec{\omega}$ decreases and so $\vec{\omega}_f$ is shorter than $\vec{\omega}_i$. The vector $\Delta\vec{\omega} \equiv \vec{\omega}_f - \vec{\omega}_i$ points from the tip of $\vec{\omega}_i$ to the tip of $\vec{\omega}_f$, which means the direction of $\Delta\vec{\omega}$ is opposite the direction of $\vec{\omega}$ (Figure S12.7). (*b*) Yes, because rotational acceleration is defined as (Eq. 11.12)

$$\alpha_\vartheta \equiv \lim_{\Delta t\to 0}\frac{\Delta\omega_\vartheta}{\Delta t}.$$

Because $1/\Delta t$ is a scalar, $\vec{\alpha}$ points in the same direction as $\Delta\vec{\omega}$.

Figure S12.7

12.8 The fact that the forearm is not moving tells you that $\Sigma\tau_{\text{ext}} = 0$. This yields

$$\frac{\ell}{5}F^{\text{c}}_{\text{mf}y} - \frac{\ell}{2}F^{G}_{\text{Ef}} - \ell F^{\text{c}}_{\text{bf}} = 0.$$

Dividing both sides by $\ell/5$ and solving for $F^{\text{c}}_{\text{mf}y}$ yields

$$F^{\text{c}}_{\text{mf}y} = \tfrac{5}{2}F^{G}_{\text{Ef}} + 5\,F^{\text{c}}_{\text{bf}}. \quad (1)$$

The condition that the vector sum of the forces exerted in the vertical direction must be zero yields

$$\Sigma F_y = F^{\text{c}}_{\text{mf}y} + F^{\text{c}}_{\text{hf}y} - F^{G}_{\text{Ef}} - F^{\text{c}}_{\text{bf}} = 0. \quad (2)$$

Substituting Eq. 1 into Eq. 2 and solving for $F^{\text{c}}_{\text{hf}y}$ yields

$$|F^{\text{c}}_{\text{hf}y}| = |-\tfrac{3}{2}F^{G}_{\text{Ef}} - 4F^{\text{c}}_{\text{bf}}| = \tfrac{3}{2}F^{G}_{\text{Ef}} + 4F^{\text{c}}_{\text{bf}}.$$

Note that the magnitude of the force that needs to be supplied by the biceps muscle is *much* greater than the sum of F^{G}_{Ef} and F^{c}_{bf}: $F^{\text{c}}_{\text{mf}} > |F^{\text{c}}_{\text{mf}y}| = \frac{5}{2}F^{G}_{\text{Ef}} + 5F^{\text{c}}_{\text{bf}} \gg F^{G}_{\text{Ef}} + F^{\text{c}}_{\text{bf}}$. This is the price one pays for the versatility and mobility of the forearm: If a load were suspended directly from the biceps muscle, our lifting capacity would increase by at least a factor of 5! Note furthermore that the downward force exerted by the humerus on the forearm is also very great. This great downward force is necessary to counter the upward force exerted by the biceps muscle on the forearm. Without this downward force, the muscle would simply pull the forearm up rather than rotate it.

12.9 (*a*) No. A nonzero vector sum of forces would cause the disc's center of mass to accelerate, and we know that the disc remains in the same place, so $\vec{a}_{\text{cm}} = \vec{0}$. (*b*) No. Even though the *vector sum* of the forces exerted on the compact disc is zero, the individual forces cause a nonzero torque. The resulting nonzero torque is what gives the disc a rotational acceleration and increases its rotational kinetic energy.

12.10 (*a*) The cylindrical shell has greater rotational inertia than the solid cylinder (MR^2 versus $\frac{1}{2}MR^2$; see Table 11.3) and so, because $\tau_\vartheta = I\alpha_\vartheta$, it requires a greater torque to be accelerated rotationally. This torque is supplied by the force of static friction, so the frictional force exerted on the shell must be greater. (You can see this directly from Eq. 12.26: The shape factor c is greater for the cylindrical shell, and so F^{s}_{ro} is greater, too.) (*b*) The maximum value of the force of static friction is, from Eq. 10.46,

$$(F^{s}_{\text{ro}})_{\max} = \mu_s F^{n}_{\text{ro}} = \mu_s mg\cos\theta.$$

Substituting this result into Eq. 12.26 yields

$$m_s\, mg\cos\theta = \frac{mg\sin\theta}{1 + c^{-1}}.$$

Solving this expression for θ, you obtain

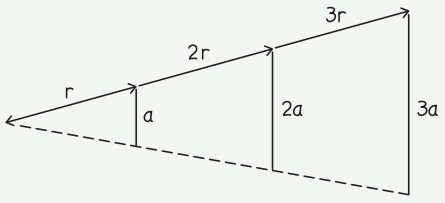
$$\tan\theta = \mu_s(1 + c^{-1}).$$

For the cylindrical shell, $c = 1$, and so with $\mu_s = 1$, $\tan\theta = 2$ and $\theta = 63°$. For the solid cylinder, $c = \frac{1}{2}$, and so with $\mu_s = 1$, $\tan\theta = 3$ and $\theta = 72°$. Beyond these angles the cylinders no longer can roll without slipping. Note that both angles are larger than the 45° angle above which a block would begin to slip down a ramp. (See part *a* of Checkpoint 10.13.)

12.11 (*a*) Yes, the force of static friction does cause a torque on the wheel. The direction of this torque is counterclockwise in Figure 12.40*a*, opposite the direction of the torque caused by the chain. (*b*) Because the wheel's rotational acceleration is clockwise, the sum of the torques must be clockwise. Thus the clockwise torque caused by the chain must be greater than the counterclockwise torque caused by the frictional force.

12.12 Yes. The component $\vec{F}_\perp$ does work on the cylinder because its point of application is displaced along the circular arc. The arc length displacement is $\Delta s_F = r\Delta\vartheta$, and so the work done on the cylinder is $F_\perp \Delta s_F = F_\perp r\Delta\vartheta = \tau\Delta\vartheta$. This is equal to the change in the rotational kinetic energy in Eq. 12.31. So, for a rigid object subject to a constant torque, the quantity $t\Delta\vartheta$ is equal to the work done on the object.

12.13 $\vec{v} = \vec{\omega}\times\vec{r}$. Because $\vec{\omega}$ and $\vec{r}$ are orthogonal, the magnitude of this product is ωr, in agreement with Eq. 11.11. You can use the right-hand rule in Figure 12.44 to verify that the vector product of $\vec{\omega}$ and $\vec{r}$ indeed gives the right direction for $\vec{v}$.



Chapter 13

13.1 (*a*) Rotational speed is the change in the rotational position divided by the time interval during which that change takes place, and so the object with the smaller period has the greater rotational speed. Because the Moon takes less time to complete one revolution, it has the greater rotational speed. Rotations you encounter in daily life—a spinning disc, a spinning wheel, the hands of a clock—rotate significantly faster and thus have significantly greater rotational speeds. (*b*) The speed is the distance traveled in 1 rev ($2\pi R$) divided by the period. Moon: $[2\pi(3.84\times10^8\text{ m})/(27.32\text{ days})]/(86{,}400\text{ s/day}) = 1.02\times10^3$ m/s. Earth: $[2\pi(1.50\times10^{11}\text{ m})/(365.26\text{ days})]/(86{,}400\text{ s/day}) = 2.99\times10^4$ m/s. Because of its much larger orbital radius, Earth's speed is considerably greater. (*c*) Moon: $a_c = v_{\text{M}}^2/R_{\text{M}} = (1.02\times10^3\text{ m/s})^2/(3.84\times10^8\text{ m}) = 0.00271\text{ m/s}^2$. Earth: $(2.98\times10^4\text{ m/s})^2/(1.50\times10^{11}\text{ m}) = 0.00595\text{ m/s}^2$. (*d*) These accelerations are much smaller than the acceleration due to gravity at Earth's surface: $g = 9.8\text{ m/s}^2$.

13.2 Earth's radius is about 6400 km, and so near the surface the distance to the center does not change much with altitude. For a plane 10 km above ground, the distance to the center of Earth is only $(10\text{ km})/(6400\text{ km}) = 0.016$ greater than that for an object on the ground. Because the gravitational force depends on the square of the distance, this increase results in a decrease in the strength of the force by a mere 2.4×10^{-6}!

13.3 (*a*) The light spreads out in a two-dimensional cone rather than a three-dimensional one, and the length of the straight line segment intersecting a two-dimensional wedge of light varies as $1/r$ (Figure S13.3), which means the force of gravity would exhibit a $1/r$ dependence. (*b*) The centripetal acceleration is still $a_c \propto R/T^2$. Because this acceleration is supplied by a gravitational force that is proportional to $1/r$, you have $R/T^2 \propto 1/R$ and so $T \propto R$.

Figure S13.3

13.4 For requirement (*i*) to hold, you must be able to interchange the indices in the expression for the gravitational force without changing the force magnitude: $F^{G}_{12} = F^{G}_{21}$. Requirement (*ii*) means that if you double one mass, the force exerted on the object must double. (*a*) No. This dependence is consistent with requirement (*i*) because $m_1 + m_2 = m_2 + m_1$, but not with requirement (*ii*) because $m_1 + 2m_2 \neq 2(m_1 + m_2)$. (*b*) Only m_1m_2 satisfies both requirements simultaneously. (*c*) If you take a very small piece m away, leaving $M - m$ behind, the attraction is proportional to $(M - m)m = Mm - m^2 \approx Mm$ (because the term m^2 is very small compared to Mm). So, the greater m is, the greater the force is. Symmetry thus suggests that the attraction is greatest when you divide the lump into two equal pieces. Mathematically you can prove this as follows: If you divide the lump into two pieces of masses cM and

$(M - cM)$, where $0 < c < 1$, then the gravitational force is proportional to $(M - cM)cM = M^2(c - c^2)$. To find the value for c at which the force is maximum, you must set the first derivative of this expression with respect to c equal to zero: $d[M^2(c - c^2)]/dc = M^2(1 - 2c) = 0$, so $1 - 2c = 0$ or $c = \frac{1}{2}$.

13.5 For the two forces to be equal in magnitude, you need

$$\frac{m_1 m_2}{r_{12}^2} = \frac{m_1 m_E}{R_E^2}.$$

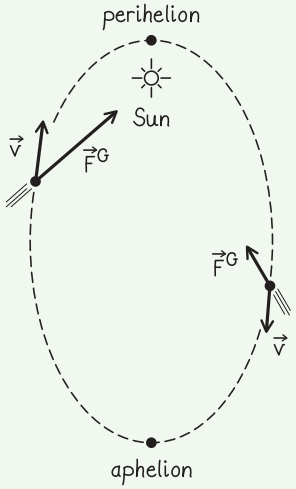
You calculated the right side in Example 13.1, so

$$\frac{m_1 m_2}{r_{12}^2} = \frac{(70\text{ kg})^2}{r_{12}^2} = 1.0 \times 10^{13}\text{ kg}^2/\text{m}^2,$$

which yields

$$r_{12}^2 = \frac{(70\text{ kg})^2}{1.0 \times 10^{13}\text{ kg}^2/\text{m}^2} = 4.9 \times 10^{-10}\text{ m}^2,$$

or $r_{12} = 2.2 \times 10^{-5}$ m. This is the required separation between the *centers* of the bodies. Because the width of a human body is many orders of magnitude greater than this value, it is not possible to verify this prediction.



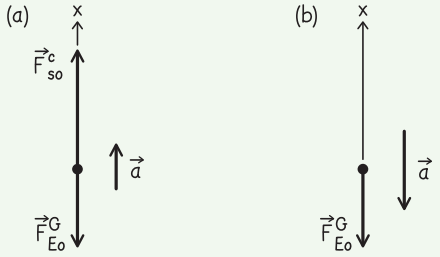
13.6 (*a*) To find the center of mass, use Eq. 6.24: $x_{cm} = (m_1 x_1 + m_2 x_2)/(m_1 + m_2)$. Let 1 be the Sun and 2 Earth. If you place the Sun at the origin, $x_1 = 0$ and x_2 equals the radius of Earth's orbit. Using the values in Table 13.1, you find

$$x_{cm} = \frac{0 + (5.97 \times 10^{24}\text{ kg})(1.50 \times 10^{11}\text{ m})}{(2.0 \times 10^{30}\text{ kg}) + (5.97 \times 10^{24}\text{ kg})}$$

$$= \frac{8.96 \times 10^{35}\text{ kg} \cdot \text{m}}{2.0 \times 10^{30}\text{ kg}} = 4.5 \times 10^{5}\text{ m}.$$

Compared with the radius of the Sun (7×10^8 m), this is a negligible distance: $x_{cm} = 0.00064 R_{Sun}$. (*b*) It speeds up because the force of gravity has a nonzero component parallel to the velocity, giving rise to an acceleration (Figure S13.6). The velocity keeps increasing until the comet reaches perihelion at the top of the ellipse. After passing that point, the comet slows down because the force of gravity causes an acceleration in the direction opposite the direction of the velocity. The slowing down continues until the comet reaches the point farthest from the Sun. At that point the velocity is a minimum.

Figure S13.6



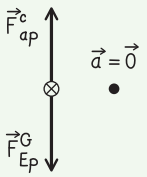
13.7 (*a*) The radius of Earth is about 6400 km, so the distance to Earth's center is increased by a factor of (6400 km + 300 km)/(6400 km) = 1.05. (*b*) Because the gravitational force changes as $1/r^2$, the force decreases by a factor of $1/(1.05)^2 = 0.91$. (*c*) The acceleration decreases by the same factor as the force: $0.91(9.8\text{ m/s}^2) = 8.9\text{ m/s}^2$. (*d*) The shuttle travels at such a high speed that the gravitational force exerted by Earth on it is just sufficient to provide its centripetal acceleration: $g = v^2/r$, with r the distance from the shuttle to the center of Earth.

13.8 (*a*) $F^G_{Eb} = mg = (1.0\text{ kg})(9.8\text{ m/s}^2) = 9.8$ N. (*b*) The scale exerts an upward contact force of magnitude F^c_{sb} on the brick. The brick is at rest, and so you know that the vector sum of the forces exerted on it is zero. Choosing the x axis in the upward direction, we have $\sum F_x = F^c_{sbx} + F^G_{Ebx} = F^c_{sb} + (-F^G_{Eb}) = 0$, and so $F^c_{sb} = F^G_{Eb}$. Furthermore, the contact force exerted by the brick on the scale and that exerted by the scale on the brick form an interaction pair, which means they are equal in magnitude, so $F^c_{bs} = F^c_{sb} = F^G_{Eb}$. (*c*) Two. Step 1: $F^c_{sbx} + F^G_{Ebx} = 0$; step 2: $F^c_{bs} = F^c_{sb}$. (*d*) Yes, because, as you found in part *b*: $F^c_{bs} = F^G_{Eb}$. (If you think this question is trivial, hold off judgment until after doing Checkpoints 13.9 and 13.10.)

13.9 (*a*) Inside the orbiting shuttle, $g = 8.9\text{ m/s}^2$ (see Checkpoint 13.7), and so $F^G_{Eb} = mg = (1.0\text{ kg})(8.9\text{ m/s}^2) = 8.9$ N—almost the same as at the surface of Earth (see Checkpoint 13.8). (*b*) Zero. The brick floats: no force is necessary to support it because everything around it has the same downward acceleration. (*c*) No. The scale measures nothing, even though Earth pulls on the brick nearly as hard as it does on Earth's surface. (*d*) The answer is different because the reference frame of the shuttle is accelerating toward the Earth reference frame.

13.10 (*a*) The same. Because the elevator is moving at constant velocity, its acceleration (and that of the spring scale and the object) is zero. Consequently the vector sum of the forces exerted on the object is zero, as it is on the ground, and so $\sum F_x = F^c_{sox} + F^G_{Eox} = 0$. (*b*) To accelerate upward, the vector sum of the forces exerted on the object must be nonzero and point upward (Figure S13.10*a*). If $a_x = +0.5g$, $\sum F_x = ma_x = +\frac{1}{2}mg$. Consequently $\sum F_x = F^c_{sox} + F^G_{Eox} = +\frac{1}{2}mg$, and so $F^c_{sox} = +\frac{1}{2}mg - F^G_{Eo} = +\frac{1}{2}mg - (-mg) = +\frac{3}{2}mg$. The scale reading is one and a half times what it is in a stationary elevator. (*c*) The object now has downward acceleration g and so is in free fall. The gravitational force exerted on it is thus the only force exerted on it (Figure S13.10*b*). The scale exerts no force on the object and so shows a zero reading.

Figure S13.10



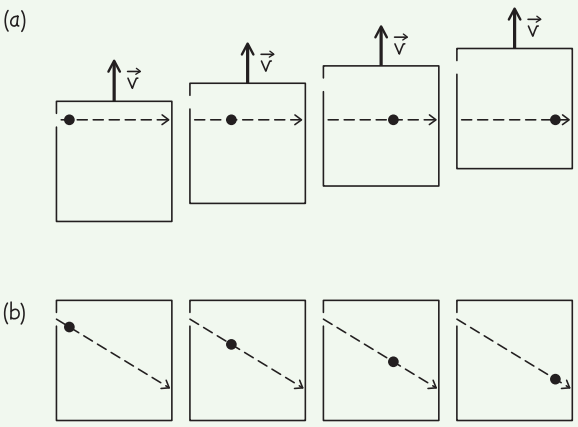
13.11 (*a*) In Checkpoint 13.7 you found that the shuttle's downward acceleration due to gravity is $g = 8.9\text{ m/s}^2$. The vertical distance Δh through which the shuttle falls in a time interval Δt is $\Delta h = \frac{1}{2}gt^2 = \frac{1}{2}(8.9\text{ m/s}^2)(1.0\text{ s})^2 = 4.5$ m. (*b*) If the shuttle remains 300 km above Earth, it is in a circular orbit, and so its centripetal acceleration is given by v^2/R, where v is its speed and R the radius of its orbit. Because the shuttle's acceleration is g, you have $v^2/R = g$, $v = \sqrt{gR} = \sqrt{(8.9\text{ m/s}^2)(6.7 \times 10^6\text{ m})} = \sqrt{5.7 \times 10^7\text{ m}^2/\text{s}^2} = 7.5 \times 10^3$ m/s.

13.12 (*a*) For the plane to be in free fall, it must have a downward acceleration of 9.8 m/s^2 (see Checkpoint 13.2). Starting with zero vertical velocity, a freely falling object drops in 40 s a distance $\Delta x = \frac{1}{2}gt^2 =$

$\frac{1}{2}(9.8\ \text{m/s}^2)(40\ \text{s})^2 = 7.8$ km. (*b*) The magnitude of the vertical speed is given by $v = gt = (9.8\ \text{m/s}^2) \times (40\ \text{s}) = 390$ m/s. (*c*) You can't tell. The instantaneous velocity of an object in free fall can be in any direction. Remember that a ball launched upward is in free fall while moving up as well as while moving down. At all times, its acceleration has the same constant downward value (see Section 3.3). The answers to parts *a* and *b* show that the plane *must* have been moving upward before going into free fall. If it had started horizontally, it would have lost almost 8 km of altitude and be dangerously close to the ground (airplanes normally fly at an altitude of about 10 km). Worse, its downward velocity at the end of the free fall would have been an amazing 1400 km/h, which is well above the maximum airspeed for most airplanes.

13.13 (*a*) The plane's speed is $v = (900\ \text{km/h})(1000\ \text{m/km})/(3600\ \text{s/h}) = 250$ m/s. Because the plane remains at a fixed altitude, it must follow a circular trajectory of radius $R \approx 6400$ km. Its centripetal acceleration is thus $v^2/R = (250\ \text{m/s})^2/(6.4 \times 10^6\ \text{m}) = 9.8 \times 10^{-3}\ \text{m/s}^2$. (*b*) See Figure S13.13. The centripetal acceleration of the plane is so small (about 0.1% of *g*) that you can safely ignore it, and so the free-body diagram is identical to what it would be if the plane were sitting on the ground. The plane is subject to two forces: a downward force of gravity and an upward force exerted by the air that is equal in magnitude to the downward force. (*c*) Because the airplane is not in free fall, its downward acceleration is only 0.1% of what it needs to be for the people to feel weightless.

Figure S13.13



13.14 A passenger in a car that takes a right turn feels pushed outward from the turn, which means toward the left. To simulate this effect, the container should be tilted to the left.

13.15 (*a*) $\Delta t = \Delta x/v = (2.0\ \text{m})/(3.0 \times 10^8\ \text{m/s}) = 6.7 \times 10^{-9}$ s—just a few billionths of a second. (*b*) In the vertical direction you have $\Delta y = \frac{1}{2}a_y(\Delta t)^2$, $a_y = 2\Delta y/(\Delta t)^2$. To obtain a 1.0-mm deviation in the time interval obtained in part *a*, you need acceleration $a_y = 2(+1.0 \times 10^{-3}\ \text{m})/(6.7 \times 10^{-9}\ \text{s})^2 = +4.5 \times 10^{13}\ \text{m/s}^2$. This is such a phenomenally large acceleration that you cannot expect to observe this effect. (*c*) In 0.0010 s, a light beam travels $(3.0 \times 10^8\ \text{m/s}) \cdot (1.0 \times 10^{-3}\ \text{s}) = 3.0 \times 10^5$ m. In that time interval, it falls like an object in free fall, and so $\Delta y = \frac{1}{2}(-9.8\ \text{m/s}^2)(1.0 \times 10^{-3}\ \text{s})^2 = -4.9 \times 10^{-6}$ m—a tiny fraction of the diameter of a hair. Measuring this tiny displacement over a travel distance of 300 km is beyond current measurement accuracy.

13.16 (*a*) Zero. In the absence of both gravity and acceleration, the container and everything inside it are weightless. (*b*) The elevator moving at constant velocity has equal displacements in equal time intervals (Figure S13.16*a*). The path of the light pulse in the reference frame of the moving elevator is thus straight but at an angle (Figure S13.16*b*).

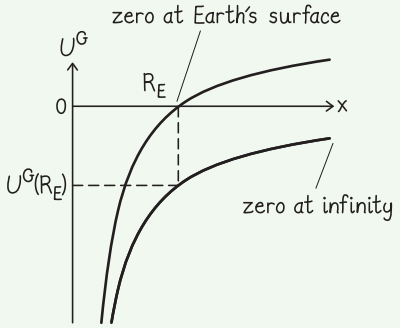


Figure S13.16

13.17 It increases because the gravitational force increases with decreasing distance r_{12}; see Eq. 13.1.

13.18 It yields values greater by an amount $|U(R_E)| = GmM_E/R_E$. See Figure S13.18.

Figure S13.18

13.19 (*a*) If we let the star be at rest at the origin, then the initial kinetic energies of the star and the object are zero. The initial gravitational potential energy U^G of the closed star-object system is given by Eq. 13.14 and is negative. The initial mechanical energy of the system $E_{mech} = K + U^G$ is thus negative. If we consider the star-object system to be closed, then its mechanical energy is constant, and so it is always negative because there is no dissipation of energy. (*b*) Because $\vec{F}^G_{so}$ is directed toward the star's center, the object accelerates in a straight line toward that center. The minimum kinetic energy is zero (see part *a*). Because the object accelerates as it moves toward the star, the maximum kinetic energy is achieved when the object reaches the star's surface. Conservation of energy tells you that $E_{mech,i} = E_{mech,f}$. From part *a*, $E_{mech,i} = U^G_i = -GMm/r$. At the star's surface, you have $E_{mech,f} = K_f + U^G_f = K_f - GMm/R_s$. So $K_f = GMm(r - R_s)/(R_s r)$. (Because r is the distance from the object to the center of the star, you have $r > R_s$, and so $K_f > 0$, as it should be.) (*c*) Yes. The angular momentum is $r_\perp mv$ (Eq. 13.36). Because the motion of the object is directed straight toward the center of the star, the lever arm distance about the center of the star remains zero throughout the object's motion. The angular momentum is thus both zero and constant. (*d*) The answer depends on the magnitude of the launch velocity: If $K_i < |U^G_i|$, then $E_{mech} < 0$; if $K_i = |U^G_i|$, then $E_{mech} = 0$; and if $K_i > |U^G_i|$, then $E_{mech} > 0$.

13.20 (*a*) At r_{max}, $U^G = E_{mech}$ and so $K = 0$. This means $v = 0$ and so $\vec{L} = \vec{0}$. (*b*) Conservation of angular momentum requires $\vec{L}$ to remain zero. This can happen only if $\vec{r} \times m\vec{v}$ is zero (or if v remains zero, which is impossible, because then nothing holds the object in place). This vector product is zero when $\vec{r}$ and $\vec{v}$ point in the same direction—in other words, when the object's motion is restricted to a straight line. (*c*) No. If $\vec{L} \neq 0$, $\vec{v}$ can never point in the same direction as $\vec{r}$ and neither of these can ever become zero. This means the object can never move all the way out to r_{max}. Although moving out that far does not violate conservation of energy, it does not allow the object to keep enough angular momentum.

13.21 (*a*) For the planet to move in a circular trajectory of radius R at constant speed v, the star must exert a gravitational force on the planet to cause the centripetal acceleration $a_c = v^2/R$. The gravitational force is thus $GMm/R^2 = ma_c$, or

$$\frac{GMm}{R^2} = m\frac{v^2}{R}.$$

To obtain the kinetic energy $\frac{1}{2}mv^2$, multiply both sides by $\frac{1}{2}R$:

$$\frac{1}{2}\frac{GMm}{R} = \frac{1}{2}mv^2.$$

(*b*) The mechanical energy in the circular orbit is the sum of the kinetic energy you just determined and the gravitational potential energy from Eq. 13.11:

$$E = \tfrac{1}{2}\frac{GMm}{R} - \frac{GMm}{R} = -\tfrac{1}{2}\frac{GMm}{R}.$$

Note that this result is the negative of the kinetic energy. So, for an object in a circular orbit, the kinetic energy is half the magnitude of the system's potential energy. (*c*) For a circular orbit, $e = 0$, and so from Example 13.5 you know

$$\frac{2E_{\text{mech}}L^2}{G^2M^2m^3} = -1,$$

which means $E_{\text{mech}} = -\tfrac{1}{2}G^2M^2m^3/L^2$. Substituting L^2 from Example 13.5 with $e = 0$ and $a = R$ gives $E_{\text{mech}} = \left(-\tfrac{1}{2}G^2M^2m^3\right)/(GMm^2R) = -\tfrac{1}{2}GMm/R$. (*d*) The two results are the same.

13.22 (*a*) At Earth's surface, the distance to the planet's center is equal to Earth's radius: $r_i = R_E$, and so Eq. 13.23 gives

$$\tfrac{1}{2}mv_{\text{esc}}^2 = \frac{Gmm_E}{R_E}$$

or $v_{\text{esc}} = \sqrt{2Gm_E/R_E}$. (*b*) $v_{\text{esc}} = [2(6.6738 \times 10^{-11}\ \text{N}\cdot\text{m}^2/\text{kg}^2)\cdot(5.97 \times 10^{24}\ \text{kg})/(6.378 \times 10^6\ \text{m})]^{1/2} = 1.12 \times 10^4\ \text{m/s}$. (*c*) No. As long as an object is fired above the horizon (so it doesn't hit the ground), only the magnitude of the velocity matters. Once the object has enough kinetic energy to reach infinity ($E = 0$), it does so regardless of the direction in which it is fired.

13.23 (*a*) The integral has two parts:

$$(r^2 - R^2)\int_{r-R}^{r+R}\frac{1}{s^2}ds + \int_{r-R}^{r+R}ds.$$

The first term yields

$$(r^2 - R^2)\left[-\frac{1}{s}\right]_{r-R}^{r+R} = (r^2 - R^2)\left[-\frac{1}{r+R} + \frac{1}{r-R}\right].$$

Bringing both terms under a common denominator yields

$$(r^2 - R^2)\frac{(R-r)+(r+R)}{r^2 - R^2} = 2R.$$

The second term of the integral yields

$$[s]_{r-R}^{r+R} = (r+R) - (r-R) = 2R.$$

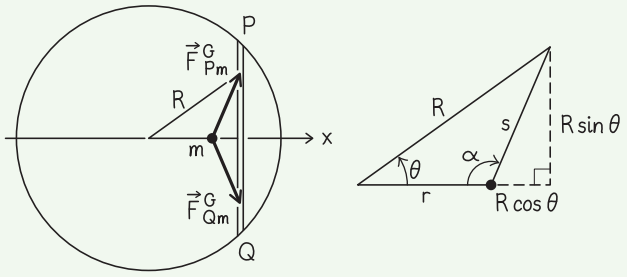
Adding both parts together yields $4R$. (*b*) Equations 13.24–13.27 still hold when m lies inside the shell. From Figure S13.23, we see that

$$R\cos\theta = r + s\cos(\pi - \alpha) = r - s\cos\alpha,$$

which yields the same relationship between α and θ as in Eq. 13.28. Equation 13.29 is also still valid and so we obtain the same result as in Eq. 13.33. (*c*) The integration boundaries are now from $R - r$ (at $\theta = 0$) to $R + r$ (at $\theta = \pi$). The first part of the integral then yields

$$(r^2 - R^2)\left[-\frac{1}{s}\right]_{R-r}^{R+r} = (r^2 - R^2)\left[-\frac{1}{R+r} + \frac{1}{R-r}\right].$$

Bringing both terms again under a common denominator gives



$$(r^2 - R^2)\frac{(r-R)+(R+r)}{R^2 - r^2} = -2r.$$

The second part of the integral yields

$$[s]_{R-r}^{R+r} = (R+r) - (R-r) = 2r.$$

Adding both parts together now yields zero. The gravitational attraction inside a uniform spherical shell is thus zero!

Figure S13.23

Chapter 14

14.1 (*a*) Because the light from event 1 reaches A before the light from event 2 reaches her, she observes event 1 first. (*b*) Because the light from event 1 and the light from event 2 reach B at the same instant, he observes the two events at the same instant.

14.2 (*a*) The light from each clock takes a finite time interval to travel from clock to observer. For clocks near the origin, this time interval is shorter than it is for clocks farther from the origin. This means (*ii*) is true: Nearby clocks display later time readings than distant clocks. (*b*) The clocks are synchronized and so by definition run at the same rate.

14.3 According to an observer moving along with the tube, the speed of the ball is l divided by Δt: $v_{\text{Mb}} = l/\Delta t$. Using the result $v_{\text{Mb}} = v_b + v_t$ from Example 14.3, you get $\Delta t = l/v_{\text{Mb}} = l/(v_b + v_t) = l/(2v)$.

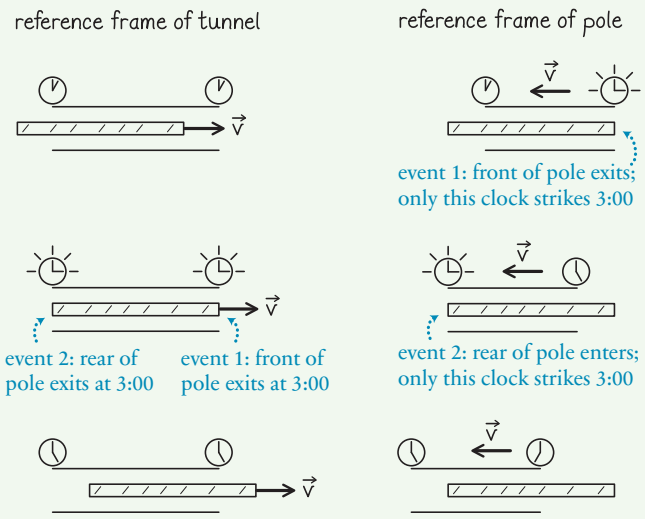
14.4 (*a*) The observers agree that the signals do not reach the detector at the same instant because they both see that the blue light does not come on. (*b*) The observer at rest sees the two signals being emitted at the same instant. His reasoning for why the detector does not record simultaneity is that, because the detector is moving toward source 2 and away from source 1, signal 2 has a shorter distance to travel than signal 1. Therefore signal 2 reaches the detector first. The observer moving with the detector notes that the sources are equidistant from the detector but sees signal 2 arriving first. Because both signals travel at speed c_0 relative to him, he concludes that source 2 must have emitted its signal before source 1. The observers agree on the observation—no simultaneity—but have different explanations for it.

14.5 (*a*) Each signal takes $\Delta t = (5.0\ \text{m})/(3.00 \times 10^8\ \text{m/s}) = 1.7 \times 10^{-8}\ \text{s}$ to reach the detector. (*b*) $(20\ \text{m/s})(1.7 \times 10^{-8}\ \text{s}) = 3.3 \times 10^{-7}\ \text{m}$. (*c*) The travel time changes by $d/c_0 = (3.3 \times 10^{-7}\ \text{m})/(3.00 \times 10^8\ \text{m/s}) = 1.1 \times 10^{-15}\ \text{s} = 1.1\ \text{fs}$. (*d*) A 1.1-fs change in travel time is just barely measurable. (*e*) The detector moves $(1.0 \times 10^8\ \text{m/s})(1.7 \times 10^{-8}\ \text{s}) = 1.7\ \text{m}$. Light takes $(1.7\ \text{m})/(3.00 \times 10^8\ \text{m/s}) = 5.6 \times 10^{-9}\ \text{s}$ to travel this distance. Such a time interval can be measured, but note how fast the detector must be moving—$1.0 \times 10^8\ \text{m/s}$, about one-third the speed of light!—in order for the time interval to be long enough (if we can call $10^{-9}\ \text{s}$ "long") to be measurable.

14.6 (*a*) Greater than. Because the signal always travels at speed c_0, the longer distance the signal must travel according to B increases the duration of the cycle and therefore the period. (*b*) Increase. The faster

the clock moves relative to B, the farther the mirror moves away from its initial position above the location where the signal was emitted in one period of a clock at rest and so the period increases.

14.7 (*a*) Slow, because the mechanical watch takes longer to complete 1 minute. (*b*) Fast.



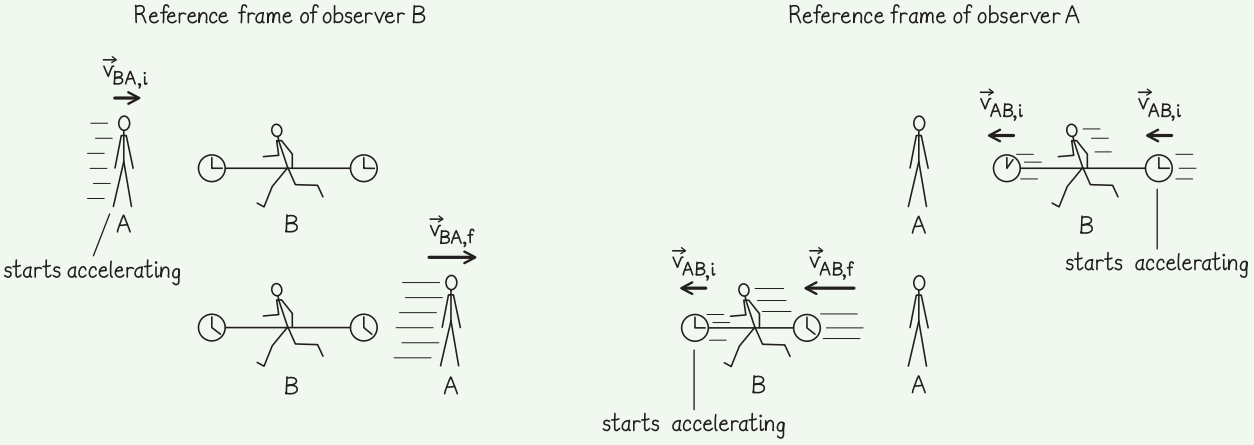
14.8 Yes and no. By moving at high speed, you could slow down your biological clock and therefore slow down the rate at which your body ages, but *only as measured by an observer who is not in your reference frame*. From your perspective, you see your biological clock running at its "regular" rate (that is, a rate that is the same as what you would measure if you remained at rest on Earth). To you, there is no slowing down of your biological clock, regardless of your motion relative to any observer. So, although you could lengthen your life in the eyes of an observer, it would be impossible to do so from your own point of view.

14.9 Figure S14.9*a* shows the situation viewed from B's reference frame. B starts accelerating relative to A when her clocks read 3 o'clock. Figure S14.9*b* shows the situation viewed from A's reference frame. Because the unit is moving, the rear clock is ahead of the front clock, and so A sees the rear clock accelerate before the front clock, which means A sees B's unit getting shorter.

14.10 No. See Figure S14.10. To the observer on the ground, the front end of the pole reaches the exit (event 1) at 3 o'clock and the rear end reaches the entrance (event 2) at the same instant. To the observer moving along with the pole, these two events do not occur simultaneously. To this observer, the tunnel is in motion, and so clocks at the two ends are desynchronized, with the clock at the exit ahead of the clock at the entrance. Consequently, this observer sees the front end of the pole exit the tunnel before the rear end enters and concludes that the pole is longer than the tunnel.

Is this disagreement a problem (like the problem of the clock fitting between the pegs in Figure 14.19)? Suppose the tunnel is equipped with doors that can close or open instantly. Initially the entrance is open and the exit is closed. When the front of the pole reaches the exit, the exit door opens. When the rear of the pole reaches the entrance, the entrance door closes. According to the observer on the ground, these two events occur at the same instant, and at that instant the pole fits exactly between the two doors. For the observer moving along with the pole, the front of the pole is at the exit before the rear is at the entrance, and so the exit door opens before the entrance door closes. The pole doesn't need to fit (and *can't* fit) in the tunnel.

Figure S14.10



14.11 No, because the two observers measure different speeds for the object, and inertia depends on speed.

14.12 (*a*) When the spring is compressed, its internal energy increases, and so its mass increases. (*b*) When the coffee cools down, its internal energy decreases, and so its mass decreases.

14.13 (*a*) Because a particle has no internal energy, the mass is constant. Because the particle is accelerated, its kinetic energy increases. Therefore the energy of the system increases, and so the inertia increases. (*b*) As with any collision, we can consider the system of colliding objects to be closed, and so neither the energy nor the inertia can change. The internal energy must increase as the particle comes to rest in the target, and kinetic energy is converted to internal energy. Therefore the mass of the system increases.

14.14 If you use Eq. 14.6, your calculator will round the result to 1 for all but *d*. A better approach is to use Eq. 14.11 to calculate $\frac{1}{2}v^2/c_o^2$ and then add 1. (*a*) $\frac{1}{2}(30\text{ m/s})^2/(3.00\times10^8\text{ m/s})^2 = 5.0\times10^{-15}$, $\gamma = 1 + 5.0\times10^{-15}$. (*b*) $\gamma = 1 + (3.5\times10^{-13})$. (*c*) $\gamma = 1 + (5.6\times10^{-10})$. (*d*) For this part you cannot use Eq. 14.11 because the speed is not small. Equation 14.6 gives $\gamma = 1/\sqrt{1-(0.60)^2} = 1.25$.

Figure S14.9

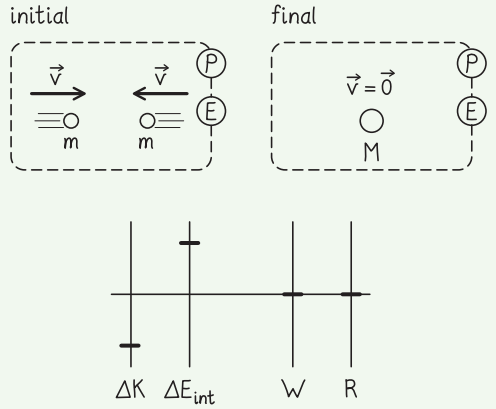
14.15 From Eq. 14.17 you obtain $s^2 = [(3.00 \times 10^8 \text{ m/s}) \cdot (5.0 \times 10^{-7} \text{ s})]^2 - (120 \text{ m})^2 = 8.1 \times 10^3 \text{ m}^2$. This value equals $(c_o \Delta t_{proper})^2$. So $(\Delta t_{proper})^2 = (8.1 \times 10^3 \text{ m}^2)/(3.00 \times 10^8 \text{ m/s})^2$ and $\Delta t_{proper} = 3.0 \times 10^{-7}$ s.

14.16 According to an observer in the car, the 1-km length of road travels past the car at 100 km/h = 28 m/s. According to this observer, the measured length l_v is l_{proper}/γ (Eq. 14.28). The amount by which the length contracts is $l_{proper} - l_{proper}/\gamma = l_{proper}(1 - 1/\gamma) = l_{proper}(\gamma - 1)/\gamma$. For low velocities, γ is close to 1. According to Eq. 14.11, $\gamma - 1 \approx \frac{1}{2}v^2/c_o^2$, and so $(\gamma - 1)/\gamma \approx \frac{1}{2}v^2/c_o^2$. The difference in length is thus $l_{proper}(\frac{1}{2}v^2/c_o^2) = (1.0 \times 10^3 \text{ m})\frac{1}{2}[(28 \text{ m/s})/(3.00 \times 10^8 \text{ m/s})]^2 = 4.3 \times 10^{-12}$ m, which is a few orders of magnitude less than the smallest distance that can be measured. For all practical purposes, the road is still 1.0 km long.

14.17 Because of symmetry, the collision seen by A is identical to that seen by B. The time interval measured by A between the throw and catch of particle 1 is therefore equal to the time interval measured by B between the throw and catch of particle 2.

14.18 (*a*) Because $\vec{v}_2$ has a nonzero component along the x axis, A sees $v_2 > v_1$. (*b*) According to Eq. 14.40, $m_{v2} > m_{v1}$. Hence A concludes that inertia increases with speed. (*c*) From the perspective of B, $v_1 > v_2$. In going from reference frame A to reference frame B, the roles of particles 1 and 2 are interchanged, and so in reference frame B, Eq. 14.40 reads $m_{v1} = \gamma m_{v2}$. According to B, $m_{v1} > m_{v2}$, and so B, too, concludes that inertia increases with speed.

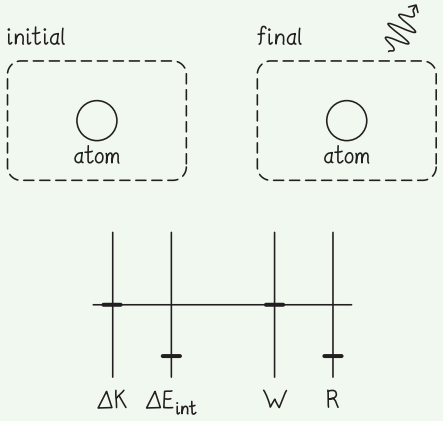
14.19 You know that for the electron at rest, m_v and m in Eq. 14.41 are identical, and so you want to know what speed v yields $\gamma = 1000$. Substituting this value into Eq. 14.9 yields:



$$v^2/c_o^2 = 1 - 10^{-6}$$
$$v = \sqrt{1 - 10^{-6}}\, c_0 = 0.9999995 c_0.$$

14.20 (*a*) Because the final relative speed is zero, the collision is totally inelastic. (*b*) Using $\vec{p} = m\vec{v}$, you find $m_p v_{px,i} + m_e v_{ex,i} = 0$, $v_{e,i} = (m_p/m_e)v_{p,i} = (1836)(0.6c_0) = 1102c_0$!

14.21 $K = (\gamma - 1)mc_o^2 \approx (\frac{1}{2}v^2/c_o^2)mc_o^2 = \frac{1}{2}mv^2$.

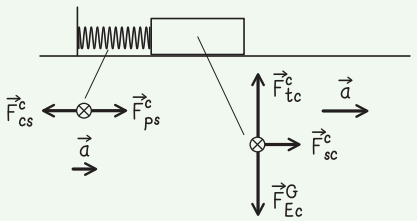


14.22 (*a*) See Figure S14.22. The collision converts kinetic energy to internal energy. (*b*) Kinetic energy is not constant because the final kinetic energy is zero. Mass is not constant because the increase in internal energy corresponds to an increase in mass. Energy is constant because the system is closed.

Figure S14.22

14.23 (*a*) See Figure S14.23. (*b*) The internal energy of the atom decreases because of the radiation emitted by it. The equivalence of mass and internal energy tells you that the mass of the atom decreases. (*c*) Because the atom is at rest, its inertia is equal to its mass. Because the mass decreases, the inertia also decreases.

Figure S14.23

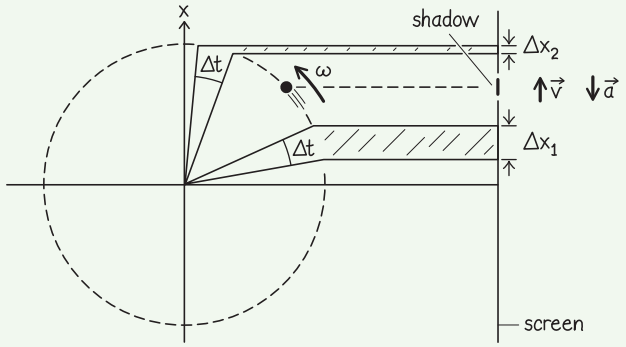


14.24 If you denote the initial energies as $E_{1i} = E_{2i} = E$, the energy law yields $E_{1i} + E_{2i} = 2E$. Because the momentum of the system is zero, we have from Eq. 14.57 $(2E)^2 = (300m_p c_o^2)^2$, or $E = 150m_p c_o^2$. From Eqs. 14.52 and 14.54, $K_{1i} = E - m_p c_o^2 = 149m_p c_o^2 = 2.2 \times 10^{-8}$ J, which is much less than the energy obtained in Example 14.13. (For this reason particle colliders use colliding beams rather than stationary targets.)

Chapter 15

15.1 (*a*) Two forces are exerted on the spring: one by the cart and the other by the post, and three forces are exerted on the cart: one by the spring, one by Earth, and one by the track. Figure S15.1 shows the free-body diagrams during compression (when the spring is stretched, the direction is reversed for the three horizontal forces in the diagrams). (*b*) None. The only forces that have a nonzero displacement along their line of action are the contact forces between the spring and the cart, but these are internal forces and so do no work on the system. (*c*) The contact force exerted by the cart on the spring points in the same direction as the force displacement, so the work done by this force on the spring is positive. This makes sense because, as the spring is compressed, its elastic potential energy increases. (*d*) The force exerted by the spring on the cart is directed in the direction opposite the force displacement, so the work done by this force on the cart is negative. Because $\vec{F}^c_{cs} = -\vec{F}^c_{sc}$ and the force displacement is the same for both forces, the work done by the spring on the cart is the negative of the work done by the cart on the spring.

Figure S15.1



15.2 (*a*) Negative. Just before reaching the position where the spring is maximally stretched, the velocity is positive (points right), and just afterward, it is negative (points left). So the change in velocity and the acceleration are both negative. (*b*) It is greatest where the curvature of the $x(t)$ curve is greatest, when the spring is maximally stretched or compressed at the instants represented in Figure 15.2*a*, Figure 15.2*e*, and Figure 15.2*i*. It is smallest (zero) when the cart is at the equilibrium position at the instants represented in Figure 15.2*c* and 15.2*g*.

15.3 (*a*) *a*: tangential component of gravitational force, *b*: vertical component of elastic force in ruler, *c*: tangential component of gravitational force, *d*: vertical component of elastic force in string. (*b*) Gravitational potential energy in *a* and *c*, elastic potential energy in *b* and *d*.

15.4 (*a*) Factor of 4. From Chapter 9 you know that the potential energy of a spring is proportional to the square of the displacement from the equilibrium position. So, if the spring is compressed twice as much, the initial potential energy is four times as much. The initial kinetic energy is zero, so the energy is four times greater. (*b*) The initial compression determines the amplitude, and so the energy in the oscillator is proportional to the square of the amplitude.

15.5 (*a*) Upward, see Figure S15.5. (*b*) Downward. The two shaded regions in Figure S15.5 indicate that the shadow moves over increasingly smaller distances Δx during a given time interval Δt until it reaches the top. In other words, the shadow slows down. This means that the direction of the acceleration vector is opposite to that of the velocity vector.

Figure S15.5

15.6 (*a*) A pure sinusoidal function requires just a single term in the Fourier series, so the spectrum consists of a single peak at frequency $f = 1/T$. The peak height A is the square of the amplitude of the function. (*b*) As T increases, $f = 1/T$ decreases, and the single peak in the spectrum shifts to a lower frequency.

15.7 (*a*) At $x = x_0$ and for large x, $\Sigma F_x = 0$, and so these are equilibrium positions. Only the position at x_0 is a stable equilibrium position. (At very large x, the equilibrium is unstable because the object will tend to accelerate in the negative x direction.) (*b*) The shape of the curve tells you that the magnitude of the restoring force is greater for a negative displacement from x_0 than for a equal positive displacement.

15.8 If you did not set your calculator to work with radians before getting the five values, you might have concluded that the small-angle approximation $\sin\theta \approx \theta$ is not correct! Because radians measure ratios of arc lengths and radii (see Section 11.4), $\sin\theta \approx \theta$ applies only if θ is expressed in radians. Thus your first step is to convert each angle from degrees to radians, and then (with your calculator set at "rad") get the sine values. As Table S15.8 shows, the approximation is correct to better than 1% up to rotational positions corresponding to polar angles of 10°.

Table S15.8 Small-angle approximation

polar angle θ in degrees	polar angle θ in radians	$\sin\theta$	error (%)
1	0.0174533	0.0174524	0.0051
5	0.0872665	0.0871557	0.1270
10	0.1745329	0.1736482	0.5095
20	0.3490659	0.3420201	2.0600

15.9 (*a*) If the length of the pendulum is increased, the displacement of the pendulum bob for a given angle increases, but the restoring force remains the same. So the restoring force for a given displacement is smaller and thus the period is longer (for a mathematical proof see Example 15.6). (*b*) The smaller acceleration of gravity on the Moon decreases the restoring force exerted on the pendulum, and so the period is increased. (*c*) Neither the mass nor the spring constant is affected by the smaller gravitational attraction on the Moon, and so the object's period is the same on the Moon and on Earth.

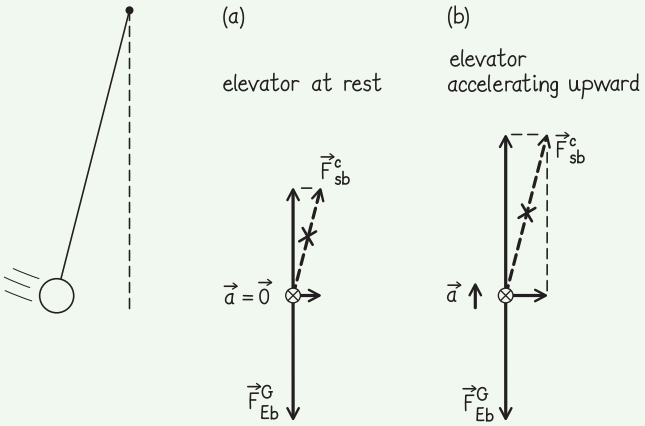
15.10 (*a*) x positive, v_x positive, a_x negative. (*b*) x negative, v_x negative, a_x positive.

15.11 (*a*) Substituting the maximum displacement $x = A$ into Eq. 15.15, you get $U = \frac{1}{2}m\omega^2A^2$. (*b*) Yes. At maximum displacement, $K = 0$ and $E = U$.

15.12 (*a*) Yes. The velocity is given by the derivative of Eq. 15.6, as Eq. 15.7 shows. Because $\phi_i = \pi/2$, at $t = 0$, $v_x \propto \cos\pi/2 = 0$. (*b*) No. In Figure 15.26, for example, the cart moves to the left (negative x component of the velocity) even after crossing the position $x = 0$. Only after reaching $x = -A$ does the cart turn around and the x component of the velocity become positive.

15.13 (*a*) Because cart 2 remains in place after the first collision, the carts collide again when cart 1 returns to its initial position at $x = -15$ mm. Because the sine function is symmetrical about the maximum, this occurs after a time interval twice as long as that required to reach maximum compression. So $t = 2(0.17\text{ s}) = 0.34$ s. (*b*) Immediately after the second collision, cart 1 has zero velocity and then begins a new oscillation with an amplitude of 15 mm. Cart 2 moves away to the right at a constant speed of 0.10 m/s.

15.14 If the block is lifted above x_{eq}, Eq. 2 remains valid—the only difference now is that $x - x_{eq}$ is negative because x is on the other side of x_{eq}. The vector sum of the forces is then positive, reflecting the fact that the restoring force is now downward.



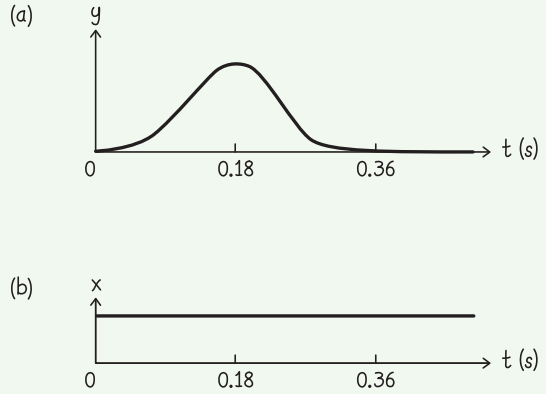
15.15 Decreasing the radius of the disk reduces its rotational inertia (which means it rotates more easily). Decreasing I increases ω (Eq. 15.29), and hence f increases (Eq. 15.4).

15.16 No. The oscillating rod experiment determines the acceleration due to gravity g, not G. The two are related (Eq. 13.4, $g = Gm_E/R_E^2$), but the relationship contains Earth's mass, which must be determined independently. [As you may remember, Earth's mass is determined from G, which is measured in the Cavendish experiment (see Section 13.5), not the other way around, see Example 13.3.]

15.17 Greater. The upward acceleration effectively increases g, which means that an object in your hand feels heavier. If g increases, the frequency of the pendulum increases too (see Example 15.6). An alternative way to see that f increases is to look at the free-body diagrams for the pendulum bob in an elevator at rest (Figure S15.17*a*, next page) and in an elevator that is accelerating upward (Figure S15.17*b*). For the elevator at rest (or moving at constant velocity), the upward

vertical component of the tensile force exerted by the string on the bob and the downward force of gravity add approximately to zero (ignoring the small vertical acceleration due to the pendulum motion). When the elevator accelerates upward, the tensile force exerted by the string on the bob must increase so that the vertical component of $\vec{F}^{c}_{sb}$ becomes greater than the gravitational force. This causes the pendulum bob to accelerate along with the elevator. If $\vec{F}^{c}_{sb}$ becomes greater, however, the horizontal component also increases, and so the restoring force for a given displacement increases, which increases f.

Figure S15.17

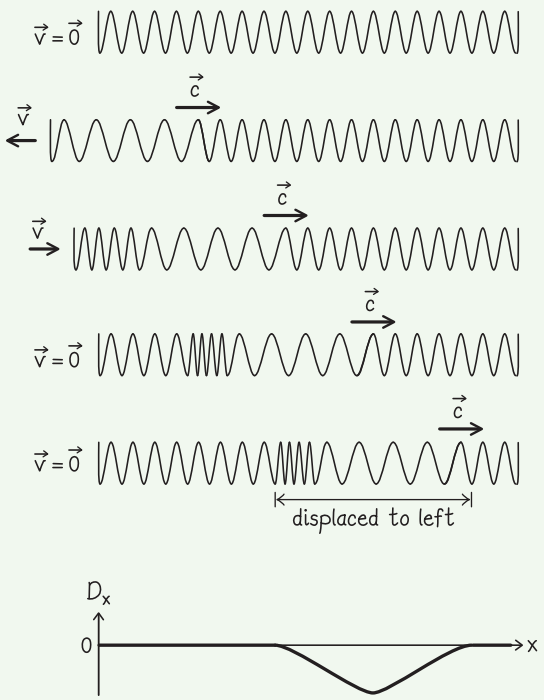


15.18 (*a*) The time-varying amplitude is given by $x_{max} = Ae^{-t/2\tau}$, where A is the initial amplitude. If the amplitude decreases by a factor of 3, $x_{max}/A = 1/3$, so $e^{-(4.0\text{ s})/2\tau} = 1/3$. Taking the natural logarithm (see Appendix B) of both sides, you get $-(4.0\text{ s})/2\tau = \ln(1/3) = -1.1$ and $\tau = (-2.0\text{ s})/(-1.1) = 1.8$ s. (*b*) $Q = \omega t = 2\pi f\,\tau = 2\pi(262\text{ Hz}) \cdot (1.8\text{ s}) = 3.0 \times 10^3$.

Chapter 16

16.1 (*a*) See Figure S16.1. (*b*) The x component of the bead's velocity is always zero because the bead moves in only the y direction. The y component of the bead's velocity is positive on the leading edge of the pulse and negative on the trailing edge.

Figure S16.1



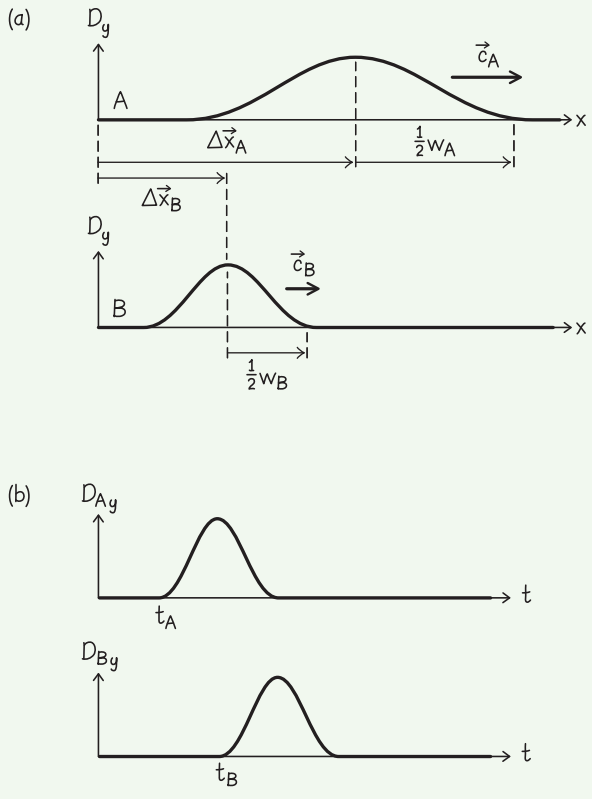
16.2 (*a*) Yes. Using a ruler, you can verify that the displacement of the pulse from one frame to the next is constant. (*b*) Between $t = 0$ and $t = 0.36$ s, the peak of the pulse moves over 16 beads, which corresponds to a displacement $\Delta x = (15)(5.0\text{ mm}) = 75$ mm, and so the wave speed is $c = (75\text{ mm})/(0.36\text{ s}) = 0.21$ m/s.

16.3 (*a*) 0.4 m. (*b*) 0.1 m. (*c*) 0. (*d*) Greater, because the pulse moves to the right and so the 1.5-m point on the string is about to be pulled upward.

16.4 (*a*) The point at $x = 0$ reaches its maximum height at $t = 0.50$ s; the point at $x = 1.0$ m reaches its maximum height at $t = 1.0$ s. So it takes the pulse 0.50 s to move 1.0 m. (*b*) $c = (1.0\text{ m})/(0.50\text{ s}) = 2.0$ m/s.

16.5 (*a*) Figure 16.16*b* plots the horizontal displacement of each coil on the spring from its *equilibrium* position. The coils between $x = 0.20$ m and $x = 0.40$ m are displaced from their equilibrium position and so $x = 0.30$ m is the midpoint of the pulse. The coil originally at $x = 0.30$ m is displaced 0.05 m to the right, as shown by the slanted line in Figure 16.6*a*. So, even though this coil appears at $x = 0.35$ m in Figure 16.6*a*, it really is at the midpoint of the pulse. (*b*) Yes, but the displacement is now negative. See Figure S16.5.

Figure S16.5



16.6 (*a*) At t_1, the free-body diagram for each bead to the right of bead 3 is identical to the one for bead 3. Because the accelerations of all these beads are zero, the forces exerted on each bead by its two neighboring beads are equal in magnitude and opposite in direction. In addition, you know that any two adjacent beads exert reciprocal forces on each other, and so at t_1 all the forces exerted on each other by the beads to the right of bead 3 must be equal in magnitude to F^{c}_{43} (5 N). To hold the right end of the string in place, some object must therefore be exerting a horizontal force of 5 N on that bead. (*b*) All beads move in only the vertical direction, and so their acceleration in the horizontal direction is always zero. You can thus use the same argument as in part *a* to show that the magnitudes of the horizontal components of all forces along the string are equal to 5 N. (*c*) The direction of the force exerted by the hand is tangent to

the direction of the string: up and to the left. (*d*) As you found in part *b*, the magnitude of the horizontal component is 5 N. Because the vertical component is nonzero, the magnitude of the force exerted by the hand must be greater than 5 N. (*e*) The horizontal component keeps the string taut; together with the force exerted by the wall at the right end, it provides the tension in the string. The vertical component accelerates the first bead vertically upward.

16.7 (*a*) The shape of the pulse does not change as it propagates along the string, and so each bead executes the same motion as the pulse passes through it. This means that each bead has velocity $\vec{v}_{\text{peak}}$ and acceleration $\vec{a}_{\text{peak}}$ when it is at its highest point, velocity $\vec{v}_{\text{half}}$ and acceleration $\vec{a}_{\text{half}}$ when it is halfway up to its highest point, and so on. Because the position of bead 4 at t_4 is the same as the position of bead 3 at t_3, $\vec{v}_4(t_4) = \vec{v}_3(t_3)$ and $\vec{a}_4(t_4) = \vec{a}_3(t_3)$. (*b*) They are the same. For each string, the motion of each point along the string is identical to the motion of the end you moved (provided the pulse doesn't change shape as it travels along the string). Because the end of A and the end of B move in identical fashion, all particles of *both* strings execute the same motion and so have equal velocities at equal displacements. (*c*) See Figure S16.7*a*. When the pulse on B has a displacement of $\Delta\vec{x}_{\text{B}}$, the displacement $\Delta\vec{x}_{\text{A}}$ of the pulse on A is twice as large because of the greater wave speed on string A. In addition—make sure you have not overlooked this—the pulse on A is twice as wide, for this reason: If, during the time interval it took your hand to move from initial position to maximum displacement, the pulse on A advanced a distance $\frac{1}{2}w_{\text{A}}$ (half the *width* of the pulse), then the pulse on B advanced only half as much: $\frac{1}{2}w_{\text{B}} = \frac{1}{2}\left(\frac{1}{2}w_{\text{A}}\right)$. (*d*) See Figure S16.7*b*. Each point carries out the same motion, taking the same amount of time to go up and then back down, and so the curves have the same shape. Because the pulse on B travels more slowly, the particle of B executes its motion at an instant t_{B} that is later than the instant t_{A} at which the particle of A executes its motion.

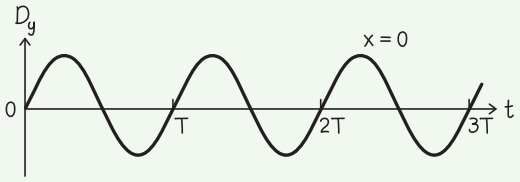


Figure S16.7

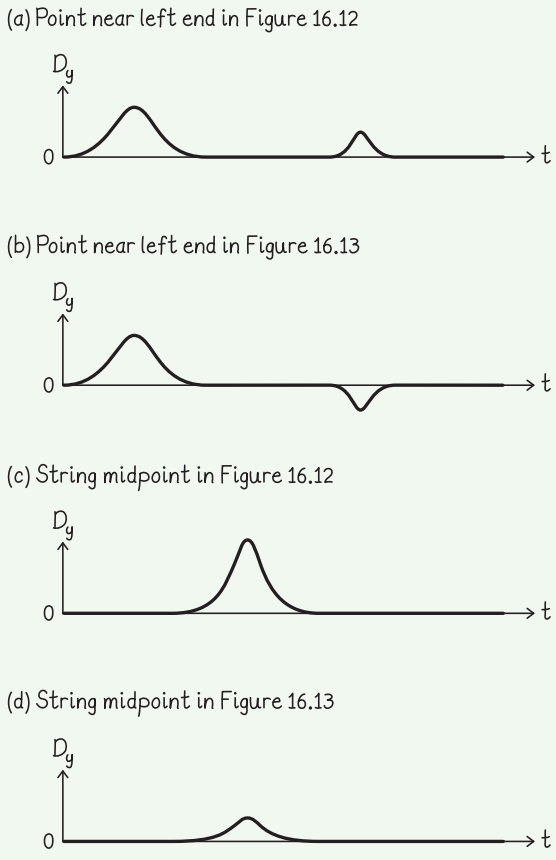
16.8 Because the tension in A is greater than that in B, the pulse travels faster on A than on B. This is the same as in Checkpoint 16.7, and so the sketches are the same. (*a*) See Figure S16.7*a*. (*b*) See Figure S16.7*b*.

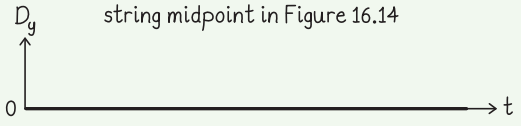
16.9 See Figure S16.9. From the motion of the hand in Figure 16.9, you see that the end of the string first moved up, then down, and so on. Similarities: Your graph and the snapshot of the wave have identical shapes. Differences: In Figure S16.9, the beginning of the wave motion is on the left at $t = 0$; in the snapshots in Figure 16.9, however, the leading edge of the wave is on the right. So, in addition to your curve having a different scale, it is a mirror image of the wave of Figure 16.9.

Figure S16.9



16.10 (*a*) Source: All particles of the string follow the motion of the source. (*b*) Properties of the string. (*c*) Both: The wavelength is determined by the wave speed and the period (see Figure 16.9). The wave speed is determined by the properties of the string, and the period is determined by the source. (*d*) Source: Because each string particle executes the same up-and-down motion as the source, the maximum speed is determined by the source.

16.11 Yes. Imagine putting some object in the path of the pulse. When the pulse displaces the string so that the string hits the object, the object is set in motion, and so the string has transferred momentum to the object.



16.12 (*a*) No. To see why, assume for simplicity that the pulses overlap at the midpoint of each string. In Figure 16.12, the maximum displacement at points away from the midpoint where the two pulses overlap is the peak displacement of the larger pulse. In the region of overlap near the midpoint, however, the maximum displacement is greater. In Figure 16.13, the maximum displacement at every point except where the pulses overlap is again the peak displacement of the larger pulse, but the maximum displacement at the midpoint is smaller than this. (*b*) See Figure S16.12*a* and *b* on the next page. In Figure S16.12*a*, the left peak shows how the point near the string's left end is displaced (just after $t = 0$) as the right-moving pulse in Figure 16.12 passes through the point. The right peak shows how, at some later instant, this same point is displaced by the left-moving pulse in Figure 16.12. Figure S16.12*b* shows the same thing for the two pulses in Figure 16.13. (*c*) See Figure S16.12*c* and *d*. Assuming, as in part *a*, that the two pulses overlap at the string midpoint, the Figure S16.12*c* peak is the algebraic sum of the two peaks in Figure 16.12, and the Figure S16.12*d* peak is the algebraic sum of the two peaks in Figure 16.13. (*d*) Comparing Figure S16.12*a* and *c* tells you that a point near the string's left end is displaced twice but the midpoint is displaced only once, justifying the answer no for Figure 16.12. Comparing Figure S16.12*b* and *d* tells you the same thing for Figure 16.13.

Figure S16.12

16.13 (*a*) See Figure S16.13. At the midpoint, the two pulses always cause displacements of equal magnitude in opposite directions. (*b*) The velocity of a point along the string is equal to the derivative of the displacement of that point with respect to time. If the displacement is in the *y* direction, the *y* component of the velocity is $v_y = dD_y/dt$. Because the displacement is the sum of the individual displacements, the velocity is the sum of the individual velocities.

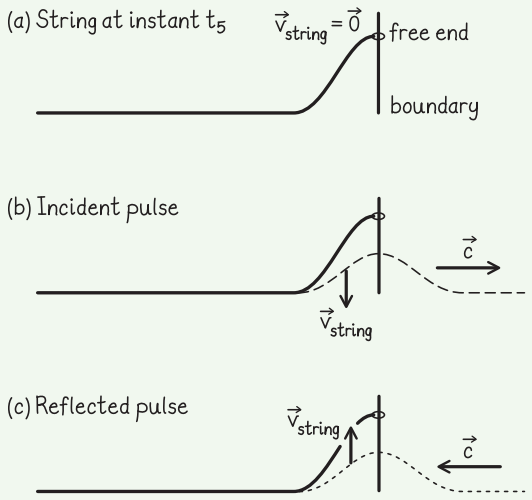


Figure S16.13

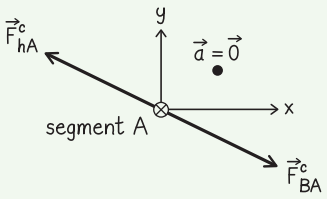
16.14 Because the string is straight, its elastic potential energy is zero, which means all the energy is kinetic energy. As Figure 16.16 shows, the pulse is in the process of inverting itself and, although the string is straight, every particle within the wave pulse is in motion.

16.15 (*a*) To see what happens, we construct the pulse shape by the superposition of the incident pulse and an imagined noninverted reflected pulse (Figure S16.15). At t_5 the peaks of both pulses have just reached the free end, and the leading edge of the reflected pulse overlaps the trailing end of the incident pulse. The velocities of particles of the leading edge of the reflected pulse are upward and those on the trailing edge of the incident pulse are downward, so the velocities of particles of the combined pulse are zero (see Checkpoint 16.13). The kinetic energy is zero. (*b*) Let the original pulse have elastic potential energy *U*; then $K = U$ (see Section 16.3) and $E = 2U$. If the string obeys Hooke's law, the potential energy is proportional to the square of the displacement. At t_5, when the displacement at the free end is equal to the sum of the amplitudes of the two pulses (that is, twice as great), the potential energy is four times as great. However, at t_5 the pulse is only half its original width, and so the potential energy is $2U$. (*c*) Yes, $E_1 = E_5 = 2U$.

Figure S16.15

16.16 (*a*) With $\mu_2 = 0$, the boundary becomes a free end, and so the reflected pulse has the same amplitude as the incident pulse and nothing is transmitted to string 2. (*b*) With $\mu_2 = \infty$, the boundary becomes fixed. Again the (inverted) reflected pulse has the same amplitude as the incident pulse and nothing is transmitted to string 2. (*c*) When $\mu_2 = \mu_1$, the strings become one: There is no boundary and so no reflection. The pulse travels unchanged from string 1 to string 2. (*d*) Because the wave speed is greater in string 2, the transmitted pulse is spread out more than the incident pulse (see Section 16.2).

16.17 (*a*) All but (*iii*), which cannot represent a traveling wave because the exponential factor e^{-x} is not a function of $(x \pm ct)$. (*b*) All three, by substituting $(x \pm ct)$ for each x.



16.18 (*a*) At $t = 0$, the string has zero velocity and so $K = 0$ and all the energy is stored as elastic potential energy. At $t = \frac{1}{8}T$, the string is moving vertically and is not in the equilibrium position, so the energy is distributed between kinetic and elastic potential. At $t = \frac{1}{4}T$, the string is horizontal, so $U = 0$. All the energy is kinetic. (*b*) Yes. Each particle of the string executes simple harmonic motion about its equilibrium position (but different points have different amplitudes—zero at the nodes, maximum at the antinodes). Because the energy of

a simple harmonic oscillator is constant, the energy of any particle or any length of string is also constant. (*c*) No. The amount of energy f_1 carries rightward is equal to the amount f_2 carries leftward, so the combined flow of energy is zero.

16.19 (*a*) No. Suppose one amplitude is twice as large as the other. Half of the large-amplitude wave forms a standing wave with the other wave, but the remaining half remains a traveling wave. The superposition of a standing and a traveling wave is not a standing wave. (*b*) No. Because the wavelengths are not the same, the interference at any position is constructive at some instants and destructive at other instants, unlike the interference illustrated in Figure 16.37, which for a given position is the same at all instants.

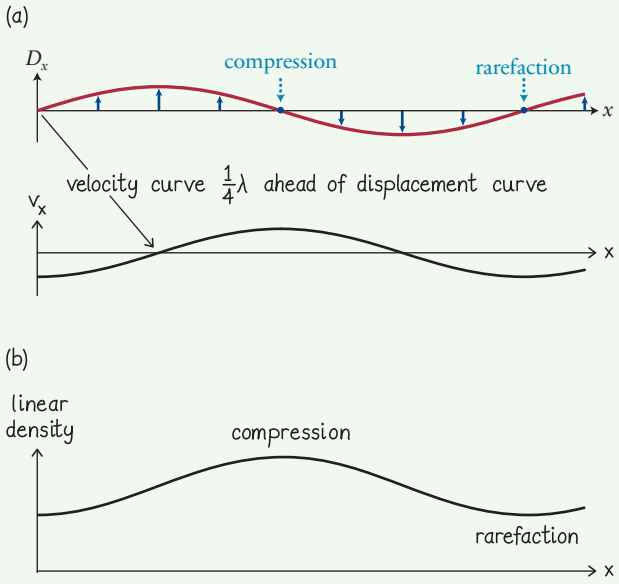
16.20 (*a*) See Figure S16.20. Two contact forces act on A: F^c_{hA} and F^c_{BA}. If the gravitational force exerted on A is much smaller than these contact forces, we can ignore it: $\Sigma F_A = 0$. (*b*) The momentum does not change, which makes sense because A moves upward at constant velocity $\vec{v}$. (*c*) Yes, because the scalar product of the force and the force displacement is nonzero and positive: $dW = \vec{F} \cdot d\vec{r}_F$. (*d*) The energy increases because an increasing amount of string moves upward at velocity $\vec{v}$.

Figure S16.20

16.21 Greater (twice as great to be precise) because *two* waves travel away from the point you are shaking, one in each direction along the string. Another way to see this is by looking at the force you must exert to move the string. For a point in the middle, this force is twice as great as the force you must exert on an end because the pieces of string on either side of your hand each exert the same force as one end of the string. So the amount of work you do on the string increases by a factor of 2.

16.22 The frequency f (and therefore the angular frequency ω) is determined by the source that causes the wave. The wave number k is equal to ω divided by the wave speed c, which is determined by the tension and linear mass density of the string.

Chapter 17



17.1 (*a*) Because the wave speed c is constant, $R_2 = 2R_1$. (*b*) The circumference at R_1 is $2\pi R_1$, making the energy per unit length $E/2\pi R_1$; at R_2 this becomes $E/2\pi R_2 = E/4\pi R_1$. (*c*) The energy varies as $1/r$ because the wavefront circumference increases with r.

17.2 By reducing the amplitude of the source as time passes so that it always matches the decrease in amplitude of the outward traveling wave. Consequently the amplitude of the wave in Figure 17.1, though uniform over *space*, is not constant in time; it uniformly decreases over the entire wave pattern.

17.3 (*a*) Increase. The greater the spring constant, the faster any disturbance is passed from one bead to the next. The effect is the same as when the tension in a string carrying a transverse wave is increased (see Section 16.2). (*b*) Decrease. The greater mass slows down the transmission of the wave just as it does for a transverse pulse on a string of beads.

17.4 (*a*) Just as for a transverse wave, the x component of the velocity of each bead is dD_x/dt. If D_x is a sine function, the x component of the velocity is a cosine function. This means that the velocity wave is always one-quarter wavelength ahead of the displacement wave, as shown in Figure S17.14*a*. (*b*) By comparing Figure 17.9*b* and Figure S17.4*a*, you can see that the linear density is greatest where the velocity is maximum and smallest where the velocity is minimum. Figure S17.4*b* shows a plot of the linear density versus position.

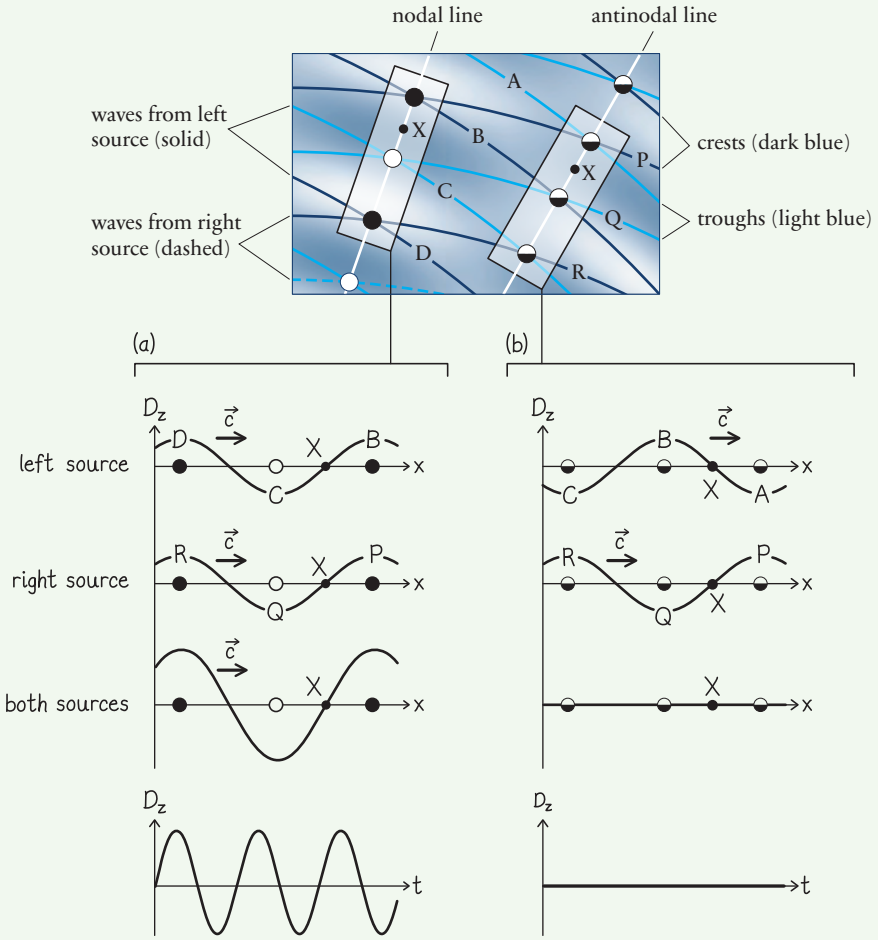


Figure S17.4

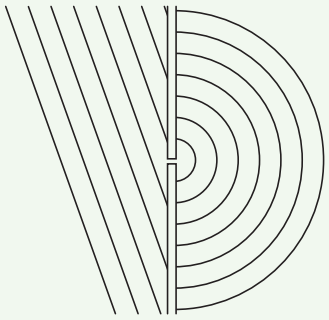
17.5 Spherical. The shape of the wavefront is determined by the distance traveled by the wavefront. Because the wave speed is the same in all directions, a given wavefront reaches the same distance from the loudspeaker in all directions. (The sound is louder in the front than in the back because of differences in the wave amplitude, which is greater in front because of the way speakers are designed.)

17.6 (*a*) Zero, because the displacement caused by each wavefront is zero. (*b*) The displacement at that point does not remain zero, however. A quarter period later, two crests (or troughs) meet at that point, and so the displacement at that point varies sinusoidally with an amplitude of 2*A* (Figure S17.6*a* on the next page). (*c*) Along the line that connects the half-filled circles, the waves generated by the two sources are 180° out of phase. Two equal-amplitude sine waves that are 180° out of phase cancel, and so the medium displacement is zero at *all* points along the nodal line, not just the ones marked with half-filled circles. (*d*) See Figure S17.6*b*.

Figure S17.6

17.7 No, because the displacement at this point doesn't remain zero. See Checkpoint 17.6.

17.8 (*a*) $A + A = 2A$ in Figure 17.16*a*; A in Figure 17.16*b*. (*b*) Increase, for two reasons: There is now twice as much energy (two sources), and instead of radiating outward uniformly, the wave energy travels in only certain directions (between nodal lines). (*c*) $E \propto A^2$, and so the energy that passes P increases by a factor of 4. The energy delivered by the sources increases by a factor of 2, while the area over which the energy is spread out is reduced by a factor of 2 (there are just as many antinodal lines as there are nodal lines). These two effects multiply to produce a fourfold increase in the flow of energy at P.



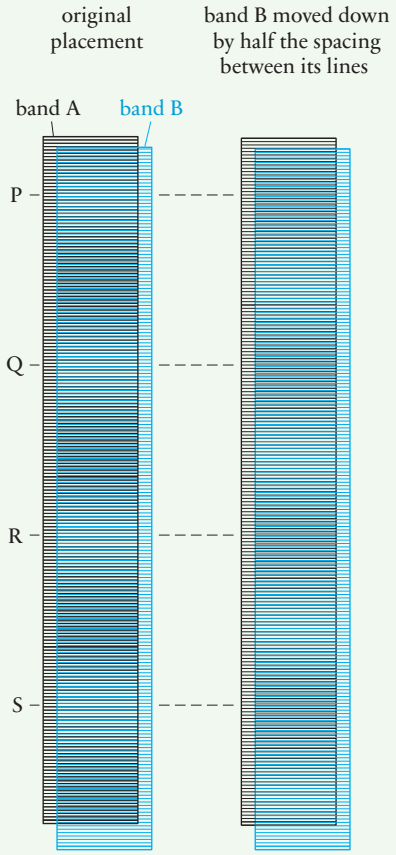
17.9 There are six nodal lines above the horizontal straight line through S_1 and S_2 (and six below also, of course). So $2(d/\lambda) = 6$, $d/\lambda = 3$, $d = 3\lambda$; the distance between the sources is three wavelengths.

17.10 Because along this line, the two waves travel in the same direction and are in phase, which means they reinforce each other everywhere.

17.11 It does not change. Except for a little spreading at the edges, the wavefronts remain straight and parallel. What reaches a 10λ-wide line segment parallel to the row of sources at a distance R also reaches a similar segment at a distance $2R$.

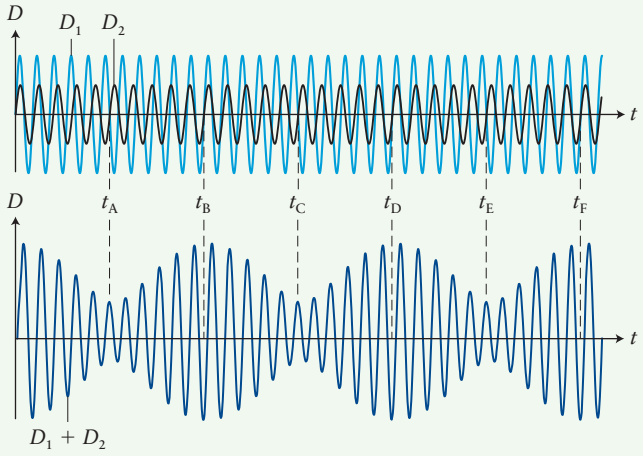
17.12 See Figure S17.12. A narrow gap causes diffraction regardless of the orientation of the incident wavefronts because the incident waves cause the gap to become a point source. (For simplicity the reflections of the planar wavefronts from the back surface of the barrier have been omitted from the drawing.)

Figure S17.12



17.13 10 dB corresponds to 1 bel or one order of magnitude (because log 10 = 1). So the intensity must be increased by a factor of 10, which means that ten clarinets must play at the same time.

17.14 (*a*) Three. The A and B lines fall exactly on top of each other at P, but as you move down they get out of step until you reach Q, where they match again. So each band has a whole number of lines between P and Q, but A has one more line. (If they had the same number of lines, each A line would fall on top of a B line. If A had more than one extra line between P and Q, the lines of A would catch up with those of B before Q.) Between Q and S the bands line up twice more, so band A has three additional lines between P and S. (*b*) Points P, Q, R, and S become dark (because the lines of the two



patterns now fall right between each other), while the dark bands turn bright (because the lines now line up; Figure S17.14). Note that the moiré pattern moves down a considerable distance (half the distance between P and Q) even though B moved down only half a line spacing. This effect can be used to measure small displacements.

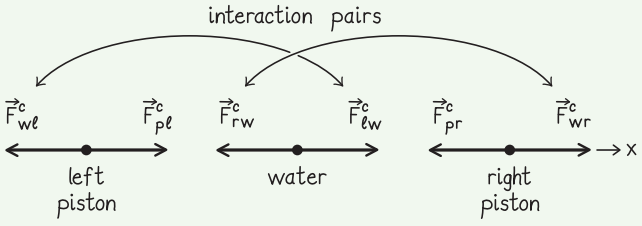
Figure S17.14

17.15 Yes, but the beats are less pronounced than when the two amplitudes are equal. Let one wave have amplitude A and the other amplitude $2A$. The first wave produces beats with half of the second wave. The other half adds to the beat pattern, resulting in an oscillating wave with a varying amplitude (Figure S17.15), but the amplitude never goes all the way to zero.

Figure S17.15

17.16 Equation 1 in Example 17.8 gives $f_s = f_1(c - v)/c$. Substituting the values for f_1, c, and v yields $f_s = 441$ Hz.

17.17 (*a*) With $v_o = \frac{1}{2}c$ and $v_s = 0$, Eq. 17.20 yields $f_o = \left[\left(c + \frac{1}{2}c\right)/(c - 0)\right]f_s = \frac{3}{2}f_s$. (*b*) With $v_o = 0$ and $v_s = \frac{1}{2}c$, $f_o = \left[(c - 0)/\left(c - \frac{1}{2}c\right)\right]f_s = 2\,f_s$. (*c*) The answers are different because there is a physical difference in the two situations. When the source moves, the wavefronts bunch up or spread out, changing the wavelength. When the observer moves, the wavelength, which is fixed by the wave speed in the stationary medium, does not change. Instead, the moving observer intercepts a different number of wavefronts per unit time. So it is not just the relative motion of source and observer that matters; the fact that their speeds are measured relative to the medium that transmits the wave also matters.



17.18 No. Shock waves are due to the piling up of wavefronts. When the source is stationary and the observer moves, the wavelength is unchanged. Setting $v_o = 2c$ with $v_s = 0$ in Eq. 17.20 yields $f_o = 3f_s$. This reflects the fact that the moving observer intercepts three times as many wavefronts per unit time as an observer at rest.

17.19 The cone angle is about 35°, and sin 35° = 0.57. From Eq. 17.22, you have $c/v_s = 0.57$, $v_s = 1.7c \approx 600$ m/s.

Chapter 18

18.1 (*a*) If the water is to remain at rest, the vector sum of the forces exerted on it must be zero. Because you initially exert a rightward 10-N force on the left piston, you must also exert a leftward 10-N force on the right piston. (*b*) Figure S18.1 shows free-body diagrams for the two pistons and the water. Because of the two interaction pairs marked in the figure, all six forces are equal in magnitude, so $\vec{F}^{c}_{pl} = \vec{F}^{c}_{wr}$. In other words, the force you exert on the left piston is transmitted by the water to the right piston.

Figure S18.1

18.2 (*a*) Yes. The water is at rest, which means the downward force of gravity exerted on it must be balanced by an upward contact force exerted by the bottom of the cup. That the bottom exerts a force on the water tells you that the water must exert a force on the bottom. (*b*) Yes. If the sides of the cup were to disappear, the water would move radially outward. That the water remains in the cup tells you that the sides must exert a force on the water, and consequently the water must exert a force of equal magnitude on the cup in the opposite direction. (*c*) Positive. Because the water pushes outward on the surfaces of the cup, the surfaces must push inward on the water, putting it under compression. By definition, compression means positive pressure.

18.3 If you divide the liquid into three equal layers, each layer is subject to an identical force of gravity. The bottom layer supports the upper two, the middle layer supports only the top one, and the top one supports no other layer. If you make the division even finer, you can see that the pressure decreases linearly with height.

18.4 10 m. The pressure at the surface is 1.0×10^5 N/m^2, and that pressure doubles when the force of gravity exerted on a column of water of height h and cross-sectional area $A = 1$ m^2 has magnitude $F^G = mg = 1.0 \times 10^5$ N. The volume of this column is $V = hA$, its mass is $m = \rho_{\text{water}} V = \rho_{\text{water}}\, hA$, and the magnitude of the force of gravity exerted on it is $mg = \rho_{\text{water}}\, hAg$. Thus $h = mg/(\rho_{\text{water}}\, Ag) = (1.0 \times 10^5 \text{ N})/[(1.0 \times 10^3 \text{ kg/m}^3)(1 \text{ m}^2)(9.8 \text{ m/s}^2)] = 10$ m.

18.5 (*a*) Nothing. Because the pressure in a liquid at rest decreases linearly with height, the pressure difference between the top and bottom of the brick is the same at every water depth. (*b*) Nothing. Pascal's principle tells you that a pressure change applied to a liquid is transmitted undiminished to every part of the liquid. So, increasing the pressure at the water surface increases the pressure at the top and at the bottom of the brick by the same amount, leaving the difference unchanged. (*c*) There is no effect because this pressure at the sides causes equal forces in opposite directions. (*d*) Yes, because the pressure in the atmosphere also decreases with height, although much less than in water. This force is upward.

18.6 The magnitude of the buoyant force exerted on the brick by the water is equal to the magnitude of the force of gravity exerted by Earth on the water displaced by the brick. Because the density of the brick is greater than the density of the water, the mass of the brick must be greater than the mass of the displaced water. Therefore the magnitude $m_{\text{brick}}\, g$ of the force of gravity on the brick is greater than the magnitude $m_{\text{water}}\, g$ of the force of gravity on the displaced water. The magnitude of the upward buoyant force exerted by the water on the brick is thus smaller than the magnitude of the downward force of gravity exerted on it, and so the brick sinks.

18.7 Equal. Because the pan-rock combination floats in both cases, the buoyant force exerted in both cases must be equal to the force of gravity exerted on the displaced water. You also know that the upward buoyant force on the combination must be equal to the downward force of gravity on the combination because the combination remains at rest. The mass of the pan-rock combination doesn't change when the rock is suspended (you can ignore the mass of the string), so the volume of water displaced doesn't change.

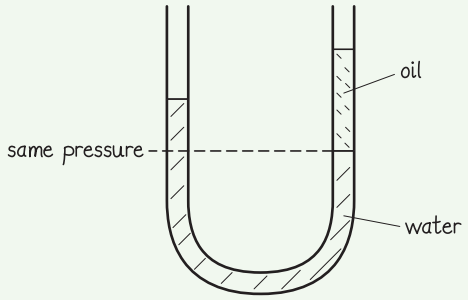
18.8 The same. The principle of relativity tells you that the laws of the universe are the same in all inertial reference frames. So, if you view the motion of an object moving at constant velocity through a stationary fluid from the reference frame of the object, you obtain the same situation—a laminar flow of fluid past a stationary object—as in Figure 18.18*a*.

18.9 As you can see in Figure 18.15, streamlines that pass over the roof of the car get closer together, indicating a higher flow speed and therefore lower pressure just above the roof. The air pressure inside the car, however, is unchanged and therefore greater than that outside, making the cloth roof bulge outward.

18.10 According to Pascal's principle, the pressure in the air in the balloon must be the same everywhere.

18.11 (*a*) Zero. The tensile forces due to surface tension are in the plane of the surface and therefore unable to compensate for any pressure difference across the surface when the surface is level. (*b*) Greater. The vector sum of the tensile forces exerted on a segment of the surface points toward the center of the drop. (*c*) It is higher. According to Laplace's law, the smaller radius of curvature of the small drop causes a greater pressure difference across the surface. Because both drops are surrounded by air at atmospheric pressure, the pressure must be greater inside the small drop.

18.12 Because the cylinder has a radius of curvature larger than that of the needle, the upward force exerted by the curved liquid surface on the cylinder is smaller than the upward force exerted on the needle. This smaller upward force is unable to support the (greater) downward force exerted by the cylinder on the surface.



18.13 The magnitude of the force exerted by the air on the cover is $F^c_{\text{ac}} = P_{\text{atm}} A = (101 \text{ kPa})(1000 \text{ Pa}/1 \text{ kPa})(0.28 \text{ m})(0.22 \text{ m}) = 6.2 \times 10^3$ N. The force of gravity exerted on the book is $F^G_{\text{Eb}} = (3.0 \text{ kg})(9.8 \text{ m/s}^2) = 29$ N. The force exerted by the atmosphere on the cover is more than 200 times greater than the gravitational force exerted by Earth on the book.

18.14 As the suction cup hits the ceiling, the bowl of the cup collapses, forcing out the air that was initially in the bowl. Consequently, the pressure in the space between the cup and the ceiling is lower than atmospheric pressure. As long as the seal between the cup edge and the ceiling is maintained, the air in the room underneath the cup exerts an upward force greater than the downward force exerted by the air inside the cup that holds the dart up against the ceiling.

18.15 That the object floats tells you that the buoyant force exerted on it must equal the force of gravity exerted on it, and so equating Eqs. 18.11 and 18.12 gives you $\rho_{\text{o,av}} V_{\text{o}} g = \rho_{\text{water}} V_{\text{disp}} g$. You are given that $V_{\text{disp}} = 0.80 V_{\text{o}}$, and so $\rho_{\text{o,av}} = (\rho_{\text{water}} V_{\text{disp}})/V_{\text{o}} = 0.80 \rho_{\text{water}}$ (see Example 18.2).

18.16 No. The pressure at the oil-water interface in the right leg must be the same as the pressure at a point that is at the same height in the left leg (Figure S18.16). Because the mass density of oil is smaller than that of water, the height of a column of oil required to cause a certain pressure difference is greater than the height of a column of water required to cause the same pressure difference. Therefore the top of the oil column must be higher than the top of the water column.

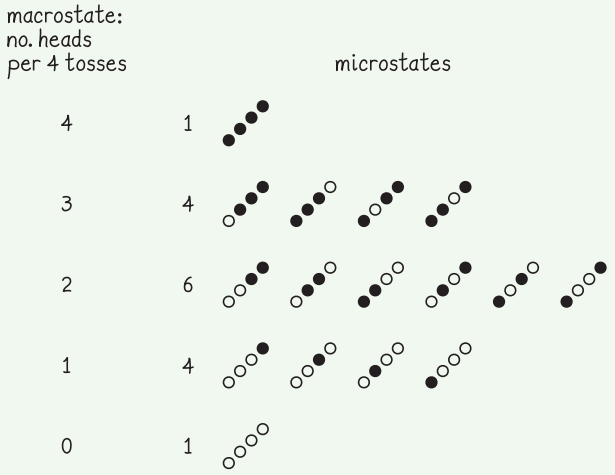
Figure S18.16

18.17 Because the atmosphere exerts a force on both pistons, it increases the pressure below them. When you add the effect of atmospheric pressure, the pressure in the liquid at the small piston is $P_1 = P_{\text{atm}} + F_1/A_1$ and the pressure at the large piston is $P_2 = P_{\text{atm}} + F_2/A_2$. Ignoring the term $\rho g h$ in Eq. 18.19 again, you have $P_1 \approx P_2$, and so $P_{\text{atm}} + F_1/A_1 = P_{\text{atm}} + F_2/A_2$. The atmospheric pressure cancels out, and you obtain the same result as in Eq. 18.21.

18.18 The continuity equation for an incompressible fluid (which means $\rho_1 = \rho_2$) gives $A_1 v_1 = A_2 v_2$ or $v_1 = v_2 A_2/A_1 = v_2 R_2^2/R_1^2$. Squaring all terms, subtracting v_2^2 from both sides, and dividing through by -1 gives you $v_2^2 - v_1^2 = v_2^2(1 - R_2^4/R_1^4)$. With $R_1 = \frac{1}{2}(0.50 \text{ m})$ and $R_2 = \frac{1}{2}(10.0 \text{ mm})$, you have $(R_2/R_1)^4 = 1.6 \times 10^{-7}$, which is so small that you can ignore this term to get the result $v_2^2 - v_1^2 = v_2^2(1 - R_2^4/R_1^4) \approx v_2^2$. Thus the assumption that $v_1 \approx 0$ in Example 18.9 is excellent, and you can use the result in that example: $v_2 = \sqrt{2gd} = 2.4$ m/s.

18.19 A soap bubble consists of a thin film of soap solution surrounding a volume of air. Because the film has two surfaces, the force due to surface tension gains an additional factor 2. Thus Eq. 18.51 becomes $P_{\text{in}} - P_{\text{out}} = 4\gamma/R$.

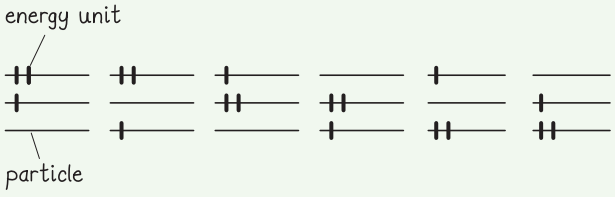
Chapter 19



19.1 (*a*) Collisions with the leading edge of the pendulum slow it down, and collisions with the trailing edge speed it up. Because of the motion of the pendulum, nitrogen molecules that collide with the leading edge move faster relative to the pendulum than nitrogen molecules that collide with the trailing edge. Therefore there are more collisions with the leading edge than with the trailing edge, and the pendulum slows down. (*b*) When the pendulum is at rest, the average speed of the nitrogen molecules that hit the left edge is the same as the average speed of the molecules that hit the right edge, which means that the momentum transfers due to the collisions tend to balance out.

19.2 Each segment of the zigzag path would decrease in length, so the Brownian motion would be less pronounced and the maximum displacement of the grain from the initial position would be smaller.

19.3 7.

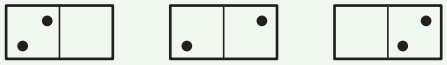


19.4 See Figure S19.4. (*a*) Five macrostates. (*b*) 16 basic states. (*c*) $4/16 = 1/4$. (*d*) The most likely macrostate is two heads because there are six basic states associated with this macrostate.

Figure S19.4

19.5 See Figure S19.5.

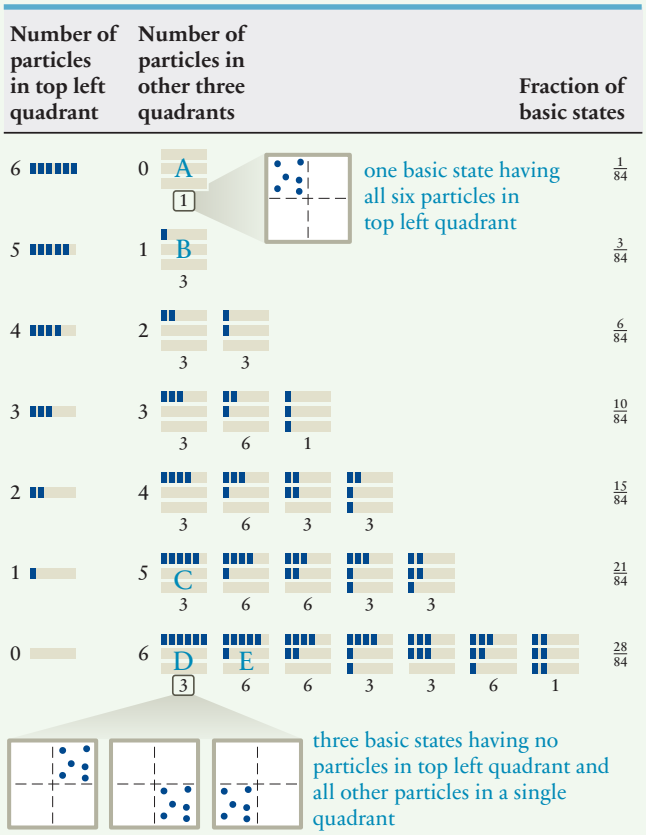
Figure S19.5



19.6 (*a*) $1/84$, which is around 1%. (*b*) $\frac{28}{84} + \frac{21}{84} = \frac{49}{84}$, which is more than 50%.

19.7 (*a*) The pendulum has more than 50% of the energy when it has four, five, or six units of energy . There are $6 + 3 + 1 = 10$ basic states associated with these macrostates. The probability that the pendulum has more than 50% of the energy is then $10/84 = 0.12$. (*b*) Figure 19.7 shows that as the number of particles increases, the relative probability of any given fraction of energy being in the pendulum decreases.

19.8 (*a*) The average kinetic energies are equal because the energy of the gas is equally distributed among all the particles. (*b*) Because the two particles have the same average kinetic energy, $\frac{1}{2} m_1 v_1^2 = \frac{1}{2} m_2 v_2^2$. Therefore $v_1 = (m_2/m_1)^{1/2} v_2 = 2^{1/2} v_2$. Particle 1 has a greater average speed by a factor of $2^{1/2}$.



19.9 There are three ways of placing the two indistinguishable particles in the two compartments (Figure S19.9). The probability of finding one particle in each side is $1/3$.

Figure S19.9

19.10 (*a*) Four basic states have all six particles in one compartment. They originate from different macrostates. Distribution A in Figure S19.10 has six particles in the top left compartment and is a macrostate. Distribution D is part of a different macrostate: no particles in the top left compartment. The three basic states in distribution D correspond to six particles in any of the other three compartments. There are 84 basic states, all equally probable, and so the probability of finding six particles in any compartment is $4/84 = 0.048$. (*b*) There are 12 basic states in which one compartment contains five particles: three for distribution B in Figure S19.10, three for distribution C, and six for distribution E. The probability of finding five particles in any compartment is thus $12/84 = 0.143$. Note that distribution E has six associated basic states, corresponding to the six ways one particle can be placed in one of three containers and five particles can be placed in another of the three containers.

Figure S19.10

19.11 The partition moves until the particles are uniformly distributed over the space enclosed by the two compartments. Because there are twice the number of particles in the left compartment, the partition moves to the right until the volume of the left compartment is twice the volume of the right compartment.

19.12 (*a*) All six energy units are initially in the pendulum, which means each collision moves one energy unit from the pendulum to one of the particles. The system then is in one of the three basic states depicted in the second of row of Figure 19.4. (*b*) Now there are three possibilities for how energy is transferred in any given collision: from the particle that initially has the one unit to either of the two other particles, from the particle that initially has the one unit to the pendulum, or from the pendulum to any one of the particles. When a unit is transferred from one particle to another, the amount of energy in the pendulum does not change, and so the macrostate does not change (that macrostate is represented in the second row in Figure 19.4). In a collision between the pendulum and a particle, the pendulum can either gain or lose a unit of energy, and so the system ends up in the macrostates represented by the top and third rows in Figure 19.4. So, after one collision the system can be in any one of the top three macrostates in Figure 19.4. (*c*) The number of basic states in the top three macrostates is $1 + 3 + 6 = 10$.

19.13 (*a*) There are three accessible macrostates: three units in pendulum, two units in pendulum, one unit in pendulum. (*b*) To find the probability for each macrostate, you need to consider the number of basic states representing each: 10, 15, and 21, respectively, for a total of 46. The probabilities are thus $10/46$, $15/46$, and $21/46$.

19.14 (*a*) There are 21 ways that two energy units can be distributed among the six particles. Label the particles 1 through 6. Place one energy unit in particle 1. The second energy unit can be placed in any of the six particles, resulting in six basic states. Now place one energy unit in particle 2. The second energy unit can be placed in the five particles 2 through 6 but not in particle 1 because we already counted that basic state. Repeat this process for particles 3 through 6. The number of basic states is then $6 + 5 + 4 + 3 + 2 + 1 = 21$.

19.15 (*a*) There are 14 particles in A, so the average energy per particle in A is $1/14 = 0.07$ energy unit. The average energy per particle in B is $9/6 = 1.5$ energy units. (*b*) At equilibrium there are seven energy units in A, corresponding to an average energy per particle of $7/14 = 0.5$ energy unit. The average energy per particle in B is $3/6 = 0.5$ energy unit.

19.16 (*a*) Over time the ice cube heats up and melts, and the water cools. Because the system irreversibly evolves toward equilibrium, Ω must be increasing. (*b*) Because everything—cup, tea, air—is in equilibrium, Ω is at its maximum value and not changing. (*c*) Over time the oil separates and floats to the top. Because this separation constitutes an irreversible process (the oil doesn't spontaneously mix back into the water), Ω must be increasing. (*d*) Germination is an irreversible process, so Ω is increasing. (*e*) As far as we know, the universe evolves irreversibly, so Ω is increasing.

19.17 (*a*) The compartment size decreasing by a factor of 10 means that $M = 1000$. The number of basic states is then $\Omega_f = M^N = 1000^{10} = 10^{30}$. The initial value is $\Omega_i = 10^{20}$ (see Example 19.8), so the change in the number of basic states is $10^{30} - 10^{20}$, which for all practical purposes is equal to 10^{30}. This represents an enormous increase in the number of basic states. (*b*) $\ln \Omega_f = \ln (10^{30}) = 69$. The initial value is $\ln \Omega_i = 46$ (see Example 19.8), so the change is $69 - 46 = 23$.

19.18 (*a*) According to Eq. 19.4, an increase in entropy means the number of basic states has increased. (*b*) For an expanding gas, $V_f > V_i$, and so the $N \ln (V_f/V_i)$ term in Eq. 19.8 is positive, as expected for a system evolving toward equilibrium. (*c*) If the gas were to contract into a subvolume, $V_f < V_i$, and so the $N \ln (V_f/V_i)$ term is negative, meaning a decrease in entropy. Such a decrease would violate the entropy law.

19.19 Even though entropy depends on volume, the entropy change depends on a ratio of volumes (Eq. 19.8). Because the volume of a compartment is a fraction of the volume V of the box, V cancels when we take the ratio of volumes for each compartment.

19.20 (*a*) Adding up the x components of the velocities and dividing by 5 gives an x component of the average velocity of 0. (*b*) Adding up the speeds (the absolute values of the x components of the velocities) and dividing by 5 gives an average speed of 2.6 m/s. (*c*) Adding up the squares of the speeds, dividing by 5, and then taking the square root gives an rms speed of 3.0 m/s. Note that the rms speed is not equal to the average speed of the atoms: in a gas, the former is typically about 10% greater than the latter.

19.21 Putting all the numerical factors in the third term of Eq. 19.29 together gives

$$\left[2a\left(\frac{2E_{th}}{mN}\right)^{1/2}\right]^3 = \left[\left(\frac{8a^2E_{th}}{mN}\right)^{1/2}\right]^3 = \left(\frac{8a^2}{mN}\right)^{3/2}(E_{th})^{3/2}.$$

19.22 (*a*) At thermal equilibrium there is equipartition of energy, and so, on average, the kinetic energy of all the atoms is the same. To the left of the dashed line, S_A is smaller and S_B is greater than at thermal equilibrium. According to Eq. 19.32, $E_{th,A}$ is therefore smaller than the equilibrium value and $E_{th,B}$ is greater than the equilibrium value. Consequently, to the left of the dashed line the average kinetic energy of the atoms in A is smaller than that in B. (*b*) At thermal equilibrium, both gases are equally hot. To the left of the dashed line gas B is hotter because the average kinetic energy of the atoms is greater. (*c*) At thermal equilibrium, $dS_A/dE_{th,A} = dS_B/dE_{th,B} = -dS_B/dE_{th,A}$ (Eq. 19.37). Figure 19.24 shows that the magnitude of the slope of curve S_A increases and the magnitude of the slope of curve S_B decreases when going left from the equilibrium point. Therefore, to the left of the equilibrium point $dS_A/dE_{th,A} > dS_B/dE_{th,B}$.

19.23 From Eq. 19.42 we have $E_{th,B}/E_{th,A} = N_B/N_A = 6/14 = 3/7$, and so 30% of the energy is in compartment B and 70% is in compartment A.

19.24 (*a*) Only the component of the momentum perpendicular to the wall changes. The atom's final momentum is away from the wall, and so the change in momentum is perpendicular to the wall and directed toward the interior of the container. (*b*) Because the system is isolated, the direction of the wall's change in momentum is opposite the direction of the atom's change in momentum. (*c*) As you saw in Section 8.7, the force exerted on an object is proportional to the object's change in momentum. The force exerted by the wall on the atom is therefore perpendicular to the wall and directed toward the interior of the container. The force exerted by the atom on the wall points in the opposite direction.

19.25 In deriving Eq. 19.20 we assumed that the system is in thermal equilibrium (see the beginning of Section 19.5), and so $T_A = T_B$. Multiplying the left and right sides of Eq. 19.20 by $k_B T_A$ gives $N_A k_B T_A/V_A = N_B k_B T_B/V_B$, or using the ideal gas law, $P_A = P_B$. In equilibrium, the pressure is the same on both sides of the partition, as we would expect.

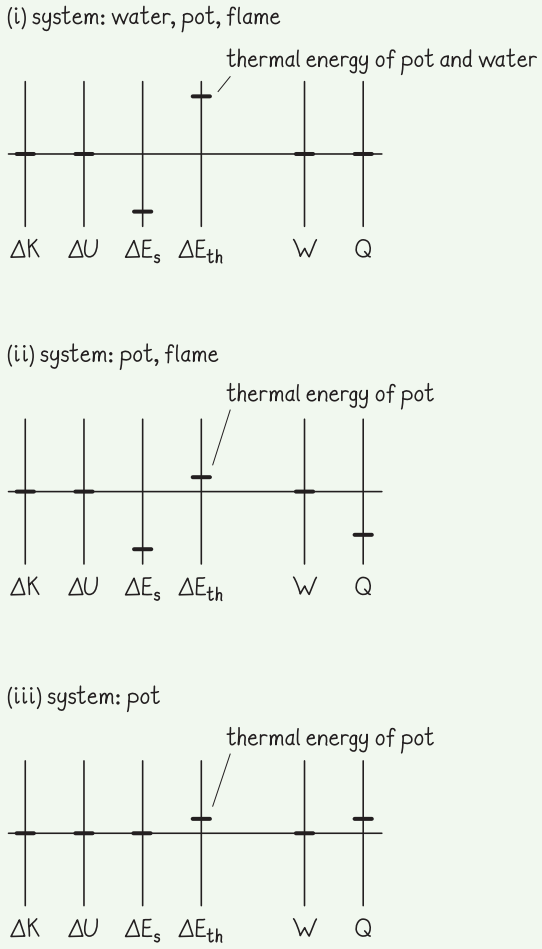
19.26 (*a*) Neither. Because the pressures and volumes are equal, the thermal energies of the two gases are equal. (*b*) Neither. Because the two containers have the same number of atoms, the average kinetic energy is the same for all atoms. (*c*) Argon. The rms speed is proportional to the square root of the average kinetic energy divided by the mass (Eq. 19.53). Although the average kinetic energies of the two gases are equal, a helium atom has a smaller mass than an argon atom, so the rms speed of a helium atom is greater than that of an argon atom.

19.27 (*a*) No, because the system is not closed; as the gas cools, thermal energy leaves the system. The entropy law applies only to closed systems. (*b*) From Example 19.12*a*, we have $T_f = 145$ K, so $\Delta T = 145\text{ K} - 290\text{ K} = -145$ K, and so, from Eq. 19.50: $\Delta E_{th} = \frac{3}{2}Nk_B\Delta T = \frac{3}{2}(10^{23})(1.38 \times 10^{-23}\text{ J/K})(-145\text{ K}) = -300$ J.

19.28 Decrease. From Eq. 19.61, because $T_f = T_i/2$ and $V_f = 2V_i$, we have

$$\Delta S = \tfrac{3}{2} N \ln \tfrac{1}{2} + N \ln 2.$$

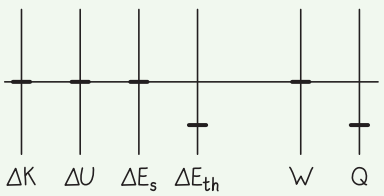
Because $\ln \frac{1}{2} = -\ln 2$, this can be written as



$$\Delta S = -\tfrac{3}{2} N \ln 2 + N \ln 2 = -\tfrac{1}{2} N \ln 2 < 0,$$

and so the entropy decreases. When the temperature of the system is halved, the energy of the system decreases, and so the system is not closed.

Chapter 20



20.1 (*a*) Joules. (*b*) See Figure S20.1.

Figure S20.1

20.2 See Figure S20.2.

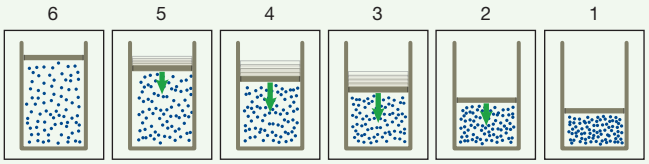


Figure S20.2

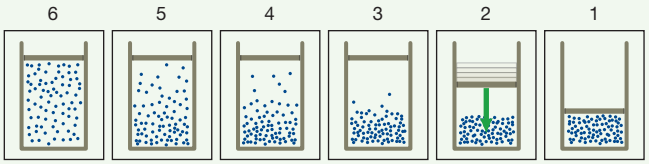


20.3 See Figure S20.3. The quasistatic process is possible because it depicts a succession of equilibrium states, all of which show an equipartition of space. The non-quasistatic process is not possible: As the first four frames show, it would require the gas molecules to "pull away" spontaneously from the piston, before the piston begins moving down in frame 2.

Figure S20.3

(*a*) Reverse quasistatic process

(*b*) Reverse non-quasistatic process

20.4 During a quasistatic process the system must remain near equilibrium at all instants during the process. (*a*) Not quasistatic; just after the balloon is popped, the pressure inside the container is not the same everywhere and so the system is not in equilibrium. (*b*) Quasistatic; even though the temperature of the coffee changes, the change is slow. The coffee therefore has a well-defined uniform temperature and is in equilibrium throughout the cooling process. (*c*) Quasistatic; as the gas pushes the piston outward, the pressure in the gas remains uniform and so the gas is in equilibrium. (*d*) Not quasistatic; the temperature of the ice cube and the hot water are different, and so the system is not in equilibrium.

20.5 (*a*) Using Eq. 2 from the "Temperature measurement scales" box, you find for $T_F = 60\ ^\circ\text{F}$:

$$T_C = \frac{5\ ^\circ\text{C}}{9\ ^\circ\text{F}} (60\ ^\circ\text{F} - 32\ ^\circ\text{F}) = 16\ ^\circ\text{C}.$$

Likewise, for $T_F = 80\ ^\circ\text{F}$, you obtain $T_C = 27\ ^\circ\text{C}$, making the range 16 °C to 27 °C. By adding 273.15 to these values, you get the corresponding range in kelvins: 289 K to 300 K.

(b) Equation 1 from the box gives you

$$T_C = \frac{1\ ^\circ\text{C}}{1\ \text{K}} (2800\ \text{K}) - 273.15\ ^\circ\text{C} = 2500\ ^\circ\text{C}.$$

The expression I used in the solution to Exercise 20.2*b* gives

$$T_F = \frac{9\ ^\circ\text{C}}{5\ ^\circ\text{F}} \left[\frac{1\ ^\circ\text{C}}{1\ \text{K}} (2800\ \text{K}) - 273.15\ ^\circ\text{C} \right] + 32\ ^\circ\text{F} = 4600\ ^\circ\text{F}.$$

20.6 (*a*) There are many more water molecules in the pool than in the glass. Thermal energy is proportional to number of molecules, and so the pool has greater thermal energy. (*b*) The heat capacity of

the pool is greater because the amount of thermal energy needed to increase the temperature of all the water in the pool by 1 K is greater than the amount needed to increase the temperature of all the water in the glass by 1 K. (*c*) The glass of warm water because thermal energy is proportional to temperature.

20.7 (*a*) All three. Unlike a hydrogen molecule, an ammonia molecule is not linear, so its rotational inertia is nonzero along the three orthogonal axes. (*b*) Because there are six degrees of freedom, three translational and three rotational, the thermal energy per molecule is $6(\frac{1}{2}k_BT) = 3k_BT$. (*c*) If you raise the temperature by $\Delta T = 1$ K, the increase in thermal energy per molecule is $\Delta E_{th} = 3k_B\Delta T$. The heat capacity per molecule is thus $\Delta E_{th}/\Delta T = 3k_B$. (*d*) It's within 10%. The experimental value listed in Table 20.3 is $3.37k_B$.

20.8 Less than. More energy must be transferred to the diatomic gas because it has more degrees of freedom, and so its heat capacity per particle is greater.

20.9 $P_1 > P_2$, $V_1 < V_2$, and $T_1 = T_2$ because the two states are on an isotherm. The entropy dependence on temperature and volume is given by Eq. 19.60, $S \propto \ln T^{3/2}V$. The temperatures are the same in the two states, and so the differences in entropy depend only on volumes. That $V_1 < V_2$ tells you that $S_1 < S_2$. Because $E_{th} \propto T$, the thermal energies of the two states are the same.

20.10 (*a*) The change in entropy is the same for the two processes (the same initial and final states and therefore the same initial and final temperatures and volumes). (*b*) No. Because the two processes have the same initial and final states, the change in temperature is the same for both. Hence the change in thermal energy ΔE_{th} is the same. This change is the sum of the work done on the gas and the energy transferred thermally to it: $\Delta E_{th} = W + Q$. Because the work done on the gas (the area under the path) is different for the two processes, the amount of energy transferred thermally must also be different.

20.11 See Table S20.11. The work done on the gas is positive during compression, negative during expansion, and zero for any isochoric process.

The thermal energy is proportional to the temperature (see Eq. 19.50). As you can see from Figure 20.25, the isentropic expansion brings the system to a lower isotherm, and so the thermal energy decreases; in the isochoric process, the temperature increases, and so $\Delta E_{th} > 0$; the isobaric process decreases the temperature, and so $\Delta E_{th} < 0$; and the isothermal compression doesn't change the temperature, so $\Delta E_{th} = 0$.

The isentropic process is adiabatic, so $Q = 0$. For the other processes, the sign of Q can be determined from ΔE_{th} and W, because the sum of the work done on the gas and the energy transferred thermally to it equals the change in thermal energy.

For the isentropic process the change in entropy is zero by definition. As you can see from Figure 20.25, the isochoric process brings the system to a higher isentrope and so $\Delta S > 0$. The isobaric and isothermal compressions bring the system to a lower isentrope, so $\Delta S < 0$. (Because the system is not closed, the entropy can decrease.)

20.12 Table 20.3 and Figure 20.15 tell you that at $T = 300$ K, the heat capacity per particle for hydrogen is $2.5k_B$ and so it has five degrees of freedom (three translational and two rotational). So, if we assume the gas can be treated as ideal, the thermal energy is $E_{th} = \frac{5}{2}Nk_BT$ (approximately N times 10^{-20} J).

20.13 Process A. The vertical legs for both A and B are at constant volume, and Eq. 20.9 tells you that no work is done on the gas. In process A, the gas undergoes an isobaric decrease in volume at a higher pressure than process B. The volume change is the same in both cases. So, by Eq. 20.9 (which has ΔV no longer equal to zero), the work done on the gas during the isobaric process in process A is greater than in process B. (Note that the area under path A in Figure 20.28 is larger than the area under path B and the work done on the gas is positive, thus confirming our answer.)

20.14 (*a*) Process C. Because the initial and final states lie on an isotherm, $\Delta E_{th} = 0$ for all three processes. The work done on the system in each process is negative and equal in magnitude to the area under the path. Because $\Delta E_{th} = 0$, $Q = -W$ and so Q is equal to the area under the path, which is largest for process C and (*b*) smallest for process A.

20.15 Yes. If $\Delta T = 0$, then the temperature doesn't change, and if the temperature doesn't change, then Eq. 20.5 tells us that E_{th} doesn't change either, so $\Delta E_{th} = 0$.

20.16 Greater. Because $PV = Nk_BT$ and Nk_B is constant, the product PV is proportional to the temperature T of the state. The final temperature T_f is greater than the initial temperature T_i, and so $P_fV_f > P_iV_i$.

20.17 The isobaric process. Both processes have the same ΔE_{th} because the temperature change is the same. No work is done on the gas during the isochoric process, which means that in this process the energy transferred thermally goes entirely into raising the temperature. During the isobaric process, more energy must be transferred thermally into the gas during the expansion because the work done on the gas is negative.

20.18 Because the initial and final states lie on the same isotherm, the thermal energy of the gas doesn't change. From this you know that $\Delta E_{th} = W + Q = 0$ and so $W = -Q$. The work done on the gas is positive for both processes ($V_f < V_i$), and so the energy transferred thermally must be negative. (*a*) The work done on the gas is equal to the area under the path. From the paths in Figure 20.37 you see that the rectangular area under path A is larger than the area under path B, which means that the work done on the gas in process A is greater than the work done on the gas in process B. (*b*) Because

Table S20.11 Checkpoint 20.11

Process	ΔE_{th}	W	Q	ΔS
isentropic expansion	negative	negative	0	0
isochoric pressure increase	positive	0	positive	positive
isobaric volume decrease	negative	positive	negative	negative
isothermal compression	0	positive	negative	negative

W is greater for process A, the magnitude of Q must be greater for process A.

20.19 No. Equation 20.36 gives the change in entropy between two equilibrium states that are at the same temperature. During an isochoric process, the temperature changes, so we cannot use Eq. 20.36.

20.20 The same. Equation 20.34 is independent of the process. The entropy change depends on only the temperatures and volumes of the initial and final states. If the two combinations of processes have the same initial and final states, the change in entropy is the same in the two cases.

20.21 See Table S20.21. ΔS is positive when a process ends on a higher isentrope. To determine the sign of Q, we approximate the ideal gas process by a series of infinitesimal isentropic and isothermal segments. (We can do this for any process.) Along the isentropic segments, $Q = 0$. Along the isothermal segments, Q has the same sign as ΔS, which is positive. Therefore for any process for which $\Delta S > 0$, we know that Q must be positive too. The change in the thermal energy is the sum $Q + W$. Because isentropes are steeper than isotherms, ending on a higher isentrope while compressing the gas means ending on a higher isotherm, and so the temperature T and the thermal energy both have to increase ($\Delta E_{th} > 0$). When the gas expands, its entropy can increase while its temperature and thermal energy increase, decrease, or stay the same. (*a*) $W < 0$ for expansion. (*b*) $W > 0$ for compression.

Table S20.21 Checkpoint 20.21

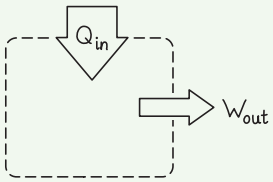
	Expansion	Compression
W	negative	positive
Q	positive	positive
ΔE_{th}	positive, negative, or zero	positive
ΔS	positive	positive

20.22 We have to calculate entropy changes associated with two processes: the cooling down of the water from 20 °C to 0.0 °C and the phase transition from water to ice. The entropy change during the cooling is given by Eq. 20.53. Substituting the specific heat capacity for water from Table 20.2, we obtain

$$\Delta S = \frac{(0.010\text{ kg})(4181\text{ J/kg}\cdot\text{K})}{1.38\times10^{-23}\text{ J/K}}\ln\left(\frac{273}{293}\right) = -2.1\times10^{23}.$$

For the phase transition, we use Eq. 20.58 and substitute the specific transformation energy for water from Table 20.4:

$$\Delta S = -\frac{(0.010\text{ kg})(3.34\times10^{5}\text{ J/kg})}{(1.38\times10^{-23}\text{ J/K})(273\text{ K})} = -8.9\times10^{23}.$$



The total entropy change is thus -11×10^{23}.

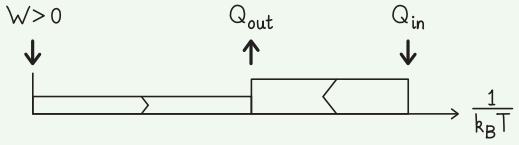
Chapter 21

21.1 (*a*) There is a change in the state of motion of the puck, which decreases its kinetic energy. Because the temperature of the puck and surface increases, their thermal energy increases. This is an irreversible process, so the entropy increases. (*b*) The spring relaxes from the compressed state, and the cart changes its state of motion. The configurational potential energy of the spring-cart system decreases, and the kinetic energy of the cart increases. The process is reversible, so the entropy does not change. (*c*) A chemical reaction changes the state of the explosives, releasing source energy. The projectile changes its state of motion, increasing its kinetic energy. The temperature and thermal energy of the cannon and projectile increase. Because the process is irreversible, the entropy increases. (*d*) The temperature of the hot object decreases, and therefore its thermal energy decreases. The temperature of the cold object increases, and therefore its thermal energy increases. This process is irreversible, so the entropy increases.

21.2 (*a*) See Figure S21.2. Energy is transferred thermally to the gas. This results in an increase in both the temperature and the volume of the gas. The expanding gas does work on the piston. (*b*) Both change. The temperature of the gas increases, so its thermal energy increases. The entropy increases because both the temperature and volume of the gas increase (Eq. 19.61).

Figure S21.2

21.3 (*a*) Pushing the piston back to its original position requires us to do as much work on the device as the device has delivered to us (Eq. 20.30). Therefore once the piston is back to its original position $W = 0$, and because $\Delta E = 0$, $Q = 0$ too. No energy has been converted. (*b*) The volume and temperature of the gas are the same before expansion and after compression, so by Eq. 19.61 the entropy stays the same. (*c*) Yes, because the device keeps returning to its initial state.



21.4 (*a*) $\Delta E_R > 0$ (energy increases), $\Delta S_R > 0$ (entropy increases with energy), $\Delta S_R/\Delta E_R > 0$. (*b*) $\Delta E_R < 0$, $\Delta S_R < 0$, $\Delta S_R/\Delta E_R > 0$.

21.5 (*a*) Energy quality decreases because $\Delta S > 0$ means that energy is transferred to the right on the dS/dE axis, as in Figure 21.16*b*. (*b*) Energy quality remains the same because it remains at the same value of dS/dE.

21.6 (*b*), (*c*), and (*f*).

21.7 See Figure S21.7.

Figure S21.7

21.8 Because the process depicted in Figure 21.22*a* is reversible, $\Delta S_{env} = 0$, and so the two rectangles must have equal areas. The rectangle on the right is less long and therefore must have a greater height.

21.9 (*a*) Because you increase T_{in}, the label Q_{in} and the point where the two rectangles meet both move to the left. The length of the upgrade rectangle decreases, which means the magnitude of ΔS corresponding to the upgrade decreases. (*b*) Because the process is reversible, the magnitude of ΔS associated with the degradation also decreases. (*c*) Because the length of the degrade rectangle increases, the height must decrease; therefore Q_{out} decreases. That means, because $W = Q_{out} - Q_{in}$ and W is constant, Q_{in} decreases.

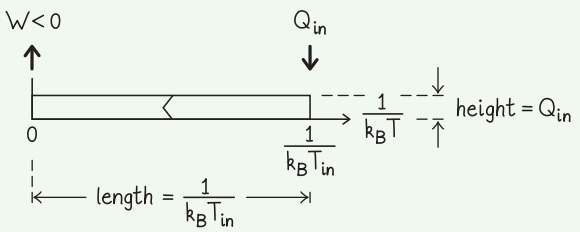
21.10 Lowering T_{out} requires a smaller thermal input of energy for the same work done on the environment, so the efficiency increases.

21.11 (*a*) In Figure 21.26, the Q_{in} arrow is roughly twice as wide as the W_{in} arrow. Because $W = W_{in}$, the coefficient of performance of cooling is $Q_{in}/W = 2$. (*b*) Because $Q_{out} = Q_{in} + W_{in} = 3W_{in} = 3W$, the coefficient of performance of heating is $Q_{out}/W = 3W/W = 3$.

21.12 (*a*) Now the area under the expansion path $1 \rightarrow 2$ is greater in magnitude than the area under the compression path $2 \rightarrow 1$, which means the negative work done on the system is greater than the positive work done on the system. So the work done on the system during the cycle is negative, and the magnitude is equal to the shaded area in Figure 21.28*d*. (*b*) The sign of the work done on the environment is the opposite of the sign of the work done on the system and so is positive. The magnitude is the same as in part *a*.

21.13 Although the transfer from low temperature to high temperature is an upgrade of the energy and therefore a decrease in entropy, the entropy increase from the degradation of the mechanical energy input is greater than the decrease.

21.14 Zero. The law of energy conservation requires that the energy of the closed system comprising the device and its environment cannot change. Because the energy of the steady device is not changing, $\Delta E = 0$ (Eq. 21.1), the energy of the environment cannot change either.



21.15 (*a*) Both negative. Because energy is transferred thermally out of the bar, the energy of the bar decreases and so its entropy decreases. (*b*) Energy is transferred thermally to the environment, and S_{env} increases. (*c*) The equilibration is irreversible, so ΔS_{env} must be greater than ΔS_{bar}, which means $S_{bar} + S_{env}$ increases.

21.16 (*a*) See Figure S21.16. (*b*) Because the transfer is to the left, the entropy change is negative. The height of the rectangle is Q_{in}. (Because $W = -Q_{in}$ you could also write the height of the rectangle as $-W > 0$.) The rectangle stretches from the origin (0 on the $1/k_BT$ scale) to $1/k_BT_{in}$, so its length is $1/k_BT_{in}$. The entropy change is thus

$$\Delta S_{env} = -(Q_{in})\left(\frac{1}{k_BT_{in}}\right) = \frac{-Q_{in}}{k_BT_{in}}.$$

This process is not allowed by the entropy law because $\Delta S_{env} < 0$.

Figure S21.16

21.17 Yes, in theory. According to Eq. 21.20, Q_{out} goes to zero if T_{out} goes to zero. As T_{out} goes to zero, the length of the degrade rectangle becomes infinite, but the area of the rectangle can remain constant. Unfortunately there are no thermal reservoirs at $T = 0$.

21.18 (*a*) $\eta_{max} = (299\text{ K} - 221\text{ K})/299\text{ K} = 0.261$. (*b*) $\eta_{max} = (300\text{ K} - 221\text{ K})/300 = 0.263$, so the efficiency increases by 0.002.

21.19 The blanket converts mechanical energy entirely to thermal energy, and so from Eq. 21.24, $COP_{heating} = Q_{out}/W = 1$, which is the smallest possible value.

21.20 (*a*) Equation 21.28 gives $COP_{heating} = COP_{cooling} + 1$. You know from Example 21.7 that $COP_{cooling}$ is 17. Therefore $COP_{heating}$ is 18. (*b*) You can use Eq. 21.24 to get the delivery rate: $dW/dt = (dQ_{out}/dt)/COP_{heating} = (500\text{ W})/18 = 28\text{ W}$.

21.21 As the gas goes from state 1 to state 2 the entropy change of the gas is (Table 21.1):

$$\Delta S_{1\rightarrow 2} = N \ln\left(\frac{V_2}{V_1}\right).$$

Substituting the values given then yields

$$\Delta S_{1\rightarrow 2} = 5.10 \times 10^{23}.$$

During the two isentropic legs, the entropy doesn't change:

$$\Delta S_{2\rightarrow 3} = 0$$

$$\Delta S_{4\rightarrow 1} = 0.$$

The entropy change over the entire cycle is zero, so the entropy change as the gas goes from state 3 to state 4 must be the negative of the entropy change as the gas goes from state 1 to state 2:

$$\Delta S_{3\rightarrow 4} = -\Delta S_{1\rightarrow 2} = -5.10 \times 10^{23}.$$

21.22 (*a*) The efficiency of the jet engine is given by Eq. 21.44. Substituting T_1 and T_4 from Example 21.9, we get $\eta = 1 - (T_4/T_1) = 1 - (288\text{ K})/(760\text{ K}) = 0.62$. (*b*) Equation 21.36 gives the Carnot efficiency: $\eta = (1520\text{ K} - 288\text{ K})/(1520\text{ K}) = 0.81$, which is significantly greater than the 0.62 efficiency of the engine running on the Brayton cycle. (Remember, however, that the Carnot cycle operates very slowly, which means the power is very low.)

Chapter 22

22.1 (*a*) You should observe that the tape and battery attract each other. (If the battery repels the tape, you can get rid of the repulsion by wiping the entire battery surface with your hand.) It makes no difference how you orient the battery or whether the battery is fresh or spent. Any wooden object should also attract the tape in the same way a battery does. (*b*) The tape and the power cord attract each other. Turning the lamp on or off doesn't make any difference. It does not appear that the power cord has an effect different from any other object.

22.2 (*a*) You should see that the two strips repel each other quite strongly. (*b*) No. Regardless of how you orient the strips—sticky sides facing, nonsticky sides facing, one sticky side facing one nonsticky side—the two always repel. As you bring them closer, they twist to avoid contact.

22.3 Paper-paper, no interaction; tape-paper, interaction; tape-tape, interaction.

22.4 (*a*) The strip should be attracted to your hand and the strip of paper and be repelled by the second charged strip. (*b*) The uncharged strip should remain motionless when you hold your hand close to it. (*c*) You should see no interaction between the uncharged hanging strip and the strip of paper, and there should be an attractive interaction between the two tape strips. This tape-tape interaction is just

like the attractive interaction between a charged tape strip and any other uncharged object.

22.5 The recharged strip should be attracted to your hand and to a strip of paper and repelled by another charged tape strip.

22.6 (*a*) There is an attractive interaction between both types of strips and uncharged objects. (*b*) A third charged strip attracts strip B and repels strip T. (*c*) Yes. Strip T must be charged because it interacts with other charged strips and with uncharged objects. (*d*) Yes. Strip B must be charged because it interacts with other charged strips and with uncharged objects. (*e*) After discharging, neither strip B nor strip T interacts with uncharged objects, and both strips are attracted to a charged strip. (See the box "Troubleshooting B and T strips" if your experimental results do not agree with these.)

Troubleshooting B and T strips

If your experiment with B and T strips doesn't work as expected, check the following:

1. You must pull off the combination in step 2 of Figure 22.5 *very* slowly. (The amount of charge that builds up on the strips is roughly proportional to the speed at which you separate them.) Be sure to remove *all* charge before proceeding.
2. Separating the B and T strips, on the other hand, must be done fairly rapidly. (If you do it too fast, however, so much charge may build up on your strips that it becomes hard to prevent them from being attracted to your hands. If they curl around and touch your hands, you must start over.)
3. Avoid any air currents on the suspended strips.
4. If the humidity of the air is high, the strips may lose their charge rapidly; you may need to repeat the experiment in a drier environment.

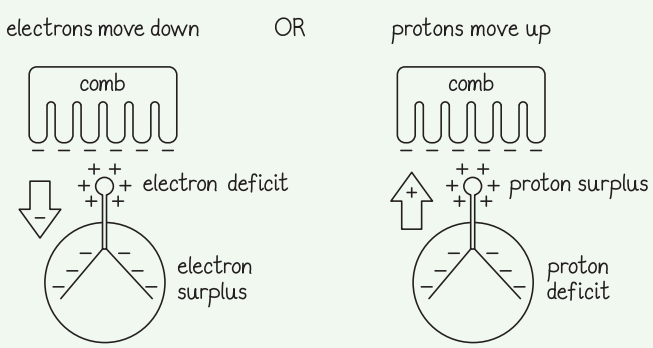
22.7 See Figure 22.6.

22.8 (*a*) The comb attracts the uncharged paper strip and repels the (charged) tape strip. (*b*) The comb repels one strip (usually the B strip) and attracts the other. (*c*) The charge on the comb behaves the same way as the charge on the strip it repels (usually B). The charge on the comb is therefore the same type as the charge on the strip it repels.

22.9 If in Checkpoint 22.8 your comb repelled the B strip, your brand of tape produces B strips that carry a negative charge. If the comb attracted the B strip, your brand of tape produces B strips that carry a positive charge.

22.10 (*a*) The red marbles, all carrying a positive charge, exert repulsive forces on one another and so move as far away as possible from one another. (*b*) The blue marbles, all carrying a negative charge, also exert repulsive forces on one another and so move as far as possible from one another. (*c*) The red and blue marbles are attracted to each other and so form red-blue pairs. The (sum of the) charge on any given pair is zero and so does not repel the other pairs. Consequently the pairs do not spread out. (The positive and negative charges do not overlap completely—a red marble and a blue one cannot be at the same place—and so, as we shall see later, some residual interaction is left.) (*d*) Each blue marble becomes part of a red-blue pair; the leftover red marbles repel one another and spread out. (*e*) Because of the surplus of positively charged red marbles, the entire collection carries a positive charge.

22.11 (*a*) Any charge deposited on the metal rod spreads out over the entire conducting system, which in this case is the metal rod plus your body. Most of the charge therefore ends up on you. (*b*) Because rubber is an electrical insulator, any charge on the rod that is not in contact with your hand stays on the rod.



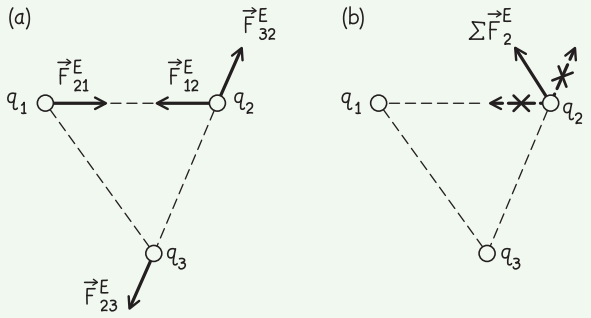
22.12 When you rub together surfaces made of the same material, friction does occur, which tells you that bonds do form between the surfaces. Because the two surfaces are made of the same material, however, there is no preferred direction to transfer charge—the same numbers of electrons are transferred in each direction.

22.13 (*a*) Before the charged rod is brought nearby, the electroscope is neutral, meaning it has as many positive charge carriers as negative charge carriers. No charge is transferred to the electroscope, and so even with the rod nearby, the electroscope still has as many positive charge carriers as negative charge carriers (although they are now separated) and is still neutral. (*b*) The magnitudes must be equal because otherwise the electroscope would not be neutral. (*c*) The negative charge carriers on the rod attract the positive charge carriers on the electroscope ball and repel the negative charge carriers on the leaves. (*d*) The positive charge on the ball is equal in magnitude to the negative charge on the leaves. Therefore, all other things being equal, the magnitudes of the forces are the same. However, the distance between leaves and rod is greater than the distance between ball and rod. Because the electric force decreases with increasing distance, the magnitude of the attractive force exerted on the ball will be *greater* than the magnitude of the repulsive force exerted on the leaves.

22.14 The electron cloud is attracted not only to the external positive charge but also to the positive nucleus. The attractive electric interaction between electron cloud and nucleus prevents the electron cloud from leaving the atom entirely.

22.15 (*a*) Attractive. When the external negatively charged body in Figure 22.21 is replaced by a positively charged body, the atoms in the paper still get polarized. The polarization is now in the other direction, however, so that the negative charge appears on the top in Figure 22.21, meaning the force is again attractive. The vector sum of the forces exerted by the charged object on the piece of paper is still attractive. (*b*) It makes no difference whether positively charged protons move up or negatively charged electrons move down. The effect is the same: a surplus of positive charge on the ball of the electroscope and a deficit of positive charge on its leaves (Figure S22.15). (*c*) No, because the outcome does not depend on the type of charge that moves. The experiment that demonstrates that it is indeed the electrons that flow in a metal—as I asserted in Section 22.3—is beyond the scope of this chapter. We will discuss it in Chapter 27.

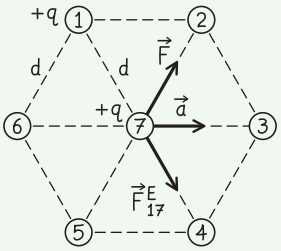
Figure S22.15



22.16 Greater. For simplicity we treat the spheres as particles so we can apply Coulomb's law. Before the spheres touch, the magnitude of the force exerted by them on each other is $k(q)(3q)/d^2 = 3kq^2/d^2$. When the spheres touch, the charge spreads out evenly over them, so each sphere carries a charge of $(q + 3q)/2 = 2q$. At separation d, therefore, the magnitude of the electric force between them is now $k(2q)(2q)/d^2 = 4kq^2/d^2$, which is greater than it was before.

22.17 Two particles carrying like charges repel each other. If you release them, they accelerate away from each other, gaining kinetic energy. Because the two particles form a closed system, this gain in kinetic energy must be due to a decrease in potential energy associated with the electric interaction. Thus the potential energy of a system consisting of two particles carrying like charges decreases as the separation of the two objects increases. Two particles carrying opposite charges attract each other and so accelerate toward each other. As with two particles carrying like charges, this acceleration means a gain in kinetic energy and a decrease in potential energy. The separation distance is decreasing, however, and we are asked about the change in the system's potential energy when the separation distance is *increasing*. We can reason that because the potential energy decreases as the separation distance between two oppositely charged particles decreases, it must increase as the separation distance increases.

22.18 (*a*) The positive charge carriers repel one another, making their separation greater than the distance between the centers of the spheres. Because Coulomb's law has a $1/r^2$ dependence, the greater separation results in a force of smaller magnitude. (*b*) If the two spheres carry opposite charges, the charge carriers attract one another, and so the distance between them becomes smaller than the distance between the centers of the spheres. Consequently, the magnitude of the attractive force is greater than that obtained from Coulomb's law.



22.19 Because particles 2 and 3 both interact attractively with particle 1, they must carry like charges, and so the interaction between 2 and 3 must be repulsive (Figure S22.19*a*). The vector sum of the forces exerted on 2 is the sum of a leftward horizontal force exerted by particle 1 and a force directed upward and to the right exerted by particle 3; see Figure S22.19*b*.

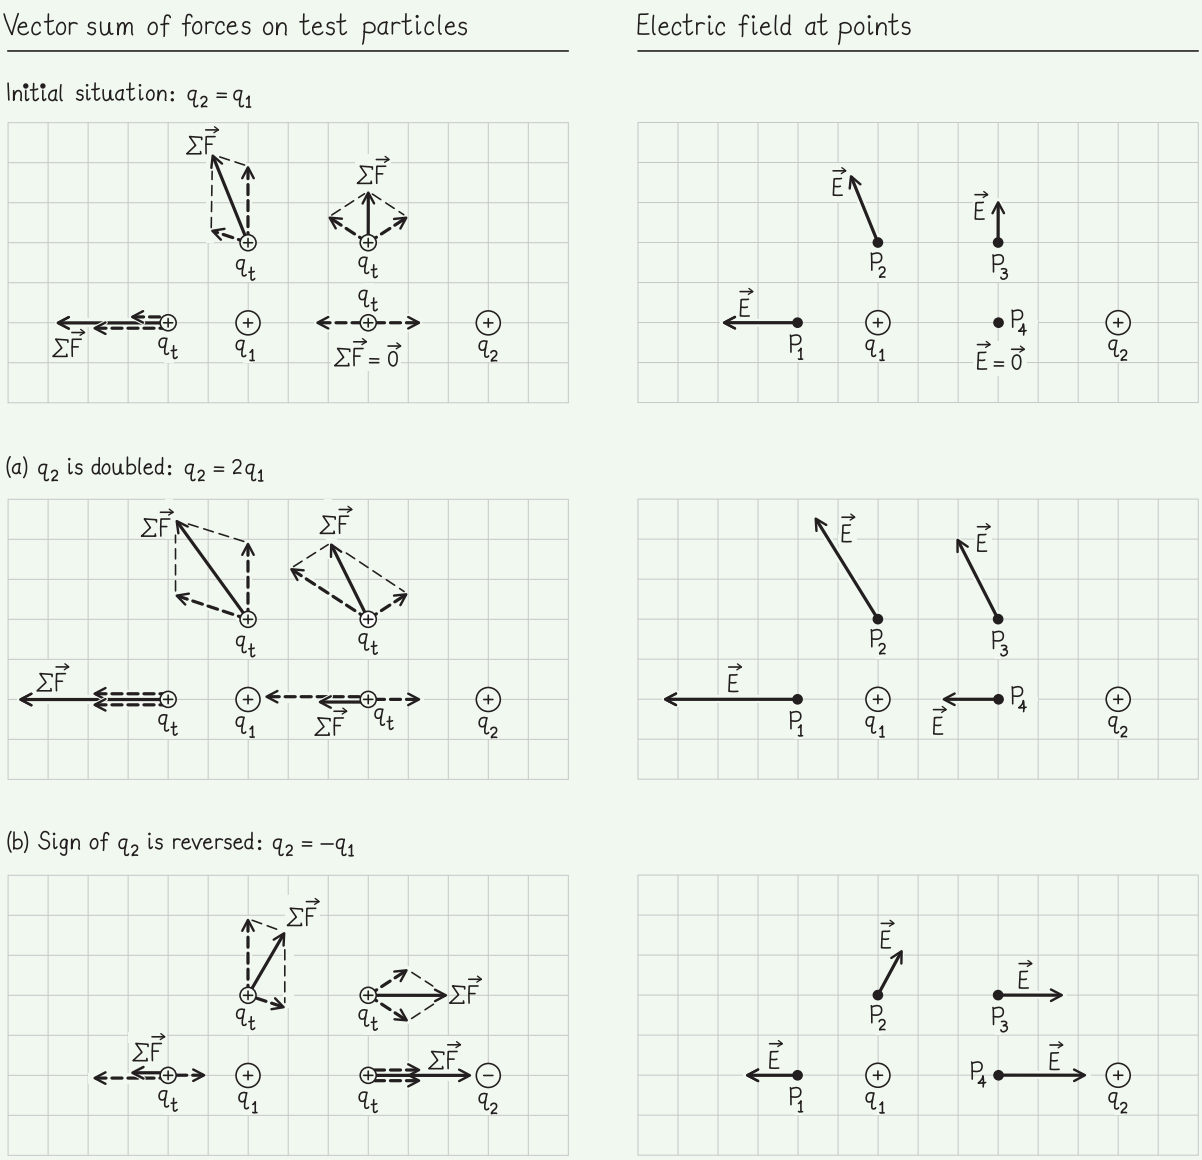
Figure S22.19

22.20 (*a*) The repulsive force $\vec{F}^E_{17}$ exerted by 1 on 7 points in the direction shown in Figure S22.20. To give 7 an acceleration to the right, the vector sum of the forces exerted on 7 must point to the right. This means that, in addition to $\vec{F}^E_{17}$, another sphere must exert a force $\vec{F}$ on 7 as indicated in the figure. Because the electric force is central (it always acts along the line connecting the two interacting objects), the only two spheres that can exert such a force are 2 and 5. (*b*) The magnitude F must be equal to $\vec{F}^E_{17}$ so that the components in the vertical direction add up to zero. So the magnitude of the charge on sphere 2 or 5 must be the same as that on 1 and 7. To give $\vec{F}$ the direction indicated in the figure, the charge must be negative if it is placed on 2 and positive if it is placed on 5.

Figure S22.20

Chapter 23

23.1 (*a*) You know that the magnitude of the gravitational force exerted by Earth on an object of mass m_o is $F^G_{Eo} = Gm_Em_o/r^2_{Eo}$, where G is the gravitational constant and r_{Eo} is the Earth-object distance (Eq. 13.2). Because G and m_E are constants and r_{Eo} is the same for both objects, the magnitude of F^G_{Eo} is proportional to m_o, and thus $F^G_{E1}/F^G_{E2} = m_1/m_2$. (*b*) Yes, because mass is the only property of the objects in the gravitational force expression. Dividing by m_o removes that one property from the expression: $(Gm_Em_o/r^2_{Eo})/m_o = Gm_E/r^2_{Eo}$.



23.2 (*a*) The gravitational field at any location gives the gravitational force exerted on each kilogram of an object at that location. Because each kilogram of the satellite is subject to a force of 2.0 N, the satellite is subject to a force of magnitude $F^G_{Es} = (2.0\ \text{N/kg})(2000\ \text{kg}) = 4000\ \text{N}$. (*b*) $F^G_{Eb} = (2.0\ \text{N/kg})(0.20\ \text{kg}) = 0.40\ \text{N}$.

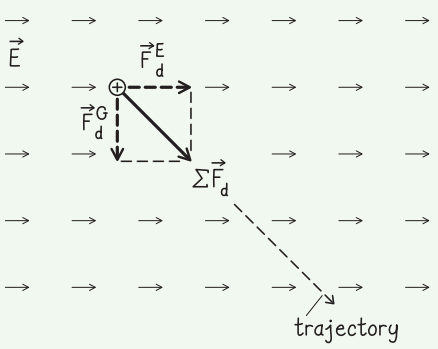
23.3 (*a*) The magnitudes are the same because the forces form an interaction pair. (*b*) Earth's gravitational field magnitude is greater than that of the ball because the gravitational pull exerted by Earth on objects is much greater than the pull of the ball on other ordinary objects. (*c*) The two forces are of equal magnitude because it is the *product* of the masses that determines the force magnitude: $F^G_{Eb} = Gm_Em_b/r^2_{Eb}$. The magnitude of the gravitational force exerted by a gravitational field on an object is equal to the product of the magnitude of the field at the location of the object and the mass of the object. Thus F^G_{Eb} is equal to the product of the magnitude g of Earth's gravitational field (proportional to m_E and large) and the (small) mass of the ball m_b. F^G_{bE} is equal to the product of the gravitational field of the ball (proportional to m_b and small) and the (large) mass of Earth m_E.

23.4 (*a*) No. $F^E_{pi} = kqq_i^2/d$ (Eq. 22.1) tells you that the magnitude of the force exerted by the particle on an object i is proportional to the charge on the object; because $q_1 \neq q_2$, the force magnitudes cannot be equal and therefore the forces cannot be equal. (*b*) The acceleration of the particle, from $\vec{a}_i = \vec{F}^E_{pi}/m_i$. (*c*) No, because the forces and mass of the particles are different (unless the difference in mass compensates for the difference in force). What is the same for both objects is $F^E_{pi}/q_i = kq/d^2$.

23.5 (*a*) Both forces point toward the particle because objects that carry charges of different types attract. (*b*) The electric field points in the same direction as the force exerted on a positively charged particle, so it points toward the particle. (*c*) Because objects that carry like charges repel, $\vec{F}^E_{p2}$ points away from the particle. The direction of the electric field, however, still points toward the particle. (*d*) The

Figure S23.7

field points away from the particle because now the force exerted by the particle on a positively charged test particle is repulsive. (*e*) The two electric field magnitudes are the same because the magnitude of the force exerted on a test particle is proportional to the magnitude of the source charge and $|+q| = |-q|$.



23.6 The magnitude of the force is the product of the electric field magnitude $E = |\vec{E}|$ and the magnitude of the charge q. If q is positive, the direction of the force is the same as that of $\vec{E}$; if q is negative, the force points in the direction opposite the direction of $\vec{E}$.

23.7 (*a*) If q_2 is doubled, the force exerted by particle 2 doubles. Both the direction and the magnitude of $\Sigma\vec{F}^E$ change, and thus both the direction and the magnitude of $\vec{E}$ change (Figure S23.7*a*). (*b*) See Figure S23.7*b*.

23.8 (*a*) In the same direction as the electric field at that point, that is, to the left. (*b*) The magnitude becomes three times as great; the direction is the same. (*c*) Yes, because the force exerted by object 3 changes. This change affects both the direction and the magnitude of $\Sigma\vec{F}^E$. (*d*) Opposite the direction of the electric field at that point, that is, down the page.

23.9 The droplet is subject to a downward force $\vec{F}_d^G$ and a horizontal force $\vec{F}_d^E$. The vector sum of these forces is downward at an angle, as illustrated in Figure S23.9. Both forces are constant in magnitude, so their vector sum is also constant. Consequently the droplet has a constant acceleration along the direction of the vector sum. Because the droplet begins at rest, its trajectory is a straight line along this direction.

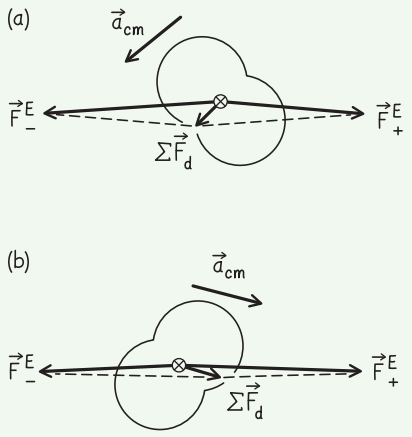


Figure S23.9

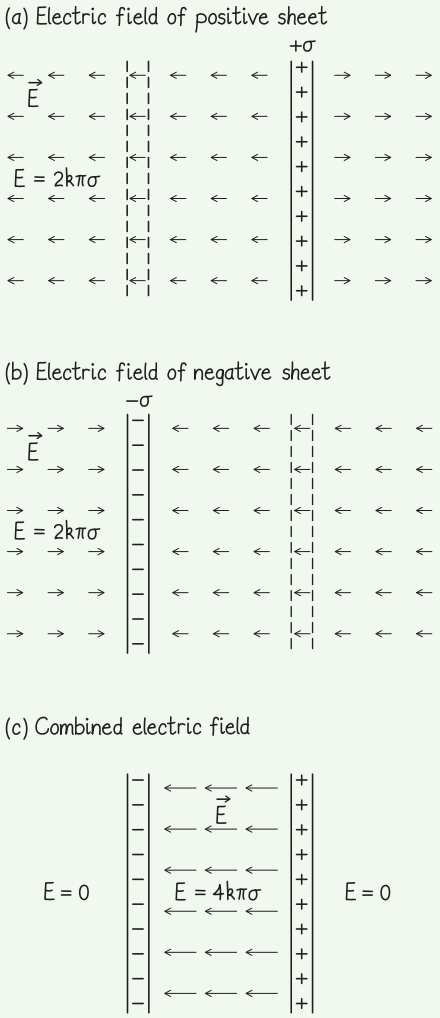
23.10 (*a*) The torque causes the molecule to rotate in the counterclockwise direction. (*b*) No. When the dipole axis that passes through the centers of the two particles is parallel to the electric field, the torque is zero because the two forces lie along the dipole axis and the lever arm of the torque is zero. When the axis is perpendicular to the electric field, the torque is a maximum.

23.11 (*a*) See Figure S23.11*a*. The vector sum of the forces—and therefore the center-of-mass acceleration—point to the left and down. (The force exerted on the negative end is greater than that on the positive end because the electric field is stronger there and both forces have a downward component.) (*b*) See Figure S23.11*b*. The acceleration now points to the right and down, and so the dipole begins by moving in that direction (*away* from the source of the electric field). The orientation of the dipole changes, however, because the forces cause a torque. As we saw in part *a*, as soon as the negative end of the dipole is more toward the left than the positive end, the dipole accelerates toward the left.

Figure S23.11



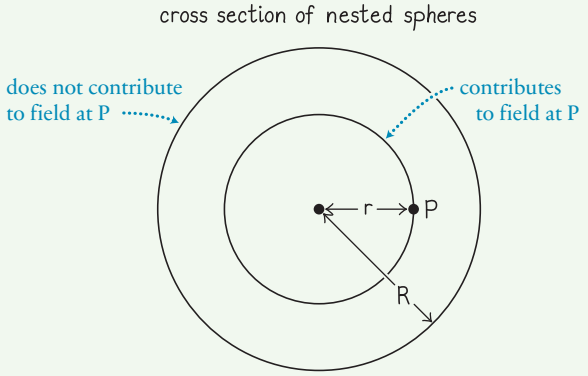
23.12 The magnitude of the electric field is $E = \sqrt{E_x^2 + E_y^2}$. Substituting the values we obtained for E_x and E_y in Example 23.3, we get $E = 1.9 \times 10^4$ N/C. The magnitude of the electric force is $F_e^E = eE = (1.6 \times 10^{-19}\ \text{C})(1.9 \times 10^4\ \text{N/C}) = 3.0 \times 10^{-15}$ N. This force causes an acceleration of magnitude $a_e = F_e^E/m_e = (3.0 \times 10^{-15}\ \text{N})/(9.1 \times 10^{-31}\ \text{kg}) = 3.3 \times 10^{15}\ \text{m/s}^2$. As this example shows, the accumulation of just tens of microcoulombs causes a phenomenally large acceleration of the electron even when it is meters away.

23.13 Equations 23.10 and 23.13 show that the magnitude of the electric field of a dipole is proportional to the dipole moment magnitude p. So the dipole that creates the stronger field (dipole B) has the greater dipole moment. The magnitude of the dipole moment is the product of dipole separation d and dipole charge q_p, which means the greater dipole moment of B can be due either to greater d or to greater q_p. Because we cannot separate these two effects, we cannot say which dipole has the greater dipole charge.

23.14 To determine the electric field created by two parallel charged sheets, you must use the superposition principle. Figure S23.14*a* and *b* shows the electric fields of a positive and a negative sheet. In Figure S23.14*c* these two fields are added. (*a*) Between the sheets the electric fields are in the same direction, and so they reinforce, giving $E = 4k\pi\sigma$ between the sheets. (*b*) Outside the sheets, the electric fields are in opposite directions and therefore add to zero.

23.15 As you saw in Section 22.5, a direct consequence of the $1/r^2$ dependence in Coulomb's law is that the force exerted on a charged particle inside a hollow uniformly charged sphere is zero. This means that the electric field inside such a sphere is zero. For the electric field at some point P inside a uniformly charged sphere of radius R (Figure S23.15), the part of the sphere farther from the center than

Figure S23.14

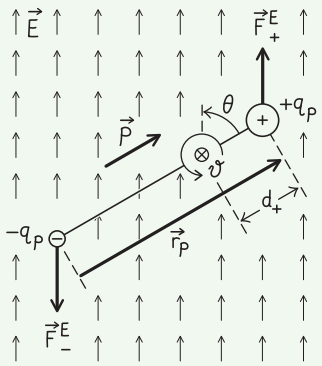


P does not contribute to the electric field at P. If the sphere carries a uniformly distributed charge q, the amount of charge on the part of the sphere closer to the center than P is $(r^3/R^3)q$, and the electric field due to this charge is

$$E_r = k\frac{r^3}{R^3}\frac{q}{r^2} = k\frac{q}{R^3}r.$$

In other words, the electric field *increases* in proportion to the distance r from the center. At the center, it is exactly zero.

Figure S23.15



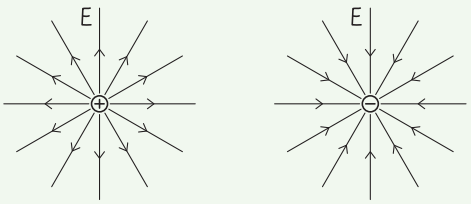
23.16 Yes. To see why, suppose the center of mass is off-center, as shown in Figure S23.16; everything else, including the magnitude of the charges and the dipole moment, is as before. Let the distance between the positive end and the center of mass be d_+. The force exerted on the positive end then causes a counterclockwise torque of magnitude $\tau_+ = r_\perp F_+^E = (d_+ \sin\theta)(q_pE)$, and the force exerted on the negative end causes a counterclockwise torque of magnitude $\tau_- = r_\perp F_-^E = [(d - d_+)\sin\theta](q_pE)$, where $d = |\vec{r}_p|$. Adding the torques yields

$$\begin{aligned}\Sigma\tau_\vartheta &= (d_+ \sin\theta)(q_pE) + [(d - d_+)\sin\theta](q_pE)\\ &= d\sin\theta(q_pE) = (q_pd)E\sin\theta = pE\sin\theta,\end{aligned}$$

identical to the result in Eq. 23.20.

Figure S23.16

23.17 (*a*) Doubles the force (Eq. 23.23). (*b*) Doubles p and thus doubles the force. (*c*) Doubles p and thus doubles the force. (*d*) Reduces the force by a factor of $\left(\frac{1}{2}\right)^3$ because of the $1/y^3$ dependence in Eq. 23.23.



23.18 The dipole moment $\vec{p}$ points in the same direction as the electric field that induces it, so α in Eq. 23.24 must be positive.

23.19 (*a*) Doubles the force (Eq. 22.1). (*b*) Quadruples the force because of the q^2 dependence in Eq. 23.26. (*c*) Doubling q_A in part *b* doubles the electric field created by *A* at the position of the induced dipole. This doubles the magnitude of p_{ind} (the stronger electric field increases the charge separation). This doubled dipole moment then interacts with a doubly strong electric field, increasing the force by a factor of 4. (*d*) No, because the polarization induced by the electric field is always along the electric field (Eq. 23.24). In other words, the induced dipole moment is parallel to the electric field, and the vector product of $\vec{p}$ and $\vec{E}$ is then zero.

Chapter 24

24.1 See Figure S24.1.

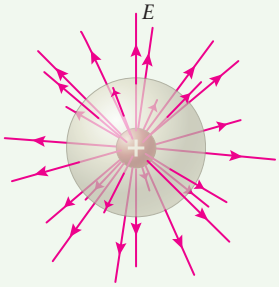


Figure S24.1

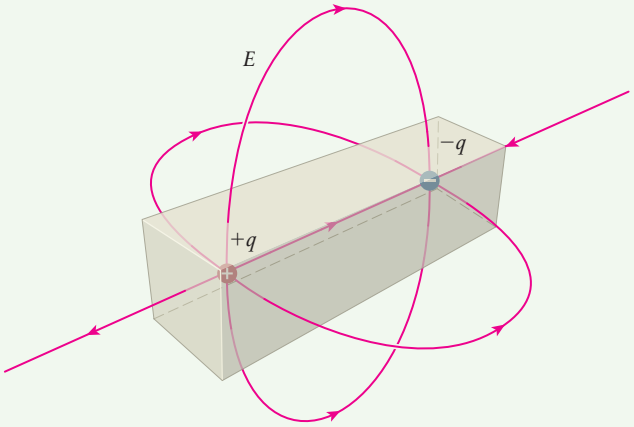
24.2 (*a*) No, because at the point of intersection the direction of the electric field would not be unique—it cannot be tangent to *both* intersecting lines at the same time. (*b*) No. Although two field lines that touch have the same tangent at the point where they touch, the two field lines would have different tangents on either side of that point, and so the direction of the electric field would again not be unique.

24.3 (*a*) As illustrated in Figure S24.3, the same 26 field lines pass through the surface of the hollow sphere. (*b*) The surface area of a sphere of radius R is $4\pi R^2$, so the number of field lines per unit area is $(26)/(4\pi R^2)$. (*c*) Again 26. (*d*) The number of field lines per unit area on the second sphere is $(26)/[4\pi(2R)^2] = (26)/(16\pi R^2)$, which is reduced by a factor of 4 from that for the sphere of radius R. (*e*) The electric field decreases as $1/r^2$, so doubling the distance reduces the electric field by a factor of 4.

Figure S24.3

24.4 (*a*) No field lines cross the surface when it is parallel to the field lines. (*b*) If 16 field lines pass through an area of 1 m^2, then 8 field lines pass through an area of 0.5 m^2. (*c*) The number of field lines per unit area is $(8)/(0.5\ m^2) = 16\ m^{-2}$, or 16 field lines per square meter. (*d*) $(16)/(1\ m^2) = 16\ m^{-2}$, as above. The field line density is the same because the field is uniform.

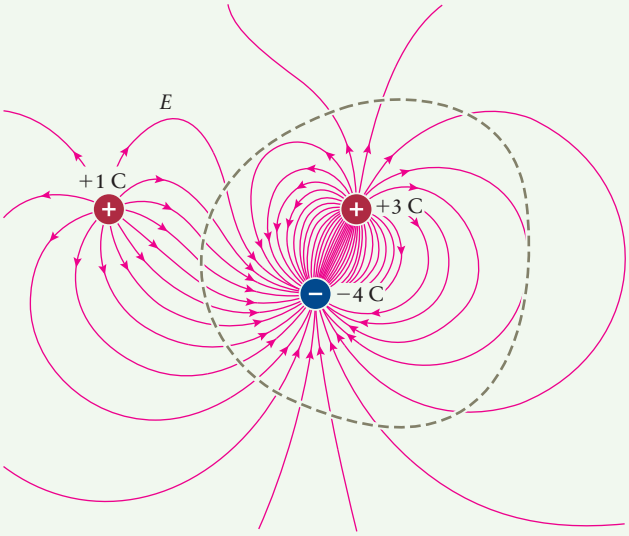
24.5 (*a*) It remains the same—each field line still passes through the surface of the sphere. (*b*) Because neither the number of field lines nor the surface area of the sphere changes, the average number of field line crossings per unit surface area remains the same. (*c*) The electric field strength increases as the distance to the charged object decreases, so moving the sphere off-center increases the electric field strength on one side and decreases it on the opposite side. (*d*) No. The answer to part *b* gives the *average* field line density. Moving the sphere off-center increases the field line density on one side and decreases it on the other, so the average field line density can remain the same.



24.6 (*a*) Sixteen field lines emanate from the object, so 16 field lines pass through the surface of the sphere. (*b*) Eight field lines emanate from each of the objects, so 16 field lines pass through the surface of the sphere. (*c*) The amount of charge enclosed by the sphere is (20 field lines)/(8/q field lines per unit charge) = 2.5q.

24.7 (*a*) Each field line that reenters the donut must also exit, contributing a value of $(+1) + (-1) = 0$ to the field line flux. Thus, regardless of how many field lines reenter the donut, the field line flux remains 6. (*b*) No. Regardless of the shape of the surface, each field line contributes no more and no less than +1 to the field line flux, so the field line flux is always equal to 6.

24.8 (*a*) The field line flux is zero because each field line that enters the sphere also exits the sphere, and so does not contribute to the field line flux. (*b*) No. Moving the particle changes the number of field lines that enter the sphere, but regardless of how many field lines enter the sphere, each of them must also leave the sphere, so the field line flux remains zero.



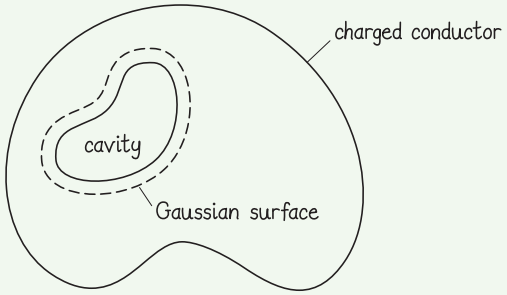
24.9 Five field lines emanating from the positively charged particle contribute a flux of +5 (the field line that points from the positive end to the negative end doesn't pass through the surface; see Figure S24.9). Five field lines terminating on the negatively charged particle contribute a flux of −5. This gives a flux of zero, which makes sense because the amount of charge enclosed by the box is $+q + (-q) = 0$. [Notice that this answer remains valid even if we make the box much larger so that all the curved field lines fit inside it. Then only two field lines pass through the box—one emanating from the positively charged particle, the other terminating on the negatively charged one. The flux is then still zero: $(+1) + (-1) = 0$.]

Figure S24.9

24.10 (*a*) Fifteen field lines go into the surface and three come out of it. The field line flux is thus $(-15) + (+3) = -12$. Twelve field lines emanate from the object carrying a charge of +1 C, so the charge inside the hidden region must be −1 C. Figure S24.10 shows the entire field line diagram; as you can see, the charge enclosed by the dashed line is indeed $(+3\text{ C}) + (-4\text{ C}) = -1\text{ C}$. (*b*) Going along the perimeter of the illustration, we note that four field lines leave the edge of the illustration and four enter it. The field line flux is thus $(+4) + (-4) = 0$. This makes sense because the charge enclosed within the diagram is $(+1\text{ C}) + (-1\text{ C}) = 0$.

Figure S24.10

24.11 If there were a flux into the shell from the left and out of the shell on the right, then the situation would no longer have the required symmetry—if you were to rotate the sphere 180° about the vertical axis, the field line flux would be reversed and therefore the situation would be different. Because the situation is spherically symmetrical, this case is not possible.



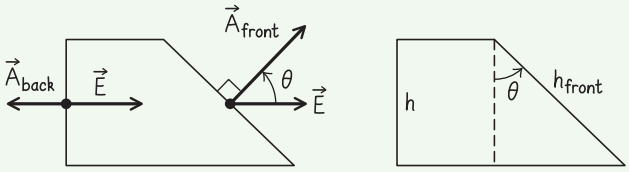
24.12 (*a*) It stays the same because the field line density is the same everywhere on that surface. (*b*) It decreases because the field line spacing increases. (*c*) Zero. The field lines are all perpendicular to the wire, so no field lines pass through those surfaces.

24.13 (*a*) It stays the same because the field line density is the same everywhere along a plane parallel to the charged sheet. (*b*) It stays the same because the field line spacing doesn't change. (*c*) Positive, because the field lines cross from inside the surface to outside. (*d*) They are the same in magnitude and in sign. (*e*) Zero. The field lines are all perpendicular to the sheet, so no field lines pass through the curved surface.

24.14 (*a*) The field line flux is zero because the field is zero everywhere inside the conducting object. (*b*) According to the relationship between field line flux and enclosed charge derived in Section 24.3, the charge enclosed by the surface must be zero.

24.15 No. Imagine a Gaussian surface around the cavity, just inside the conducting object (Figure S24.15). Because $E = 0$ everywhere inside the object, the field line flux through this Gaussian surface is zero and so the charge enclosed by it must also be zero. So, the surplus charge on the object cannot reside on an inner surface.

Figure S24.15

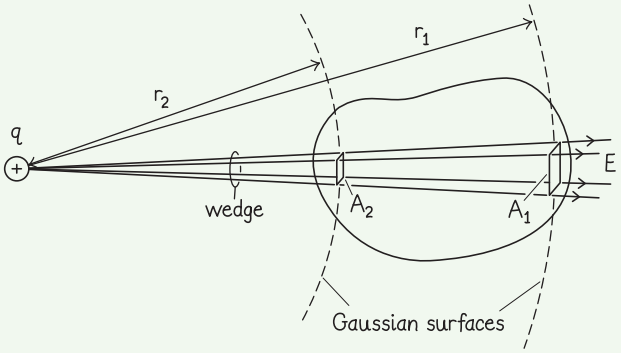


24.16 No. Field lines emanate from the positively charged particle and terminate on the negative charge carriers that line the cavity wall. Thus, "$E = 0$ everywhere inside a conducting object" means everywhere inside the bulk of the object. Cavities don't count!

24.17 (*a*) (*i*) Increases (more field lines intercepted); (*ii*) increases (greater field line density so more field lines intercepted); (*iii*) increases (more field lines intercepted). (*b*) (*i*) Increases (greater A yields greater Φ_E, by Eq. 24.1); (*ii*) increases (greater $|\vec{E}|$ yields greater Φ_E); (*iii*) increases (greater slope means smaller θ, which yields a greater $\cos\theta$).

24.18 (*a*) The area of the back surface is 1.0 m^2, so the magnitude of the corresponding area vector $\vec{A}_{\text{back}}$ is 1.0 m^2. From Figure S24.18 we see that $h/h_{\text{front}} = \cos\theta = \cos 30° = 0.87$, so the area of the front surface is larger by a factor of $h_{\text{front}}/h = 1.2$. The magnitude of the area vector $\vec{A}_{\text{front}}$ is thus 1.2 m^2. (*b*) We use Eq. 24.2 to calculate the electric fluxes. For the back surface we get $\Phi_E = EA_{\text{back}} \cos(180°) = (1.0\text{ N/C})(1.0\text{ m}^2)(-1) = -1.0\text{ N}\cdot\text{m}^2/\text{C}$; for the front surface we have $\Phi_E = EA_{\text{front}} \cos\theta = (1.0\text{ N/C})(1.2\text{ m}^2)(0.87) = 1.0\text{ N}\cdot\text{m}^2/\text{C}$.

Figure S24.18



24.19 (*a*) At a distance r from a particle carrying a charge $+q$, the magnitude of the electric field is kq/r^2 (see Eq. 23.4). (*b*) Because the electric field is perpendicular to the sphere at all points and has the same constant magnitude, the electric flux is given by the product of the electric field and the area of the sphere: $\Phi_E = EA = E(4\pi r^2) = (kq/r^2)(4\pi r^2) = 4\pi kq$. (*c*) The enclosed charge is $+q$, so $\Phi_E = 4\pi kq_{enc}$. (*d*) No. If we double the radius r, the field decreases by a factor of 4 but the area of the sphere increases by a factor of 4. Thus the electric flux and its relationship to q_{enc} remain the same.

24.20 (*a*) With the modified Coulomb's law, the magnitude of the electric field at the surface of the sphere would be $kq/R^{2.00001}$. The electric flux thus becomes $\Phi_E = EA = E(4\pi R^2) = (kq/R^{2.00001})(4\pi R^2) = 4\pi kqR^{-0.00001}$. (*b*) $4\pi kqR^{-0.00001} = q_{enc}/\epsilon_0 = 4\pi kq_{enc}$ or $qR^{-0.00001} = q_{enc}$, which is not an equality. The cancellation of the radius R happens only when the dependence on r in Coulomb's law is *exactly* $1/r^2$.

24.21 Figure S24.21 shows how a wedge from q intersects the surface. The electric flux through intersection A_1 is equal to the electric flux through the intersection of the wedge with a sphere of radius r_1 centered on q. Likewise, the electric flux through A_2 is equal to the electric flux through the intersection of the wedge with a sphere of radius r_2 centered on q. As we saw in Checkpoint 24.19, the magnitudes of the electric flux through a sphere are independent of the radius. Because the intersections of the wedge with the two concentric spheres represent a fixed fraction of the total surface area of the spheres, the electric fluxes through these two intersections must also be the same. Consequently, the magnitudes of the electric fluxes through A_1 and A_2 are the same. Because the electric field points out of the sphere at A_1 and into the sphere at A_2, however, the algebraic signs of the electric fluxes are opposite: $\Phi_{E1} = -\Phi_{E2}$, so $\Phi_{E1} + \Phi_{E2} = 0$. Because this holds for *any* wedge, we learn that the electric flux through the surface due to q is zero when q is outside the surface.

Figure S24.21

24.22 The electric field is also given by Eq. 24.15 because none of the arguments leading up to that result change: The field is still spherically symmetrical, and the enclosed charge is still $+q$.

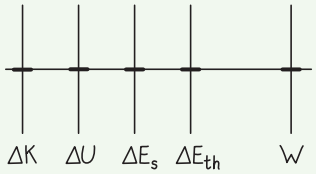
24.23 No, because such a charge configuration does not have sufficient symmetry to make the calculation practical. A finite rod still has *rotational* symmetry (you can rotate it about its axis without changing the configuration), but it cannot be translated about its axis without changing the configuration. For a finite rod the field changes as you move up and down parallel to the y axis in Figure 24.30. With only rotational symmetry, we cannot easily find a closed surface such that for the separate regions of the surface either the magnitude of the field is constant or the electric flux is zero.

24.24 (*a*) The charge spreads out over the outside surface area of the plate. If we ignore the edges of the plate, $\frac{1}{2}q$ spreads out over each side of surface area A, and so the surface charge density (charge per unit surface area) is $\frac{1}{2}q/A$ on each side. The magnitude of the field is given by Eq. 24.17: $E = \sigma/\epsilon_0 = (\frac{1}{2}q/A)/\epsilon_0 = q/(2\epsilon_0 A)$. (*b*) The surface charge density is q/A; the magnitude of the electric field is given by the solution of Exercise 24.8: $E = \sigma/(2\epsilon_0) = (q/A)/(2\epsilon_0) = q/(2\epsilon_0 A)$, which is the same result as in part *a*. The point to remember therefore is that the difference between the solutions of Exercise 24.8 and Eq. 24.17 arises solely from the difference in the surface charge that should be used in each of them.

Chapter 25

25.1 (*a*) The kinetic energies are the same because the two particles are subject to the same force and the force displacements are the same, so the work done on them is the same. (*b*) Particle 2 has the greater momentum. As you may recall from Chapter 8, the change in momentum of an object is given by the product of the force exerted on it and the time interval during which the force is exerted. Because particle 2 has greater mass, its acceleration is smaller, and so it takes longer to fall the same distance as particle 1. (*c*) Both have the same momentum (because the product of force and time interval is the same for both), but particle 1 has greater kinetic energy (because particle 1 has smaller mass, its acceleration is greater and so it undergoes a greater displacement than particle 2; therefore the work done on it is greater and it gains more kinetic energy). (*d*) The electric force exerted on each particle is equal to the product of the electric field and the charge on the particle. Thus, their accelerations are given by

$$\vec{a}_1 = \vec{F}_1^E/m_1 = q_1\vec{E}/m_1$$
$$\vec{a}_2 = \vec{F}_2^E/m_2 = q_2\vec{E}/m_2.$$



Equating these two accelerations yields $q_1/m_1 = q_2/m_2$ or, rearranging terms, $q_1/q_2 = m_1/m_2$. In other words, if we make the ratio of the charges on the particles equal to the ratio of their masses, their accelerations are the same.

25.2 (*a*) When the dipole is vertical, the electric potential energy has reached a minimum because the separation between the positive end of the dipole and the charged object is at a maximum and the distance between the negative end and the object is at a minimum. As the dipole rotates past the vertical, the electric potential energy increases. (*b*) When the dipole is vertical, the torque due to the electric field is zero. Because of its (rotational) kinetic energy, however, the dipole continues to rotate beyond this point and the torque due to the electric field reverses direction. The rotation of the dipole therefore slows down and (rotational) kinetic energy is converted back to electric potential energy. The dipole comes to rest when all of its kinetic energy has been converted—this happens when it is again horizontal (but now with the positive end to the right). The motion then reverses and the dipole continues to oscillate back and forth. (*c*) The same principles apply, but the oscillation would take place over different angles. In other words, if the dipole started at an angle of 45° to the vertical, then the oscillation would occur between $\pm 45°$ instead of $\pm 90°$ as in part *b*.

25.3 (*a*) The work done by the electric field on the particle is the product of the x components of the force exerted on it and the force displacement. The x component of the particle's displacement is $x_B - x_A$ and the x component of the force exerted on it is qE_x, so $W_{Ep}(A \to B) = qE_x(x_B - x_A)$. (*b*) As the particle is moved back to its initial position, the force displacement is reversed, so the work done by the electric field on the particle is the negative of the amount done in part *a*: $W_{Ep}(B \to A) = -qE_x(x_B - x_A)$. (*c*) There is no change in

the particle's kinetic energy and the particle possesses no internal energy, so its energy does not change as the agent moves it back. Therefore the agent must do an amount of work on the particle that is the negative of the work done by the electric field on it calculated in part *b*: $W_{ap}(B \to A) = -W_{Ep}(B \to A) = +qE_x(x_B - x_A)$. (*d*) The sum of the work done by the agent and by the electric field on the particle is zero. (*e*) See Figure S25.3. (There are no changes in the particle's energies and so the total work done on the particle is zero.)

Figure S25.3

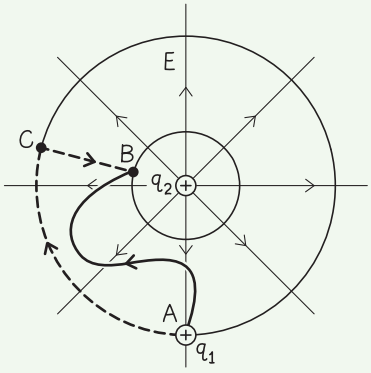
25.4 (*a*) The electrostatic work done on a particle as it moves along the gray path from A to C is equal to the electrostatic work done on it from A to B: $W_{Ep}(\text{gray path}) = W_{Ep}(A \to B)$. The work done from B to C is zero, as is that from C to B: $W_{Ep}(B \to C) = W_{Ep}(C \to B) = 0$. Thus, the electrostatic work done on the particle from C to B to A is just that done from B to A: $W_{Ep}(CBA) = W_{Ep}(B \to A)$. Because the electrostatic work done from B to A is the negative of that done from A to B (which is equal to W), the electrostatic work done from C to B to A must be $-W$. (*b*) Adding the result we found in part *a* to the electrostatic work done along the gray path, we calculate for the work along the closed path from A to C to B and back to A $W + (-W) = 0$.

25.5 (*a*) No. See Checkpoint 25.4. Although the electrostatic work done along the entire path is zero, that along segment AC is nonzero. (*b*) No. The electric field varies in magnitude (and therefore the electric force varies too) along the path AB. We must use integral calculus to calculate the work done by a variable force (see Section 9.7). (*c*) (*i*) If the charge on the particle is doubled, then the electric force exerted on the particle doubles and so the electrostatic work done on it doubles. (*ii*) The electric force does not depend on the mass m of the particle, so the electrostatic work done on it, too, is independent of m.

25.6 (*a*) Negative, because the electrostatic work done on a positively charged particle moving along any path from A to C is positive and the potential difference is the negative of the electrostatic work done per unit charge. (*b*) Zero, because the electrostatic work done on the particle is zero along any path from C to B. (*c*) Positive, because the electrostatic work done on the particle is negative (along the straight path from B to A the force and force displacement are in opposite directions). (*d*) The electrostatic work done on the particle is positive because the electric force and the force displacement are in the same direction. The potential difference is therefore negative. (*e*) The electrostatic work done on the particle is equal to the change in kinetic energy: $W_{Ep} = \Delta K$. This is the electrostatic work done on a particle carrying a charge q, and so the electrostatic work done per unit charge is $\Delta K/q$. The potential difference is the negative of this quantity: $-\Delta K/q$.

25.7 Yes. The surface of any sphere that is centered on the particle constitutes an equipotential surface. (The electric field is always perpendicular to such a surface, and so the electrostatic work done on a particle as it is moved along any path—regardless of its shape—that lies on such a surface is always zero.)

25.8 Zero. As we have seen in Section 24.5, the electric field inside a conducting object that is in electrostatic equilibrium is zero. The accumulation of positive and negative charge carriers on opposite ends of the sphere occurs precisely to cancel the effect of the external field of the charged rod anywhere inside the sphere: The electric field caused by the polarization of charge on the sphere exactly cancels the electric field of the rod. Therefore, because $\vec{E} = 0$ inside the conducting object, the electrostatic work done on a charged particle inside the object is zero, too. Consequently the potential difference between two points on or inside the object is zero.



25.9 (*a*) Along path CB, $r_i > r_f$, so the left side of Eq. 25.5 is negative. (*b*) Positive work must be done to push a positively charged particle toward another positively charged particle because the force the external agent doing the pushing must exert and the force displacement are in the same direction. Because the kinetic energy of particle 2 doesn't change, the total work done on 2 (the sum of the electrostatic work done by particle 1 on 2 and the work done by the external agent on 2) must be zero: $W_2 = W_{12} + W_{a2} = 0$. So if the electrostatic work done by particle 1 on 2 is negative ($W_{12} < 0$), then the work done by the external agent on 2 must be positive: $W_{a2} > 0$. (*c*) It we take both particles as our system, there is no longer any electrostatic work done on the system (the electric interaction is now internal). Consequently the work done by the external agent in moving 2 changes the electric potential energy of the two-particle system: $\Delta U^E = W_{a2}$. Using our answer to part *b*, we have $W_{a2} = -W_{12}(C \to B)$ or, using Eq. 25.4,

$$\Delta U^E = -W_{12}(C \to B) = -\frac{q_1 q_2}{4\pi\varepsilon_0}\left[\frac{1}{r_C} - \frac{1}{r_B}\right].$$

Because $r_C > r_B$, this change in energy is positive.

25.10 Yes. Figure S25.10 shows particle 1 moving instead of particle 2 (compare with Figure 25.15). We follow the same derivation as in Eq. 25.2, substituting $\vec{F}_{21}^E$ for $\vec{F}_{12}^E$. Because the magnitudes of these two forces are the same, the right-hand side of Eq. 25.2 remains the same. The initial and final separations are also still the same and so we obtain the same end result (Eq. 25.4). Alternatively, you can look at Eq. 25.5 and note that the expression is symmetrical in q_1 and q_2 and that r_{12i} and r_{12f} are independent of which of the two charged particles is moved.

Figure S25.10

25.11 Yes. The electrostatic work done on 3 as it is brought in first is zero: $W_3 = 0$; the electrostatic work done on 1 as it is brought in next is (compare with Eq. 25.9)

$$W_{31} = -\frac{q_3 q_1}{4\pi\varepsilon_0}\frac{1}{r_{31}}.$$

Likewise, the electrostatic work done on 2 when bringing in 2 is (compare with Eq. 25.12)

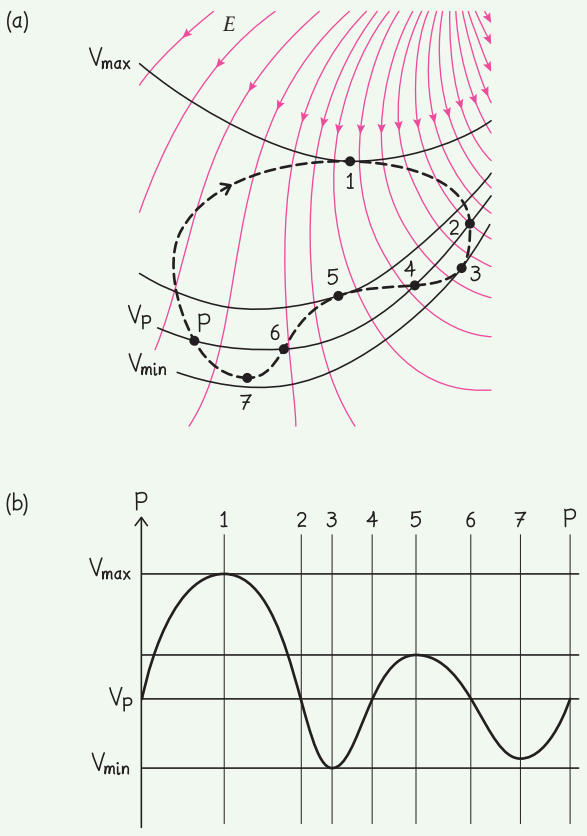
$$W_{12} + W_{32} = -\frac{q_1 q_2}{4\pi\varepsilon_0}\frac{1}{r_{12}} - \frac{q_3 q_2}{4\pi\varepsilon_0}\frac{1}{r_{32}}.$$

The total electrostatic work $W = W_{31} + W_{12} + W_{32}$ done on the system is still the same.

25.12 (*a*) Positive. The potential difference between A and B is $V_B - V_A$, so A is the initial point and B is the final point: $r_i = r_A$ and $r_f = r_B$. Because $r_A > r_B$, the right side of Eq. 25.20 is positive. (*b*) Along the straight path from A to B the angle between the electric force and the force displacement is between 90° and 180°, so the electrostatic work done on the particle is negative. This is consistent with the answer to part *a*; see Eq. 25.15.

25.13 The electric field of a charged particle is given by Eq. 23.4, $\vec{E}_s(P) = (kq_s/r_{sP}^2)\hat{r}_{sP}$, so Eq. 25.25 becomes

$$V_{AB} = -\int_A^B \vec{E}\cdot d\vec{\ell} = -\frac{q}{4\pi\varepsilon_0}\int_A^B \frac{\hat{r}}{r^2}\cdot d\vec{\ell}.$$



The scalar product on the right-hand side is zero along a circular arc because $\hat{r}$ and $d\vec{\ell}$ are perpendicular. Along a radial line, $\hat{r}$ and $d\vec{\ell}$ are parallel, so $\hat{r}\cdot d\vec{\ell} = dr$. Therefore

$$V_{AB} = -\frac{q}{4\pi\varepsilon_0}\int_{r_A}^{r_B}\frac{dr}{r^2} = \frac{q}{4\pi\varepsilon_0}\left[\frac{1}{r}\right]_{r_A}^{r_B}$$
$$= \frac{q}{4\pi\varepsilon_0}\left[\frac{1}{r_B}-\frac{1}{r_A}\right],$$

which is the same result we obtained in Eq. 25.20.

25.14 We begin by sketching some equipotentials for the electric field pattern shown in Figure 25.22. Because equipotentials are always perpendicular to field lines, we can sketch equipotential lines by always drawing them perpendicular to the field lines, as in Figure S25.14*a*. Based on the equipotential lines I have drawn, I choose a set of representative points to evaluate how the potential varies. Moving clockwise around the path from P, I note that the displacement is upward, whereas the direction of the electric field (and therefore the direction of the electric force exerted on a positively charged test particle) is downward. Thus, the electrostatic work done on the particle is negative and the potential difference between a point above the equipotential passing through P and P is positive. In other words, the potential *increases*. At point 1 we reach maximum potential; moving beyond 1, the potential decreases again. At point 2 we cross the equipotential through point P again (the value of the potential is again V_P). The potential continues to decrease until point 3, where it reaches a minimum value. The potential then increases again until a local maximum at point 5 is reached. As we return to P, the potential reaches another local minimum at 7 before increasing again to the initial value. See Figure S25.14*b*.

Figure S25.14

25.15 If the rod and the disk are positively charged and the zero of potential is at infinity, then both potentials should be *positive* (the electrostatic work done on a positively charged particle is negative as we bring it in from infinity). In the answer to Example 25.6, the factor in the logarithm is greater than 1 because $\sqrt{\ell^2+d^2}$ is greater than d, so the numerator is always greater than the denominator. The logarithm is thus positive, yielding a positive V for positive q. Likewise, in the answer to Example 25.7, the factor in parentheses is always positive because $\sqrt{z^2+R^2}$ is greater than $|z|$ so, for positive σ, the potential is positive.

25.16 In Example 25.5, we found for the potential between the plates, $V(a) = E(d-a)$, where a is the distance from the positive plate. Rewriting this result as a function of x, we have $V(x) = E(d-x)$. Because $V(x)$ is not a function of y and z, the partial derivatives of V with respect to y and z are zero. Thus $E_y = E_z = 0$. Therefore, the electric field must be in the positive x direction, and the component in that direction is

$$E_x = -\frac{\partial V}{\partial x} = -\frac{\partial}{\partial x}[E(d-x)]$$
$$= -\frac{\partial}{\partial x}(Ed) + \frac{\partial}{\partial x}(Ex) = 0 + E = E.$$

The electric field is in the x direction and of magnitude E, $\vec{E} = E\hat{\imath}$, in agreement with the situation shown in Figure 25.20.

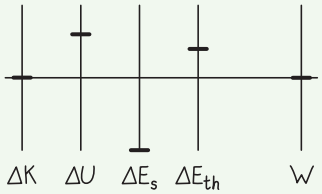
25.17 The potential we obtained in Example 25.7 is a function of z only, so the x and y components of the electric field are zero. The z component is given by

$$E_z = -\frac{\partial V}{\partial z} = -\frac{\sigma}{2\varepsilon_0}\frac{\partial}{\partial z}(\sqrt{z^2+R^2}-|z|)$$
$$= -\frac{\sigma}{2\varepsilon_0}\left(\frac{z}{\sqrt{z^2+R^2}}-\frac{z}{|z|}\right).$$

Substituting $k = 1/(4\pi\varepsilon_0)$, we get, for $z > 0$

$$E_z = 2k\pi\sigma\left[1-\frac{z}{\sqrt{z^2+R^2}}\right]$$

which is the same result we obtained by direct integration in Example 23.6 (see Eq. 2). Note how much easier and shorter the derivation of the electric field via the potential is compared to the direct integration of Section 23.7.



Chapter 26

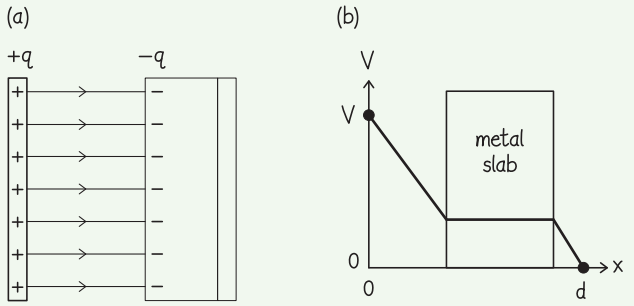
26.1 (*i*) The force exerted on a unit positive charge at P is the vector sum of the electric forces due to all the charge carriers on the rod and the fur exerted on the unit charge. If the distribution of charge on the rod and the fur is the same as before, then doubling the charge doubles the magnitude of the individual electric forces without changing their direction. Consequently the direction of the electric field should be the same, but its magnitude should be twice as great. (*ii*) Because the electric field increases by a factor of 2, the potential difference (which is equal to the negative of the line integral of the electric field along any path between the two fixed points) increases by a factor of 2 as well. (*iii*) The potential energy stored in the system increases *by more than a factor of 2* because as charge is transferred from the fur to the rod, the charges already on the rod and the fur make the transfer more difficult because their field opposes the transfer. Thus, the transfer of each additional amount of charge requires more energy than the previous amount of charge. Put differently, the second half of the charge is transferred against a much greater potential difference than the first half.

26.2 The charged fur and rod attract each other, so you must do positive work on the rod-fur system to increase the separation of the rod and the fur. This work increases the electric potential energy of the rod-fur system.

26.3 See Figure S26.3. No external agent does any work on the system. The person, now part of the system, provides the energy from source energy.

Figure S26.3

26.4 (*a*) When the wires are disconnected, any charge already on the plates remains there, so the potential difference between the plates remains the same. (*b*) The charging of the capacitor continues until the potential difference across the capacitor is equal to that across the battery. Thus, if the battery has a greater potential difference, then the potential difference between the plates is greater too. This greater potential difference requires more charge on each plate.



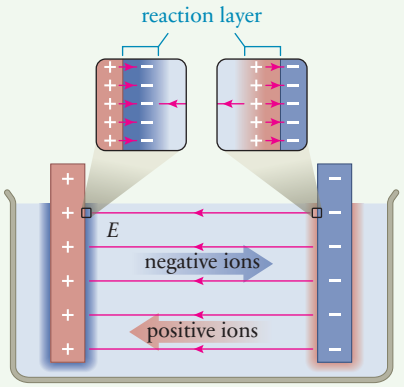
26.5 (*a*) Connecting the capacitors to a 9-V battery means that the potential difference across each capacitor is 9 V. As we saw in Section 25.5, the potential difference across a parallel-plate capacitor is the product of the electric field E and the plate separation d (see Example 25.5). Therefore, the capacitor with the smaller plate separation has the greater electric field. Because the electric field of a charged plate is proportional to its surface charge density (see Exercise 24.8), the plates of the capacitor with the smaller plate separation carry the greater charge. (*b*) The size and shape of the plates don't enter into the expression for the electric field, so the smaller plates must have the same surface charge density as the larger ones. Consequently, the capacitor with the smaller plate area stores less charge.

26.6 (*a*) The amount of charge remains the same; there are no other conductors to or from which charge carriers can go. (*b*) The charge carriers in the conducting slab always rearrange themselves so as to cancel the electric field inside the slab (see Section 24.5). To do so, they must set up an electric field of the same magnitude as that inside the capacitor, but in the opposite direction. The charge carriers in the slab rearrange themselves at the surfaces as shown in Figure 26.9*b*. For the electric field due to the charge carriers at the surfaces of the slab to be equal in magnitude to that caused by the capacitor plates, the magnitude of the surface charge density on the slab surfaces must be the same as that on the plates. Because the surface area of the slab (or at least the part of the slab that is in the electric field) is the same as that of the capacitor plates, the magnitude of the charge on each side of the slab is the same as that on the capacitor plates. (*c*) Zero, because the electric field inside the slab is zero. (*d*) It decreases. Between the capacitor plates and the surfaces of the slab, the electric field is the same as before, but inside the slab the electric field is now zero. The electrostatic work done on a unit charge as it is moved from one plate to the other is therefore less than it was before because it is zero inside the slab. Therefore the potential difference is decreased.

26.7 (*a*) No. Regardless of where the slab is inserted, the field inside it is always zero, while the field between the capacitor plates and the slab is equal to what it was before the slab was inserted. In the extreme case that the slab makes contact with one of the plates, the charge carriers on the plate move through the slab, all the way to its opposite side, as illustrated in Figure S26.7*a*, effectively reducing the plate separation. The magnitude of the electric field, however, remains the same. (*b*) See Figure 26.7*b*. Note that the slope of $V(x)$ on either side of the slab does not depend on the position of the slab.

26.8 The direction of the electric field created by a given source is defined to coincide with the direction of the electric force exerted on a *positive* charge carrier (see Section 23.2). Because electrons carry a negative charge, the force exerted on them is in a direction opposite the direction of the electric field.

Figure S26.7



26.9 (*a*) The electric field is zero above the surface (so it has no direction) because the electric fields of the two surfaces cancel each other outside the dielectric, just like the fields of the two plates of a capacitor (see also Figure S23.14). (*b*) It points from the positively to the negatively charged surface—that is, opposite the direction of the electric field due to the capacitor plates.

26.10 (*a*) Zero, because the electric field due to the bound surface charge would be equal in magnitude and opposite in direction to that due to the free charge on the capacitor plates. In effect, the dielectric is like a conductor. (*b*) No. Suppose the bound charge accumulation at the surfaces becomes so great as to cancel the electric field due to the free charge on the capacitor plates, as in part *a*. Because the electric field inside the dielectric is zero, there is nothing that would cause the material to polarize even further.

26.11 The capacitor with the dielectric, because the battery must do *additional* work on the charge carriers to increase the magnitude of the charge on each plate above that of the capacitor without the dielectric.

26.12 The electric field is in the direction of the flow of positive ions. (The electric force exerted on a positive charge carrier is in the same direction as the electric field.) Wait! Shouldn't the field be in the opposite direction, given the charge on the terminals and the fact that the electric field lines point away from positive charge carriers? The key to reconciling these two facts is to realize that the mechanism of the voltaic cell occurs in the small layers of electrolyte near the electrodes. There the field is in the opposite direction and chemical reactions push charge carriers against the electric field. The result is the pattern of charge and electric fields shown (not to scale) in Figure S26.12.

Figure S26.12

26.13 The work is negative because the system under consideration comprises the molecules undergoing chemical reactions, not the electrons. The molecules do positive work on the electrons, which are part of the molecules' environment, so the environment does *negative* work on the molecules.

26.14 A. The charge on each capacitor follows from Eq. 26.1: $q = C\,V_{cap}$. Thus, for the same V_{cap}, the capacitor with the greater capacitance C holds the greater charge q.

26.15 (*a*) Using the result of Example 26.2, we have

$$A = \frac{Cd}{\epsilon_0} = \frac{(1.0\times10^{-6}\ \text{F})(50\times10^{-6}\ \text{m})}{8.85\times10^{-12}\ \text{C}^2/(\text{N}\cdot\text{m}^2)} = 5.6\ \text{m}^2.$$

This is the area of a small room! A 1.0-F capacitor would therefore have a surface area of 5.6×10^6 m^2—the size of a small town. (*b*) At the breakdown threshold, the potential difference across the capacitor is $V_{\text{cap}} = Ed = (3.0\times10^6\ \text{V/m})(50\ \mu\text{m}) = 150$ V. The charge on the capacitor is then $q = C\,\Delta V = (1.0\ \mu\text{F})(150\ \text{V}) = 1.5\times10^{-4}$ C. (*c*) This charge corresponds to $(1.5\times10^{-4}\ \text{C})/(1.6\times10^{-19}\ \text{C}) = 9.4\times10^{14}$ electrons.

26.16 The capacitance is given by the expression we obtained in Example 26.3. Substituting the values given in the checkpoint, we get

$$C = \frac{2\pi\epsilon_0\ell}{\ln(R_2/R_1)}$$

$$= \frac{2\pi[8.85\times10^{-12}\ \text{C}^2/(\text{N}\cdot\text{m}^2)](100\ \text{m})}{\ln[(2.0\times10^{-3}\ \text{m})/(2.0\times10^{-4}\ \text{m})]} = 2.4\ \text{nF}.$$

One nanofarad (1 nF) is 1×10^{-9} F, so this is a rather small capacitance. (A large capacitance is undesirable because it would allow charge carriers to "pile up" in the cable.)

26.17 (*a*) Example 26.4 gives an expression for the capacitance of a spherical capacitor. As R_2 approaches infinity, the R_1 in the denominator of this expression becomes negligible and so the capacitance reduces to

$$C = \lim_{R_2\to\infty}\left[4\pi\epsilon_0\frac{R_1R_2}{R_2-R_1}\right] = 4\pi\epsilon_0\frac{R_1R_2}{R_2} = 4\pi\epsilon_0R_1.$$

(*b*) Substituting values for ϵ_0 and the radius R_1, we get

$$C = 4\pi[8.85\times10^{-12}\ \text{C}^2/(\text{N}\cdot\text{m}^2)](2.5\ \text{m})$$

$$= 2.8\times10^{-10}\ \text{F}.$$

(*c*) The electric field is maximum at the surface of the dome. From Eq. 24.15 we know that the electric field at the surface of a charged sphere is

$$E = \frac{1}{4\pi\epsilon_0}\frac{q}{R^2} = \frac{1}{4\pi\epsilon_0}\frac{q}{R}\frac{1}{R} = V_R\frac{1}{R},$$

where V_R is the potential at the surface of the sphere and the potential is zero at infinity. Therefore, $V_R = ER$ and the charge stored on the dome is

$$q = CV_{\text{cap}} = CER$$

$$= (2.8\times10^{-10}\ \text{F})(3.0\times10^6\ \text{V/m})(2.5\ \text{m})$$

$$= 2.1\times10^{-3}\ \text{C}.$$

26.18 (*a*) The potential difference across the capacitor is

$$V_{\text{cap}} = Ed = (3.0\times10^6\ \text{V/m})(50\times10^{-6}\ \text{m}) = 150\ \text{V}.$$

The energy stored in the capacitor then follows from Eq. 26.4:

$$U^E = \tfrac{1}{2}(1.0\times10^{-6}\ \text{F})(150\ \text{V})^2 = 1.1\times10^{-2}\ \text{F}\cdot\text{V}^2.$$

Because 1 F = 1 C/V and 1 V = 1 J/C, we have $(1\ \text{F}\cdot\text{V}^2) = (1\ \text{J})$, so the energy stored in the capacitor is 11 mJ.

(*b*) The increase in gravitational potential energy is given by $\Delta U^G = mg\,\Delta y$, so $\Delta y = \Delta U^G/(mg) = (11\ \text{mJ})/[(2\ \text{kg})(10\ \text{m/s}^2)] = 0.6$ mm.

26.19 (*a*) The surface charge density on each plate is given by $\sigma = q/A$, so the magnitude of the field due to one plate is

$$E_{\text{plate}} = \frac{\sigma}{2\epsilon_0} = \frac{q}{2\epsilon_0A}.$$

Note that this is not the electric field between the capacitor plates. The field between the plates is twice as great because each plate contributes to that field. The force exerted by the electric field of one plate on the other plate is thus

$$F_{E\text{p}} = qE_{\text{plate}} = \frac{q^2}{2\epsilon_0A}.$$

(*b*) To increase the separation between the plates you must exert a force $\vec{F}$ of magnitude equal to the force exerted by the electric field on the plate calculated in part *a*. Because this force is constant, and because the force you exert must point in the same direction as the force displacement, we can write for the work you must do on the capacitor

$$W = F\Delta x_F = \frac{q^2\Delta x}{2\epsilon_0A}.$$

(*c*) The change in the electric potential energy is equal to the work done on the capacitor, which we determined in part *b*.

(*d*) The volume of the additional space is $A\,\Delta x$, so the energy stored in the electric field in this additional space is $u_E\,A\,\Delta x$. Because the electric field between the plates of the capacitor is twice the electric field of a single plate calculated in part *a*, the energy density of the electric field is

$$u_E = \tfrac{1}{2}\epsilon_0E^2 = \tfrac{1}{2}\epsilon_0\left(\frac{q}{\epsilon_0A}\right)^2 = \frac{q^2}{2\epsilon_0A^2},$$

so the additional energy is

$$\Delta U^E = u_E\,A\Delta x = \frac{q^2}{2\epsilon_0A^2}A\Delta x = \frac{q^2\Delta x}{2\epsilon_0A} = W.$$

26.20 (*a*) The energy stored in the capacitor is given by Eq. 26.4, so

$$U^E = \tfrac{1}{2}(10^{-4}\ \text{F})(300\ \text{V})^2 = 4.5\ \text{J}.$$

(*b*) The average power is given by the change in energy divided by the time interval over which the change takes place (Eq. 9.29):

$$P_{\text{av}} = \frac{4.5\ \text{J}}{1\times10^{-3}\ \text{s}} = 4.5\times10^3\ \text{W}.$$

This is a phenomenally large power (but it is delivered for only a very short amount of time)—much greater than the few watts that can be delivered by a typical battery. Because it requires a great amount of power to illuminate a large space for a short amount of time, all flash units use a capacitor that is charged by a battery between flash firings.

26.21 (*a*) Because $q_0 = q_{\text{free}} - q_{\text{bound}}$ (see Figure 26.29), we have $q_{\text{bound}} = q_{\text{free}} - q_0$. If we substitute Eq. 26.21, this becomes

$$q_{\text{bound}} = (\kappa - 1)q_0.$$

(*b*) The bound surface charge density on the dielectric is $\sigma_{\text{bound}} = q_{\text{bound}}/A$, where A is the area of the dielectric. Together with our answer to part *a*, this becomes

$$\sigma_{\text{bound}} = (\kappa-1)\frac{q_0}{A} = (\kappa-1)\epsilon_0E,$$

where $E = q_0/(\epsilon_0A)$ (Eq. 24.17).

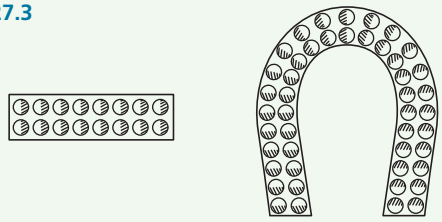
26.22 (*a*) Because 1 V = 1 J/C and 1 J = 1 N·m, we have

$$\frac{\text{C}^2}{\text{N}\cdot\text{m}} = \frac{\text{C}^2}{\text{J}} = \frac{\text{C}}{\text{V}} = \text{F}.$$

(*b*) Similarly,

$$\text{F}\cdot\text{V}^2 = \frac{\text{C}}{\text{V}}\text{V}^2 = \text{C}\cdot\text{V} = \text{C}\left(\frac{\text{J}}{\text{C}}\right) = \text{J}.$$

26.23 Consider a cylindrical Gaussian surface of radius $r > R$. The electric flux through the surface of the cylinder is $\Phi = E(2\pi rL)$, where E is the electric field outside the insulation. The Gaussian surface encloses both bound and free charges. The enclosed bound charge is zero, however, because the surface encloses both the negative bound charge on the inside surface of the insulation and the positive bound charge on the outer surface. The free charge is still λL, so we obtain the same result as in Eq. 26.25 because $\kappa = 1$ for $r > R$.



Chapter 27

27.1 No. Whether a pole is N or S is determined by the way the magnet orients itself with respect to Earth's North Pole. The experiment illustrated in Figure 27.3 then *shows* that like poles repel and unlike poles attract.

27.2 (*a*) Yes, because the charged object always pulls charge carriers of the opposite type toward itself, exerting an attractive force on the near side of the neutral object and a repulsive force on the far side. Because the electric force decreases with increasing distance, the magnitude of the attractive force is greater than that of the repulsive force and so the sum of the forces is attractive. (*b*) A north pole is induced in the clip on the left and a south pole on the right because the interaction between opposite magnetic poles is attractive.

27.3 (*a*) See Figure S27.3. (*b*) No poles because there are no faces where only one type of elementary magnet is exposed. (*c*) If you broke the ring in half and put the exposed faces near paper clips and other magnets, you would find that the faces of the cuts are magnetic poles.

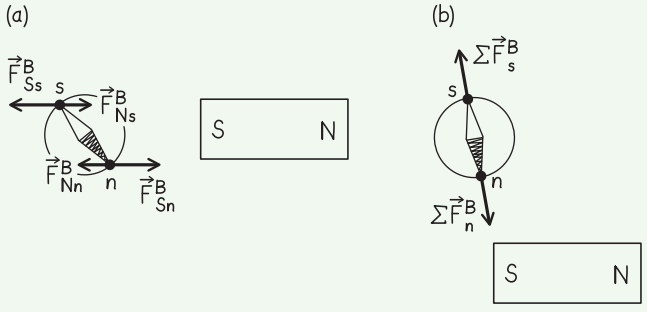


Figure S27.3

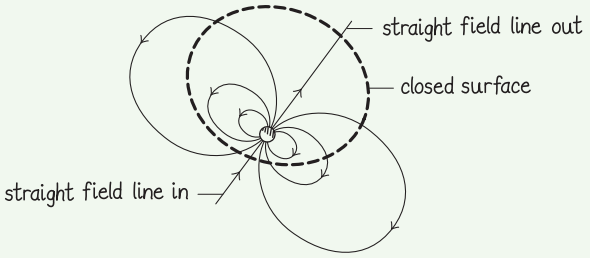
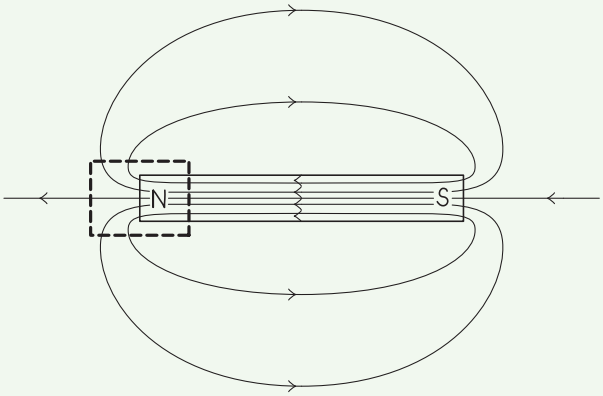
27.4 (*a*) By definition, the end that orients itself northward is the north pole of the needle. (*b*) The north pole of the magnet attracts the south pole of the needle and repels the north pole of the needle. Because the compass needle is free to rotate, the needle rotates so that its north-pointing end is as far away as possible from the north pole of the magnet. (*c*) No; if it were, it would repel the north pole of the compass needle. The earth's geographic North Pole is a magnetic south pole.



27.5 (*a*) The bar magnet's north pole attracts the needle's south pole and repels the needle's north pole. The two forces cause a torque on the needle that tends to align the needle with its north pole pointing away from the bar magnet's north pole. (*b*) Because the distance from the needle to the bar magnet's north pole is greater than the distance from the needle to the bar magnet's south pole, the magnitudes of the forces exerted by the north pole are smaller than those exerted by the south pole (Figure S27.5*a*). Consequently, the needle still aligns itself as in Figure 27.11*a*. (*c*) Once the needle has settled, we know that the torque on it must be zero. This means that the sum of the forces exerted by the poles of the bar magnet on each end of the needle must be aligned with the needle (Figure S27.5*b*).

Figure S27.5



27.6 (*a*) Because elementary magnets have no physical extent, the magnetic field lines form loops that close on themselves (Figure S27.6). Because a particle cannot be cut in half, it must lie either inside or outside the closed surface. Consequently, each line that passes out through the closed surface must also pass back in through the surface. The straight field line entering at the bottom in Figure S27.6 is not an exception. It is balanced by the straight field line leaving at the top. The magnetic flux is zero. (*b*) No, because for this elementary magnet, too, each field line that leaves the surface must eventually reenter it. (*c*) Zero. Because the magnetic flux must be zero for each elementary magnet making up a bar magnet, the magnetic flux of the magnet must also be zero. (*d*) No. Because an elementary magnet cannot be divided, there is always a whole number of elementary magnets inside the closed surface, so the magnetic flux is still zero.

Figure S27.6

27.7 If we draw a closed surface around the north pole of the bar magnet (Figure S27.7), we see that all the field lines on the outside of the magnet are directed out of the closed surface. Because the magnetic flux through a closed surface must be zero, this means that the field lines inside the bar magnet point from the south pole to the north pole.

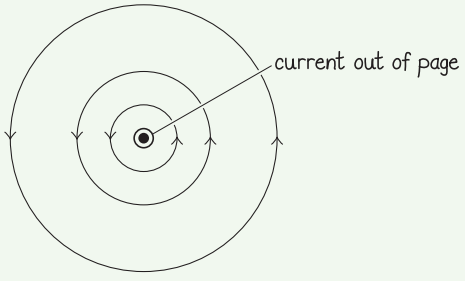


Figure S27.7

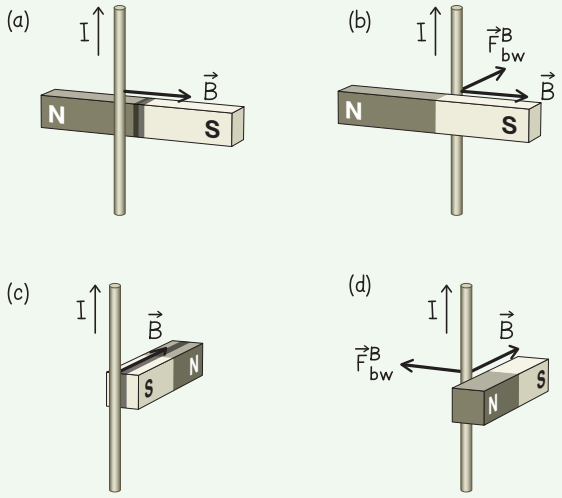
27.8 (*a*) No. If the rod were charged, the battery would have to carry an opposite charge, and charge carriers would start flowing back (see also Section 26.2). (*b*) No. Because it carries no surplus charge carriers, the rod cannot exert an electric force on another charged particle, and therefore there is no electric field due to the rod.

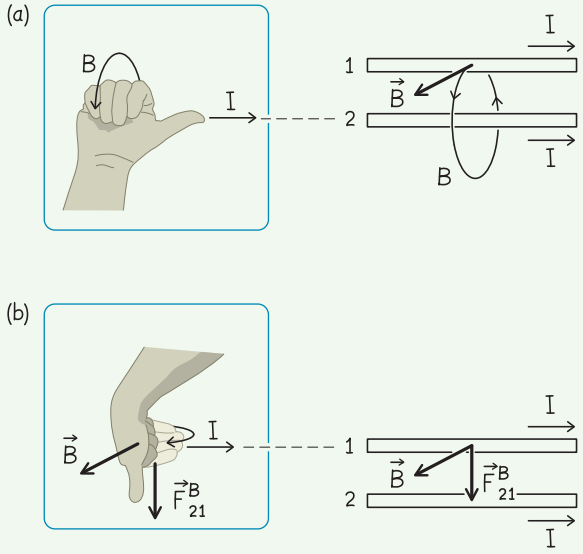
27.9 See Figure S27.9. If the needles align in a circular pattern, the magnetic field lines must be circular, curling in the direction that the north poles of the needles point.

Figure S27.9



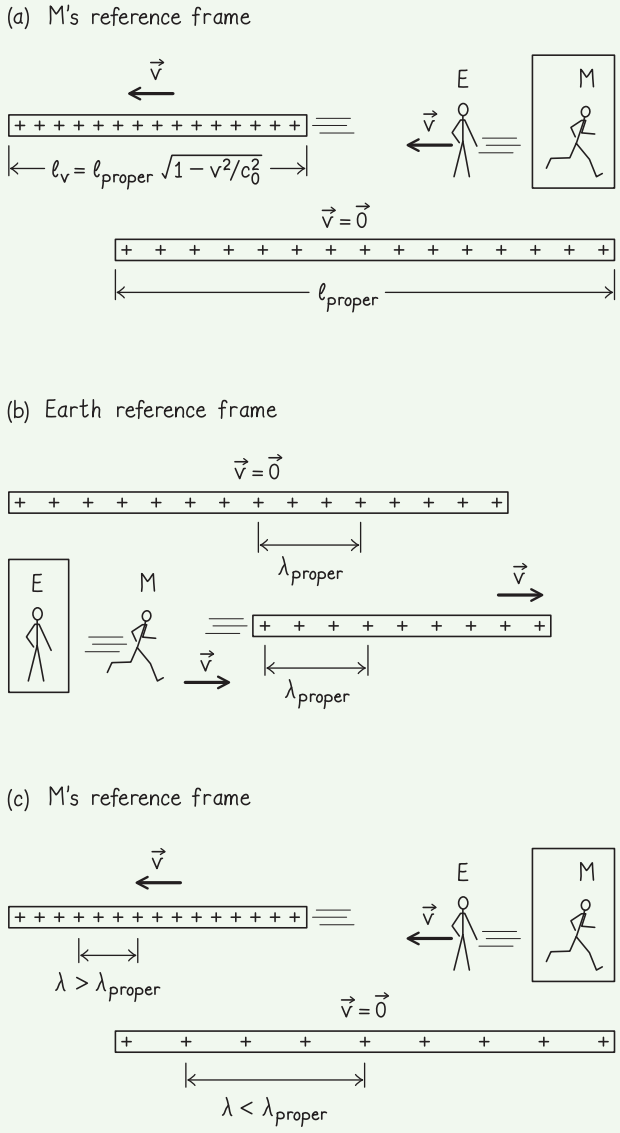
27.10 No. The circular magnetic field pattern generated by a current-carrying wire is unlike the field generated by any magnet or the elementary magnets of which any magnet is made. As we shall see in

the next chapter, however, it is possible to use a current to generate a magnetic field pattern that approximates that of a bar magnet.



27.11 (*a*) Flipping the magnet in Figure 27.20*b* horizontally while keeping it behind the wire yields the situation in Figure S27.11*a*, with the magnetic field at the location of the wire pointing to the right. A field in the same direction can also be obtained by placing the magnet in front of the wire (Figure S27.11*b*). This is the same situation as shown in Figure 27.20*b*, but now seen from the back. Because the magnetic force exerted on the wire in Figure 27.20*b* is toward the front, it must be directed toward the back in Figure S27.11*b*. In other words, the force is directed *toward* the actual position of the magnet in Figure S27.11*a*. (*b*) Because the magnetic field lines loop from the north pole to the south pole outside the magnet (see Figure 27.13), the magnetic field at the wire points straight toward the south pole (Figure S27.11*c*). A magnetic field in the same direction can be obtained by placing the magnet to the right of the wire (Figure S27.11*d*). Comparing this situation with Figure 27.20*b*, you can conclude that the magnetic force exerted on the wire is now to the left. In other words, with the magnet in back of the wire as in Figure S27.11*c*, the magnet exerts a *sideways* force on the wire!

Figure S27.11



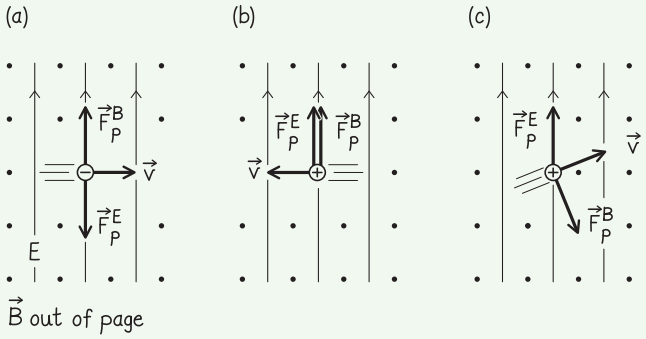
27.12 Reverse the direction of the current through rod 1 in Figure 27.23. As Figure S27.12*a* shows, at rod 1 the magnetic field due to the current through rod 2 is still out of the page. Placing the fingers of your right hand parallel to the current and curling them toward the magnetic field yield a downward-pointing thumb (Figure S27.12*b*), which means the magnetic force exerted by rod 2 on rod 1 is downward. The same reasoning tells you that the magnetic force exerted by rod 1 on rod 2 is upward. The two rods exert attractive forces on each other.

Figure S27.12

27.13 (*a*) From the point of view of observer M, the upper rod is moving to the left and the lower rod is at rest (Figure S27.13*a*). Consequently, the upper rod's length is contracted and the lower one has length ℓ_{proper}. Because both rods carry the same charge, the shorter rod—that is, the upper one—has the greater charge density. (*b*) In Figure S27.13*b*, the charge on the lower rod has been adjusted so that the charge density matches that of the upper rod. (Because the lower rod's length is contracted according to observer E, the charge it carries is now smaller than the charge carried by the upper rod.) According to observer M, the upper rod, which is moving, is shorter than the lower rod. Thus observer M sees the shorter upper rod carrying more charge than the longer lower rod and says $\lambda_{\text{upper rod}} > \lambda_{\text{proper}}$ and $\lambda_{\text{lower rod}} < \lambda_{\text{proper}}$ (Figure S27.13*c*).

Figure S27.13

27.14 (*a*) The positive ions moving to the left correspond to a current to the left. (*b*) The negative electrons moving to the right correspond to a current to the left. (*c*) Yes. The positive particle moving to the right corresponds to a current to the right, and so the situation in Figure 27.27*c* corresponds to two parallel rods carrying currents in opposite directions. As you saw in Example 27.1, the force between two such rods is repulsive, in agreement with the repulsive force exerted by the rod on the particle. (*d*) The arguments for the wire remain unchanged: It appears electrically neutral to observer E and positively charged to observer M. The positively charged wire exerts an attractive electric force on the negatively charged particle. (*e*) Yes. Because a negative particle moving to the right corresponds to a current to the left, the situation is identical to that of two rods carrying currents in the same direction. As you saw in Checkpoint 27.12, the force between such rods is indeed attractive.



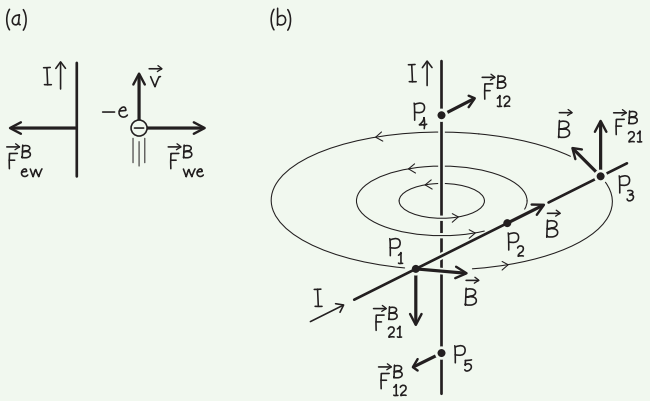
27.15 Example 27.2 shows that the current I is to the right in Figure 27.33. If this current is caused by negative charge carriers, the definition of current tells you that they must flow to the left.

27.16 (*a*) On the side through which the field enters, the field points into the cube but the area vector points outward, so $\theta = 180°$: $\Phi_B = AB\cos\theta = (1.0\ \text{m}^2)(1.0\ \text{T})\cos 180° = -1.0\ \text{Wb}$. The minus sign reflects the fact that the magnetic field points *into* the cube. (*b*) Because as many field lines enter the cube as leave it, the magnetic flux is zero.

27.17 Because the magnitudes of the charge on the proton and the electron are the same, Eq. 27.23 tells you that the ratio of the radii of the paths is equal to the ratio of the masses: $R_p/R_e = m_p/m_e = (1.67\times10^{-27}\ \text{kg})/(9.11\times10^{-31}\ \text{kg}) = 1.83\times10^3$.

27.18 (*a*) See Figure S27.18*a*. For negative charge carriers, $\vec{F}_p^E$ points in the direction opposite the direction of the electric field lines. Because q changes sign, $\vec{F}_p^B = q\vec{v}\times\vec{B}$ (Eq. 27.19) reverses direction as well. The magnitudes of the two forces are unchanged, and so they still add up to zero. (*b*) See Figure S27.18*b*. Reversing the direction of motion of the charge carriers does not affect $\vec{F}_p^E$, but it does reverse the direction of $\vec{v}$ and thus the direction of $\vec{F}_p^B = q\vec{v}\times\vec{B}$. Both forces therefore point in the same direction and so do not cancel. (*c*) See Figure S27.18*c*. Because $\vec{F}_p^B$ is always perpendicular to both the magnetic field and the velocity $\vec{v}$, the direction of $\vec{F}_p^B$ no longer lines up with that of $\vec{F}_p^E$, and so the two forces do not cancel.

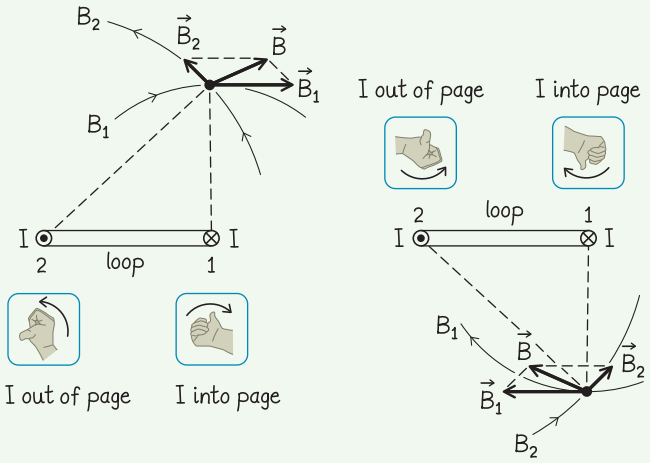
Figure S27.18



27.19 (*a*) The charge distribution is similar to that of a charged capacitor, so E is given by $E = |V_{RL}|/w$ (see Example 25.5), with the width w of the strip substituted for the separation between the positively and negatively charged sides. (*b*) Because the electric and magnetic forces exerted on the charge carriers are equal in magnitude, we have from Eq. 27.26 $v = E/B = |V_{RL}|/(wB)$. (*c*) From Eq. 27.16, $n = I/(A|q|v)$. Substituting the result from part *b*, we obtain $n = (IwB)/(A|qV_{RL}|)$. Because the charge carriers carry an elementary charge e and because $A = wh$, with h the height of the strip, we have $n = IB/(eh|V_{RL}|)$.

27.20 The wire has cylindrical symmetry and so the magnetic field spreads out only in two dimensions. The electric force seen by observer M must therefore decrease as $1/r$ (see Section 24.4). Because the electric force seen by observer M is the same as the magnetic force seen by observer E, that force must also decrease as $1/r$.

Chapter 28

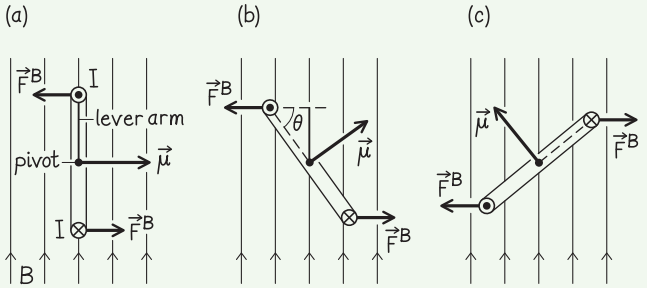


28.1 (*a*) See Figure S28.1*a*. (*b*) The two particles exert no magnetic forces on each other because it takes a moving charged particle to detect the magnetic field of another moving charged particle. (*c*) See Figure S28.1*b*. The forces exerted on the horizontal wire cause a torque that tends to align that wire with the vertical one. Conversely, the forces exerted on the vertical wire cause a torque in the opposite direction, tending to align that wire with the horizontal one.

Figure S28.1

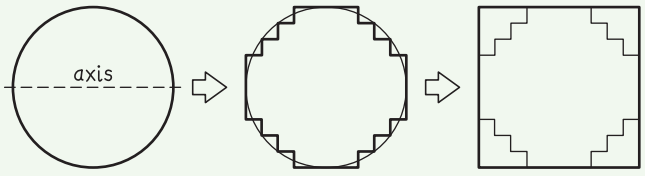
28.2 See Figure S28.2.

Figure S28.2



28.3 Comparing Figures 28.6*b* and 28.7, you see that the positively charged ring has a magnetic field similar to the field of a bar magnet, with its north pole up. The negatively charged ring thus has its north pole down, and this north pole is directly above the north pole of the positive ring. Because two north poles repel each other, the interaction is repulsive.

28.4 No. By definition the electric field points from positive charge carriers to negative charge carriers (see Section 23.2). The electric field along the axis passing through the poles of an electric dipole therefore points from the positive end to the negative end. The electric dipole moment, however, by definition points in the opposite direction (see Section 23.6).



28.5 (*a*) Because the magnetic field remains perpendicular to the horizontal sides of the loop, you know from Eq. 27.4 that the magnitude of the magnetic force exerted on each side is $F^B_{\max} = |I|\ell B$, where ℓ is the length of each side of the loop. Because none of these quantities changes, the magnitude of the force exerted on the horizontal sides stays the same. (*b*) See Figure S28.5*a* and *b*. The lever arm of the force exerted on the horizontal sides become smaller as the loop rotates, and so the torque caused by these forces decreases. (*c*) In the initial position, the vertical sides are parallel to the magnetic field, which means the magnetic force exerted on them is zero (Eq. 27.7, $F^B = |I|\ell B \sin\theta$ with $\theta = 0$). After the loop has rotated 90°, the vertical sides are perpendicular to $\vec{B}$ and thus subject to an outward magnetic force. For $0 < \theta < 90°$, the magnitude of the force is again given by Eq. 27.7. As you can verify using the right-hand force rule, the forces exerted on the vertical sides are directed outward along the rotation axis and so cause no torque. (*d*) See Figure S28.5*c*. Because the top and bottom of the loop are now reversed, the direction of the torque reverses.

Figure S28.5

28.6 See Figure S28.6, where the circular loop is approximated by a series of vertical and horizontal segments. The vertical segments experience no force, but the horizontal ones do. All the horizontal segments add up to the same length as two sides of a square straddling the circle, and thus Eq. 27.4, $F^B_{\max} = |I|\ell B$, tells you that the magnitude of the magnetic force exerted on the horizontal segments is the same as the force exerted on the horizontal side of the square loop. Some horizontal segments are closer to the rotation axis, however, and so the lever arms of the forces acting on these closer segments are smaller than the lever arms of the forces acting on the square loop. Therefore the torque on the circular loop is smaller than that on the square loop.

Figure S28.6

28.7 With the magnetic field on the left stronger than that on the right, $F^B_{\text{left}} > F^B_{\text{right}}$. Therefore the vector sum of the forces exerted on these two sides is nonzero and points upward. The effect is a clockwise rotation due to the torque and an upward acceleration due to the upward vector sum of the forces.

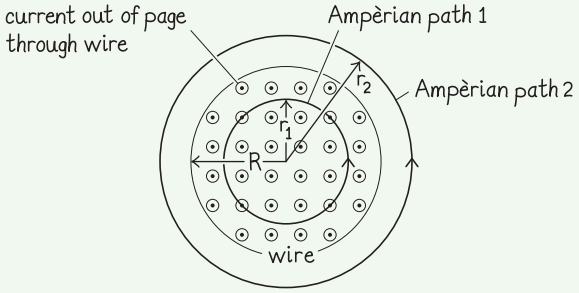
28.8 Increasing the current increases the magnitude of the magnetic field, and so the line integral increases.

28.9 (*a*) If the direction of the current is reversed, the direction of the magnetic field is reversed, and so the algebraic sign of the line integral is reversed. (*b*) Because the value of the line integral of the magnetic field around a closed path does not depend on the position of the wire inside the path, the second wire by itself gives rise to the same line integral as the first wire. Adding the second wire thus doubles the value of the line integral. (*c*) Reversing the current though the second wire flips the sign of the line integral. If its value was C, it is $-C$ after the current is reversed. The sum of the two line integrals is thus $C + (-C) = 0$.

28.10 No. If the path tilts, you can break it down into arcs, radial segments, and *axial* segments, which are segments parallel to the wire. Because the magnetic field is perpendicular to the axial segments, they don't contribute to the line integral. For the same reason, of course, the radial segments contribute nothing. So the line integral again is that along all the arcs, which is equivalent to a single complete circular path.

28.11 (*a*) Reversing the direction of the current through wire 1 changes the sign of its contribution from negative to positive, so adding the contributions of wires 1 and 3 yields a positive value. (*b*) The path does not encircle wire 2, so reversing the current through wire 2 does not affect the answer to Exercise 28.2. (*c*) Reversing the direction of the path inverts the signs of all the contributions to the line integral, but because the integral is zero, the answer doesn't change.

28.12 See Figure S28.12. Inside the wire, use Ampèrian path 1 of radius $r < R$. For this path,



$$\oint \vec{B}\cdot d\vec{\ell} = B_{\text{inside}} \oint d\vec{\ell} = B_{\text{inside}}\, 2\pi r,$$

but the path encircles only part of the cross section and so encircles only part of the current I through the wire. The area of the cross section of the wire is πR^2, and the cross-sectional area of Ampèrian path 1 is πr^2, making the fraction of the wire cross section enclosed by the path $(\pi r^2)/(\pi R^2) = r^2/R^2$. Thus, the right side of Ampère's law is $\mu_0 I_{\text{enc}} = \mu_0(r^2/R^2)I$. Ampère's law thus yields $B_{\text{inside}}(2\pi r) = \mu_0(r^2/R^2)I$, or $B_{\text{inside}} = \mu_0 Ir/2\pi R^2$. Outside the wire, use Ampèrian path 2 in Figure S28.12. For this path,

$$\oint \vec{B}\cdot d\vec{\ell} = B_{\text{outside}} 2\pi r.$$

Because the path encircles all of the current I through the wire, $\mu_0 I_{\text{enc}} = \mu_0 I$, and so the magnetic field outside the wire is the same as that for a long thin wire: $B_{\text{outside}} = \mu_0 I/2\pi r$.

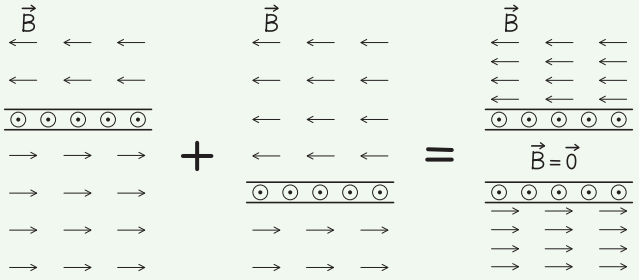


Figure S28.12 Cross section through a current-carrying wire

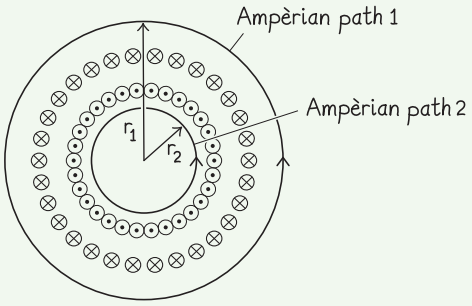
28.13 (*a*) Figure S28.13 on the next page shows a head-on view of the magnetic fields of the two sheets separately and their sum. The magnetic fields add up to zero between the sheets. Below and above the sheets, the magnetic field points to the left and its magnitude is twice that of a single sheet: $2(\frac{1}{2}\mu_0 K) = \mu_0 K$. (*b*) With the current through the lower sheet reversed, its magnetic field is also reversed.



Now the magnetic fields add up to zero below and above the sheets. Between them the magnetic field is to the right and its magnitude is twice that of a single sheet: $\mu_0 K$.

Figure S28.13

28.14 Outside the toroid, you use Ampèrian path 1 in Figure S28.14. The left side of Ampère's law is still given by Eq. 28.7, but the path now encircles both the current upward through the inside of each winding and the current downward through the outside of each winding. The encircled current is thus $NI - NI = 0$, making B outside the toroid zero. Inside the toroid's inner radius, use Ampèrian path 2. This path encloses no current, so here, too, $B = 0$.

Figure S28.14

28.15 For this wire the integration in Example 28.6 extends from $x = 0$ to $x = +\infty$:

$$B = \frac{\mu_0 I d}{4\pi}\int_0^{+\infty}\frac{dx}{[x^2+d^2]^{3/2}}$$

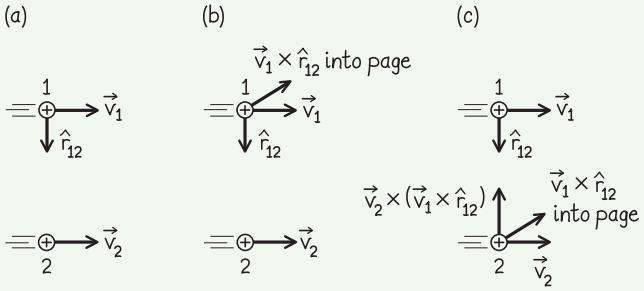
$$= \frac{\mu_0 I d}{4\pi}\left[\frac{1}{d^2}\frac{x}{[x^2+d^2]^{1/2}}\right]_{x=0}^{x=+\infty} = \frac{\mu_0 I}{4\pi d}.$$

28.16 (*a*) Using our result from Example 28.7 with $\phi = 2\pi$:

$$B = \frac{\mu_0 I(2\pi)}{4\pi R} = \frac{\mu_0 I}{2R}.$$

(*b*) The outer arc spans an angle $\phi = \pi/2$ and has a radius $2R$. Using our result from Example 28.7 again, it contributes a magnetic field

$$B_{\text{outer}} = \frac{\mu_0 I(\pi/2)}{4\pi(2R)} = \frac{\mu_0 I}{16R}.$$



The inner arc also spans an angle of $\phi = \pi/2$, but it has radius R, and the current through it runs in the opposite direction so the magnetic field due to this arc is directed into the page. For this arc, the magnitude of the magnetic field is

$$B_{\text{inner}} = \frac{\mu_0 I(\pi/2)}{4\pi(R)} = \frac{\mu_0 I}{8R}.$$

The two straight segments do not contribute because they point straight toward P. Because B_{inner}, which points into the page, is greater than B_{outer}, which points out of the page, the magnetic field $\vec{B} = \vec{B}_{\text{inner}} + \vec{B}_{\text{outer}}$ is into the page rather than out of the page. The magnitude of the magnetic field is $B = \mu_0 I/8R - \mu_0 I/16R = \mu_0 I/16R$.

28.17 (*a*) The direction of the magnetic force is given by the vector products in Eq. 28.23. Figure S28.17*a* shows the vectors that appear in this expression. You must first evaluate $\vec{v}_1 \times \hat{r}_{12}$. The direction of the resulting vector is obtained by curling the fingers of your right hand from $\vec{v}_1$ to $\hat{r}_{12}$, which tells you $\vec{v}_1 \times \hat{r}_{12}$ points into the plane of the page (Figure S28.17*b*).

Figure S28.17

Next evaluate the vector product between $\vec{v}_2$ and the vector product you just found. The right-hand vector product rule tells you this yields a vector that points upward from proton 2 to proton 1. Thus, $\vec{F}_{12}^{B}$ points upward. Applying the same procedure to obtain $\vec{F}_{21}^{B}$, you find that it points downward, telling you that the magnetic interaction is attractive, like that of two parallel current-carrying wires.

(*b*) Because the angles involved in the vector products in Eq. 28.23 are all 90°,

$$F_{12}^{B} = \frac{\mu_0}{4\pi}\frac{q_1 q_2}{r_{12}^2} v_1 v_2.$$

The magnitude of the electric force is given by Coulomb's law:

$$F_{12}^{E} = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r_{12}^2}.$$

The ratio is

$$\frac{F_{12}^{B}}{F_{12}^{E}} = \frac{\left(\frac{\mu_0}{4\pi}\right)\frac{q_1 q_2}{r_{12}^2} v_1 v_2}{\left(\frac{1}{4\pi\epsilon_0}\right)\frac{q_1 q_2}{r_{12}^2}} = \mu_0 \epsilon_0 v_1 v_2.$$

Substituting numerical values, you find that this ratio is 10^{-6}.

Chapter 29

29.1 The magnetic force exerted on the charge carriers points in the opposite direction—that is, upward rather than downward. As a result, positive charge accumulates at the upper end of the rod rather than the lower end.

29.2 Yes, in positions (*b*) and (*d*) in Figure 29.4. The only difference between moving the field and moving the loop is the observer's frame of reference. It would not make any sense for an observer in one reference frame to observe a current and an observer in another reference frame to see no current.

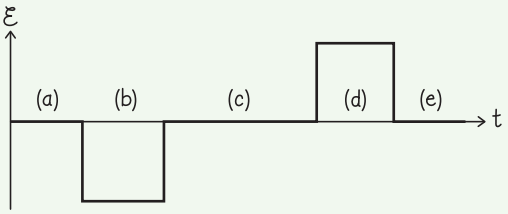
29.3 No, because magnetic forces are exerted only on moving charged particles, not on stationary ones.

29.4 There are two electric fields in Figure 29.10: the "regular" electrostatic field due to the charge separation and the electric field that accompanies the changing magnetic field due to the moving magnet. The charge distribution in the rod is in mechanical equilibrium when these two fields have the same magnitude and opposite directions, producing zero electric field inside the stationary rod, as we would expect.

29.5 Situation 1: The induced current must be the same as if the loop were moving to the left with the magnet stationary (the same relative motion). The upward component of the magnetic field exerts a force on a positive charge carrier that is directed into the page (toward the back of the loop). Because at this point in the magnet's motion the magnetic field is stronger on the left side of the loop than on the right side, the induced current is clockwise.

Situation 3: The induced current must be the same as if the loop were moving downward with the magnet stationary. The upward component of the magnetic field does not contribute to the magnetic force (because it's parallel to the motion of the charge carriers). The component pointing radially outward (looking down on the loop) produces forces that drive a clockwise current around the loop (viewed from above).

29.6 (*a*) In Example 29.4 we saw that the induced current is clockwise as viewed from above in Figure 29.12*b*. Inside the loop $\vec{B}_{\text{ind}}$ points down, and outside the loop $\vec{B}_{\text{ind}}$ points up. Remember that $\vec{B}_{\text{ind}}$ is stronger inside the loop than outside and that the direction of the force exerted by $\vec{B}_{\text{ind}}$ on the south pole is opposite the direction of $\vec{B}_{\text{ind}}$. Thus, the force exerted on the magnet by $\vec{B}_{\text{ind}}$ pushes the magnet upward, opposing the downward motion of the magnet that induced the current and field $\vec{B}_{\text{ind}}$.
(*b*) If Lenz's law indicated that the induced current and field should add to the change that produced them, the force exerted on the magnet by $\vec{B}_{\text{ind}}$ would accelerate the magnet downward more rapidly (and in the process increase the induced current).



29.7 (*a*) Zero. Once the loop is completely in the magnetic field, the magnetic flux enclosed by the loop is no longer changing. The loop's motion ceases to induce current, and the force that resists the motion vanishes, which means no further work is required to keep the loop moving at constant speed. (*b*) Positive. Once the right edge leaves the field, the magnetic flux enclosed by the loop begins to decrease. Lenz's law says that a force resists the magnetic flux decrease and therefore resists the loop's motion. Thus, the loop must be pulled out. The pulling force you exert points in the same direction as the motion, so the work done is positive.

29.8 More work must be done to move a magnet toward a closed conducting loop because the motion induces a current in the loop, and the work done on the magnet must provide the energy for this current. Because there cannot be a current through a rod, moving a magnet toward a rod induces only a static charge separation, which requires less work.

29.9 (*a*) The magnitude decreases through a small region around P because the magnet is moving away from P. It remains unchanged through a small region around Q because the magnet is directly overhead. It increases through a small region around R because the magnet is moving toward R. (*b*) The direction of any eddy current is such that the magnetic field associated with the current opposes the change in magnetic flux. A counterclockwise current (viewed from overhead) creates a field that points upward. Therefore the eddy current around P is counterclockwise and that around R is clockwise. The magnetic flux through a small region around Q remains unchanged, so there are no eddy currents around Q.

29.10 See Figure S29.10 (with magnetic flux out of the page in Figure 29.4 chosen to be positive). The induced emf is zero when the loop is completely outside (*a* and *e*) or completely inside (*c*) the field. The emf has the same constant value when it is moving into (*b*) or out of (*d*) the field. (The sign of the emf is different in *b* and *d*, but the magnitude is the same because $|\Delta\Phi_B/\Delta t|$ depends only on the speed of the loop and the magnitude of $\vec{B}$, both of which are constant.)

Figure S29.10

29.11 Although the solenoid orientation looks the same, the two sides have interchanged their positions. Because the two sides have changed positions, the sense of circulation has changed too. The emf thus has changed sign too.

29.12 (*a*) There is no change in the magnetic flux and thus no electric field. (*b*) They look like counterclockwise-pointing circular loops. By Lenz's law, the magnetic field of the induced current must oppose the decrease in the magnitude of the magnetic field. Therefore the induced current is counterclockwise and the electric field lines must form circles and the electric field points in the direction opposite the direction it has when the magnetic field is increasing.

29.13 For $r > R$, the left side of Eq. 29.17 is still given by Eq. 1 in Example 29.7, but the right side of Eq. 29.17 is $\pi R^2\, dB/dt$. This gives

$$2\pi r\, E = \pi R^2 \frac{dB}{dt}$$

$$E = \frac{R^2}{2r}\frac{dB}{dt}.$$

Substituting $dB/dt = 0.050$ T/s, $R = 0.20$ m, and $r = 0.30$ m into this expression yields

$$E = \frac{(0.20\text{ m})^2(0.050\text{ T/s})}{2(0.30\text{ m})} = 3.3\times10^{-3}\text{ N/C}.$$

29.14 You can calculate the induced emf from the inductance of the solenoid (Example 29.8) and Eq. 29.19:

$$L = \frac{(4\pi\times10^{-7}\text{ T}\cdot\text{m/A})(2760)^2\pi(50\times10^{-3}\text{ m})^2}{0.60\text{ m}} = 0.13\text{ H}$$

$$|\mathscr{E}_{\text{ind}}| = L\frac{dI}{dt} = (0.13\text{ H})(1.0\times10^{-1}\text{ A/s}) = 13\times10^{-3}\text{ V}.$$

29.15

$$u_B = \frac{B^2}{2\mu_0} = \frac{(1.0\text{ T})^2}{2(4\pi\times10^{-7}\text{ T}\cdot\text{m/A})} = 4.0\times10^5\text{ J/m}^3$$

$$u_E = \tfrac{1}{2}\epsilon_0 E^2 = \tfrac{1}{2}(8.85\times10^{-12}\text{ C}^2/\text{N}\cdot\text{m}^2)(1.0\text{ V/m})^2 = 4.4\times10^{-12}\text{ J/m}^3.$$

The ratio of u_B to u_E is 9.0×10^{16}.

Chapter 30

30.1 (*a*) Yes. The wire is intercepted by the surface three times, but the directions of the intercepts are different. Because the magnetic field points in the same direction as the integration direction along the closed path, we can use the right-hand current rule (see the Procedure box in Chapter 28, point 4) to determine that intercepts 1 and 3 are positive and intercept 2 is negative. The direction of the current at intercepts 1 and 3 is from inside to outside; at intercept 2 it is from outside to inside. We can expect current intercepted going from inside to outside to contribute oppositely to current intercepted going from outside to inside. From Figure 30.1 we see that current intercepted going from inside to outside through surface B is positive, so the current intercepted by the surface is $+I$ at 1 and 3 and $-I$ at 2, for a total of I, which is equal to the current encircled by the path. (*b*) Yes. The current intercepted by the surface is I: $+I$ for the top intercept, $-I$ for the middle intercept, and $+I$ for the bottom intercept. Again, the current intercepted by the surface is equal to the current encircled by the path.

30.2 (*a*) While the capacitor is charging, there is a current through the wire leading to or from the capacitor, and the electric field between the plates is nonzero and changing. (*b*) Once the capacitor is fully charged, the current through the wire drops to zero. There is still a nonzero electric field between the plates, but that field is no longer changing.

30.3 Although the electric field direction does not change, the direction of the *change* $\Delta\vec{E}$ in the electric field is reversed because the electric field is now decreasing. Taking the direction of $\Delta\vec{E}$ as the "current," you see that the direction of the magnetic field is reversed from what it was when the unit was charging, and the right-hand current rule applies.

30.4 The magnetic dipole moment of the neutron indicates that it must have an internal structure consisting of charged particles that form current loops. Indeed, in Chapter 7 we learned that the neutron consists of one up and two down quarks (Figure 7.17). These quarks do indeed carry charge.

30.5 You can estimate v by comparing the distance the particle moves in the time interval between parts *b* and *c* of Figure 30.8 with the distance the kinks have moved in that interval as measured from the point where they originate, which is at the center of each panel. The kinks move roughly twice as far as the particle, which means $v \approx 0.5c$.

30.6 The electric field is changing at the kinks and in the region between the kinks and the particle. In these regions there is a magnetic field. Beyond the kinks, the magnetic field is zero because the electric field is static.

30.7 (*a*) In a time interval equal to the period T, the wave travels a distance equal to its wavelength. Because the wave travels horizontally, you should measure the distance traveled along the horizontal axis through the electric field pattern. Between $t = 0$ and $t = T/2$ the wave advances half a wavelength. The distance that the rightmost field line advances in this time interval is 16 mm, so the wavelength is 32 mm. (*b*) From Eq. 16.10, $f = c/\lambda = 9.4 \times 10^9$ Hz. (*c*) From Eq. 15.2, $T = 1/f = 1.1 \times 10^{-10}$ s, or 0.11 ns.

30.8 (*a*) Figure 30.15*a* shows the bottom electric field pattern of Figure 30.14, so the motion of the particles must be the same in those two cases. From Figure 30.14 you see that at $t = \frac{3}{4}T$, the positively charged particle is moving up and the negatively charged particle is moving down, which means the current direction is up. (Although the dipole moment is zero at this instant because the particles are in the same location, the current is not zero because they are both moving. The current is instantaneously zero when the particles are at the two extremes of their travel paths and thus have zero velocity for an instant.) (*b*) Yes, because the magnetic field lines closest to the dipole are in the proper direction for the magnetic field of an upward current: Immediately to the right of the dipole, the magnetic field lines point into the page; immediately to the left of the dipole, they point out of the page.

30.9 Parallel, because parallel to the polarization means parallel to the electric field. From Section 23.4, you know that an electric field exerts a force on charged particles (see Figure 23.15, for instance). Only electric forces with a component along the axis of the antenna can accelerate the charge carriers in the antenna in a direction that produces current (along the antenna's length), so an electric field with a component parallel to the antenna is needed.

30.10 Whether between the plates or outside the capacitor, the magnetic field accompanies a change in the electric field that points left (the electric field is decreasing). From Section 30.1, you know that the "current" you must use with the right-hand current rule for determining the direction of $\vec{B}$ also points left. If you point the thumb of your right hand to the left along the axis in Figure 30.24, your curled fingers point into the page above the axis of the capacitor and out of the page below the axis. This means $\vec{B}$ is into the page at both P and S.

30.11 (*a*) Use a surface that lies between the plates, like the one in Figure 30.28 but with a radius $r < R$. Then follow the approach used in Example 30.5, substituting r for R in Eq. 1:

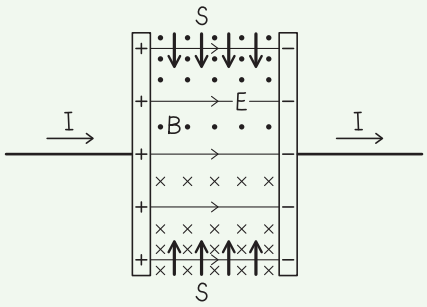
$$B = \frac{\mu_0\epsilon_0 r}{2}\frac{dE}{dt}.$$

To determine E, use Eq. 1 from Example 26.2 with $A = \pi R^2$ (because A is the area of each plate, not the area of the surface bounded by the path of integration). This substitution gives you

$$B = \frac{\mu_0\epsilon_0 r}{2}\frac{d}{dt}\left(\frac{q}{\epsilon_0\pi R^2}\right) = \frac{\mu_0 r}{2\pi R^2}\frac{dq}{dt}.$$

You know that dq/dt is the current, so you can write $B = \mu_0 Ir/(2\pi R^2)$. Thus, the magnetic field between the plates is smaller closer to the axis of the plates. (*b*) To the right of the right plate (and, of course, to the left of the left plate), the magnetic field is simply that of a current-carrying wire at a distance r from the wire. The result we obtained in Example 28.3 gives you $B = \mu_0 I/(2\pi r)$.

30.12 Equation 30.10 relates the electric field to its source charge distributions and thus needs no modification. The right side of Eq. 30.11 is zero because there are no magnetic monopoles. If monopoles having a $1/r^2$ relationship did exist, Eq. 30.11 would have to be analogous to Eq. 30.10. This means the right side must be proportional to m_{enc} rather than zero. You would expect electric fields to form loops around monopole currents, in the same way that magnetic fields form loops around currents, so the right side of Eq. 30.12 must gain a term proportional to dm/dt. Equation 30.13 needs no modification because $\oint \vec{B}\cdot d\vec{\ell}$ for a static distribution of monopoles should be zero, just as $\oint \vec{E}\cdot d\vec{\ell}$ for a static charge distribution is zero.



30.13 In vacuum, the line integral of the electric field is proportional to the time rate of change of magnetic flux through the surface bounded by the path (Eq. 3), and the line integral of the magnetic field is proportional to the time rate of change of electric flux through the surface bounded by the path (Eq. 4). To satisfy these relationships, as shown in Figure 30.30*e* and *f*, the magnetic field and electric field must be perpendicular to each other. The magnetic field must form loops around the electric field, and the electric field must form loops around the magnetic field.

30.14 When an electromagnetic wave enters a dielectric medium, the electric field of the wave accelerates charged particles in the medium back and forth with the frequency of the wave. The accelerated particles radiate electromagnetic waves that propagate with the same frequency as the incoming wave. The electromagnetic wave in the medium is the combination of all of these waves and hence has the same frequency, $f = c_0/\lambda = (3.00 \times 10^8 \text{ m/s})/(600 \text{ nm}) = 5.00 \times 10^{14}$ Hz. The wavelength in the dielectric medium decreases because the speed of the wave in the medium is smaller than in vacuum:

$$\lambda_{\text{new}} = \frac{c}{f} = \frac{c_0}{f\sqrt{\kappa}} = \frac{\lambda}{\sqrt{\kappa}} = \frac{600 \text{ nm}}{\sqrt{1.30}} = 526 \text{ nm}.$$

30.15 The electric field points from one plate to the other, and the magnetic field forms loops around the electric field. (Figure 30.4 represents this situation.) The vector product of these two vectors points radially inward, toward the capacitor axis (Figure S30.15). The Poynting vector thus represents the flow of energy into the region between the capacitor plates, where energy is being stored in the electric field. This makes sense because the energy density associated with the electric field inside the cylindrical surface defined by the capacitor plates is increasing. So there must be a flow of electromagnetic energy into this region.

Figure S30.15

30.16 The SI units of μ_0 are T · m/A; those of the electric field N/C and of the magnetic field T. Using Eq. 30.36, I thus get for the SI units of the Poynting vector:

$$\frac{[\text{N/C}][\text{T}]}{\text{T}\cdot\text{m/A}} = \frac{\text{N}\cdot\text{A}}{\text{C}\cdot\text{m}} = \frac{\text{N}\cdot\text{A}}{\text{A}\cdot\text{s}\cdot\text{m}} = \frac{\text{N}}{\text{m}\cdot\text{s}} = \frac{\text{J}}{\text{m}^2\cdot\text{s}} = \frac{\text{W}}{\text{m}^2}.$$

Chapter 31

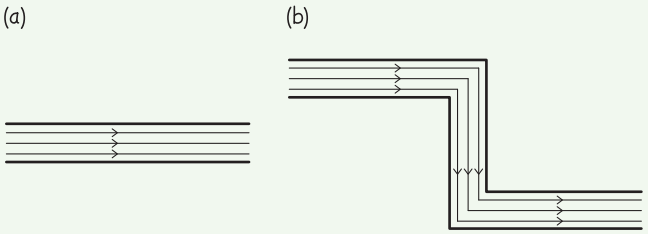
31.1 (*a*) Yes. In practice, the light and thermal energy travel away from the bulb, so you need either a flexible definition of the system or a container capable of keeping the light and thermal energy in a well-defined volume. (*b*) Yes. (*c*) The energy to produce light and thermal energy comes from the electric potential energy associated with the potential difference between the battery terminals. This energy comes from chemical reactions taking place inside the battery.

31.2 (*a*) Yes. The charged capacitor is the source, and the bulb is the load. (*b*) The bulb glows during the brief time interval when the capacitor is discharging. Electrons flow from the negatively charged capacitor plate through the connecting wires and the bulb to the positively charged plate until the capacitor plates are no longer charged. (*c*) Electric potential energy stored in the charged capacitor is converted to light and thermal energy in the bulb.

31.3 These answers are appropriate for a flashlight bulb connected to four D batteries that are fresh. For different batteries and different bulbs, the times may vary somewhat. (*a*) The current should stay constant for many minutes. (*b*) After 24 hours, the batteries are depleted and the current is zero.

31.4 (*a*) Gains electric potential energy. (*b*) Loses the same amount of electric potential energy. (*c*) In the load (they lose very little energy when flowing through the wires).

31.5 (*a*) That resistance is proportional to potential difference tells you that A has the greater resistance. (*b*) The greater resistance of bulb A means that a greater potential difference is required to obtain a given current in A. Thus, the same potential difference across both bulbs produces a smaller current in A than in B.



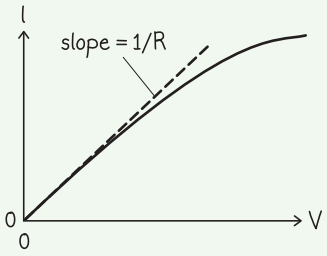
31.6 Smaller than. When the circuit load consists of the parallel combination of two bulbs, the current out of the battery is greater than the current out of the battery when the load consists of a single bulb. (To be exact, the current is twice as great with the parallel combination of bulbs as with the single bulb, as shown in Example 31.3.) The potential difference across the load is the same in both cases. Therefore, the resistance of the parallel combination of two bulbs is half the resistance of the single bulb.

31.7 (*a*) One contact of A is connected to the positive terminal of battery 1, and the other contact is connected to the negative terminal of battery 2. The negative terminal of battery 1 is connected to the positive terminal of battery 2. Therefore the potential difference across A equals the potential difference across the two-battery combination, which is the sum of the potential differences across each battery, or 18 V. (*b*) One contact of bulb B is connected to the positive terminal of battery 1, and the other contact of bulb B is connected to the negative terminal of the same battery. Therefore, the magnitude of the potential difference across B must be 9 V. (*c*) Bulb A glows more brightly because there is a greater potential difference across it.

31.8 Because the electric field is uniform throughout the rod, the magnitude of the electric field is equal to the magnitude of the potential difference across the rod divided by the length of the rod, $E = |V_{12}|/\ell$ (see Eq. 1 in Example 25.5).

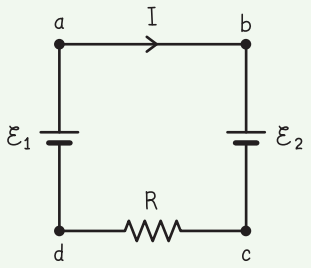
31.9 See Figure S31.9. The electric field lines are parallel to the sides of the conductors everywhere. The electric field line density is also uniform, representing the uniform magnitude of the electric field.

Figure S31.9



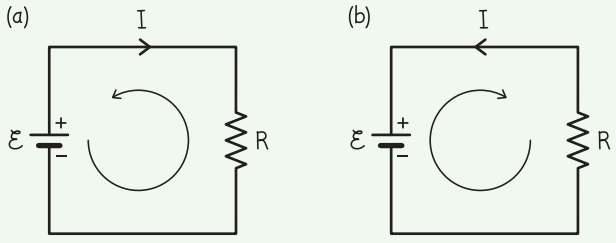
31.10 (*a*) You know from the text that $V_{\text{wide}} = V_{\text{narrow}}/4$. You also know that the magnitude of the potential difference across the entire conductor is 9 V. Therefore $V_{\text{wide}} + V_{\text{narrow}} = V_{\text{wide}} + 4V_{\text{wide}} = 9$ V, so $V_{\text{wide}} = 9\text{ V}/5 = 1.8$ V. (*b*) $V_{\text{narrow}} = 9\text{ V} - 1.8\text{ V} = 7.2$ V.

31.11 (*a*) Yes. The electric field does work on the electrons to accelerate them. (*b*) On average, the kinetic energy does not change over time because the average final velocity (drift velocity) does not depend on time. (*c*) Because the electric field does work on the electrons but their kinetic energy does not increase over time, some other form of energy in the system must increase. (As you'll see shortly, the increase takes the form of thermal energy.)



31.12 (*a*) Greater vibrations cause the ions to move around within a greater volume, increasing the probability of ion-electron collisions and decreasing the average time interval between collisions. Because conductivity is proportional to this time interval and resistance is inversely proportional to conductivity, decreasing the interval causes the resistance to increase. (*b*) A current causes the metal to heat up because the work done on the electrons by the applied electric field gets converted to thermal energy of the lattice ions. (*c*) See Figure S31.12 on the next page. At low current, the heating is negligible. Because metals are ohmic at constant temperature, the curve is a line with slope $1/R$ at low current. At high current, which causes the metal to heat up, the resistance increases as the current increases, and so the line curves downward.

Figure S31.12



31.13 No. Because the positive terminals of the two batteries are connected to each other with a wire, the potential is the same at points a and b (Figure S31.13). So, if $\mathscr{E}_1 < \mathscr{E}_2$, then the potential at d must be greater than the potential at c. Because the direction of current is from high to low potential, the current is counterclockwise though the circuit, in the direction opposite the reference direction for the current indicated in the diagram.

Figure S31.13

31.14 (*a*) See Figure S31.14*a*. If we go counterclockwise from the top, the first circuit element is the battery; because we are traveling from the positive to the negative terminal, the potential difference is $-\mathscr{E}$. Next is the resistor; because we are traveling in the opposite direction as the reference direction for the current, the potential difference is $+IR$. Substituting these values in Eq. 31.21, we get $-\mathscr{E} + IR = 0$ or $I = \mathscr{E}/R$, which is identical to the result we obtained in Eq. 31.24. We should get the same sign for the current because we have chosen the same reference direction for the current as in Figure 31.34. (*b*) See Figure S31.14*b*. If we go clockwise from the bottom, the first circuit element is the battery; because we are traveling from the negative to the positive terminal, the potential difference is again $\mathscr{E}$. Next is the resistor; because we are traveling in the opposite direction as the reference direction for the current, the potential difference is IR. Substituting these values in Eq. 31.21, we get $\mathscr{E} + IR = 0$ or $I = -\mathscr{E}/R$, which is opposite in sign to the result we obtained in Eq. 31.24. The negative sign means that the current direction is opposite the chosen reference direction for the current. That is, the current direction is not counterclockwise, but clockwise, in agreement with our earlier analysis.

Figure S31.14

31.15 (*a*) The potential difference is now positive because you are moving closer to the positive terminal of the battery. The magnitudes of the current and resistance are the same, however, so the magnitude of the potential difference must be the same. Thus, $V_{cb} = IR_1$. (*b*) From the solution I obtained in Exercise 31.8, $I = (9\text{ V})/(10\ \Omega + 5\ \Omega) = 0.6$ A. Therefore, $V_{cb} = (0.6\text{ A})(10\ \Omega) = 6$ V. This result makes sense because the resistance of R_1 is two-thirds of the resistance of the combination of R_1 and R_2, which means you expect the potential difference across R_1 to be two-thirds of 9 V, the potential difference across the combination.

31.16 (*a*) From Eq. 31.32, $R_{eq} = [1/(3\ \Omega) + 1/(10\ \Omega) + 1/(5\ \Omega)]^{-1} = 1.6\ \Omega$. (*b*) From Eq. 31.31, $I = (9\text{ V})/(1.6\ \Omega) = 5.7$ A.

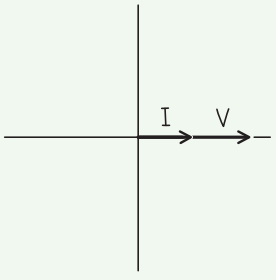
31.17 Now the resistance in the path from a to d is smaller than it is when $R_{var} = 12\ \Omega$. More charge carriers now flow from a to d, so a small number of carriers flow from b to a through the bulb to increase the current from a to d.

31.18 Because 1 A = 1 C/s and 1 V = 1 J/C = 1 A · Ω,

$$1\text{ A}\cdot\text{V} = 1\frac{\text{C}}{\text{s}}\cdot\frac{\text{J}}{\text{C}} = 1\text{ J/s} = 1\text{ W}$$

$$1\text{ A}^2\cdot\Omega = 1\text{ A}\cdot\text{A}\cdot\Omega = 1\text{ A}\cdot\text{V} = 1\text{ W}.$$

31.19 (*a*) If I travel counterclockwise around the circuit starting at *a*, the loop rule yields $6.0\text{ V} + I(0.25\ \Omega) + I(0.25\ \Omega) - 9.0\text{ V} = 0$. Solving this expression for the current again yields $I = 6.0$ A, so the answer remains unchanged (as it should because nothing has physically changed). (*b*) Because the current is the same in both batteries and because they have the same internal resistance, the rate at which energy is dissipated is also the same: $P = 9.0$ W.



Chapter 32

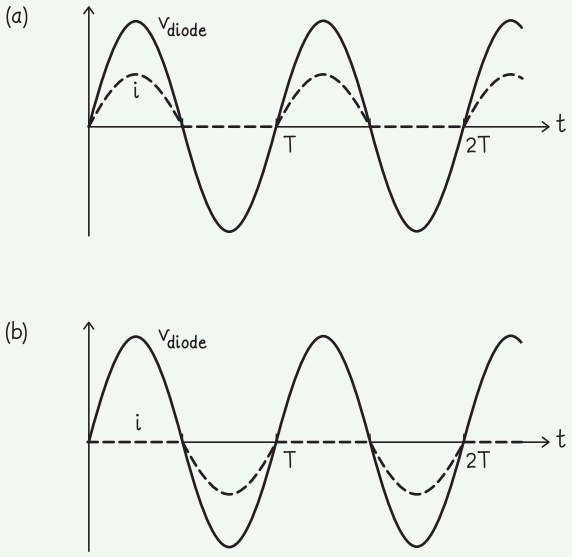
32.1 (*a*) Electric potential energy in the electric field of the capacitor. (*b*) As the capacitor discharges, that energy is converted to magnetic energy stored in the magnetic field in the inductor. (*c*) Magnetic energy in the inductor.

32.2 (*a*) Yes (see Eq. 31.43). (*b*) Energy is supplied by the AC source, and so as long as the AC source delivers energy at the rate at which it is dissipated by the resistor, the amplitudes of the current and potential difference oscillations remain constant. (Because the power is proportional to the current *squared*, the changing sign of the current does *not* imply that sometimes the resistor delivers energy to the AC source. We discuss this point in Section 32.8.)

32.3 See Figure S32.3. Because the current and potential difference are in phase with each other, the phasors V_R and I overlap as in Figure 32.13. Because v_R and i are both zero at $t = 0$ and increase as time goes on, the phasors must lie on the horizontal axis.

Figure S32.3

32.4 Figure 32.13: zero for both v_R and i. Figure 32.20: zero for i and $\pi/2$ for v_L.



32.5 A piece of doped silicon, whether *n*-type or *p*-type, is electrically neutral because the dopant atoms have the same number of protons as electrons. Although in a doped semiconductor there is either

a surplus or a deficit of electrons relative to the number of electrons in a perfect silicon lattice, there is also an equal surplus or deficit of protons in the nuclei of the dopant atoms.

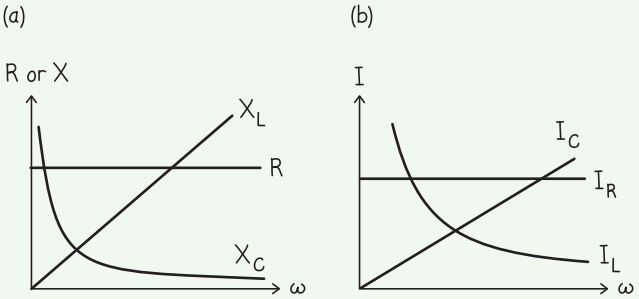
32.6 Holes travel from left to right (but only in the *p*-type region; in the *n*-type region they recombine with free electrons); simultaneously, electrons travel from right to left.

32.7 The current in the diode is in one direction only. If you assume the diode is attached in the circuit so that it conducts current only when $v_{diode} > 0$, your sketch looks like Figure S32.7*a*. If you assume the diode is attached so that it conducts current only when $v_{diode} < 0$, your sketch looks like Figure S32.7*b*.

Figure S32.7

32.8 According to the junction rule, you must have $I_b + I_c = I_e$.

32.9 The AND gate is the one in Figure 32.39*a*. Both field-effect transistors function as switches and are closed (conducting) when their gates are positively charged. If the potential at A is positive with respect to ground, transistor 1 is conducting. If the potential at B is positive with respect to ground, transistor 2 is conducting. Because the transistors are connected in series, both must be conducting in order for the output potential to be different from ground, and so both A and B must be positive to obtain a nonzero output.



The OR gate is the one in Figure 32.39*b*. Again, the two transistors function as switches, but this time they are connected in parallel. Therefore only one of them needs to be conducting in order for the output potential to be nonzero, and so if either A or B (or both) is positive we obtain a nonzero output.

32.10 (*a*) Higher. (*b*) Because R is always positive, Eq. 32.2 tells you that v_R must be positive when i is positive. According to Eq. 32.3, $\mathscr{E}$ is positive, too. Given that v_R is positive and that $v_a > v_b$, you must have $v_R = v_a - v_b$. (*c*) Because the current is now negative, v_R and $\mathscr{E}$ must be negative, too. (Indeed, with the current now running counterclockwise, v_a is now smaller than v_b.) The potential difference across the resistor is still given by $v_R = v_a - v_b$.

32.11 The current in the circuit. The velocity of a simple harmonic oscillator is equal to the time derivative of its position. Because the potential difference v_C is proportional to the charge on the upper capacitor plate, the rate at which v_C changes—that is, the time derivative of v_C—is proportional to the rate at which the amount of charge on the plate changes, dq/dt. This quantity is the current.

32.12 See Figure S32.12. The two horizontal lines mean that the resistance and the current in the resistor do not depend on angular frequency. The hyperbolic X_C curve shows that the capacitive reactance is inversely proportional to ω (Eq. 32.14). Consequently the amplitude of the current in the capacitor is directly proportional to ω, which means the I_C curve has a constant slope. The straight, positive-slope X_L curve means that the inductive reactance is directly proportional to ω (Eq. 32.26); consequently the current in the inductor is inversely proportional to ω, as shown by the hyperbolic I_L curve.

Figure S32.12

32.13 No. You cannot use the phasor method because the two phasors for the potential differences do not rotate as a unit with a constant phase difference.

32.14 We analyze this circuit as we did in Example 32.8, except that now $V_{out} = V_C$ instead of $V_{out} = V_R$. To take the high-ω and low-ω limits of V_{out}, we rewrite Eq. 32.36 as

$$V_{out} = V_C = \frac{\mathscr{E}_{max}}{\sqrt{\omega^2 R^2 C^2 + 1}}.$$

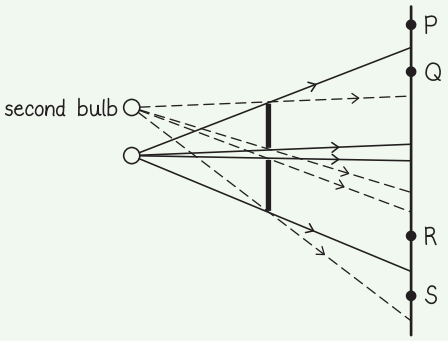
The low-ω limit of V_{out} is then $V_{out} = \mathscr{E}_{max}$, while the high-$\omega$ limit is $V_{out} = \mathscr{E}_{max}/\omega RC$, which approaches zero for large ω. This circuit therefore passes low-frequency signals essentially unchanged and attenuates high-frequency signals.

32.15 (*a*) The maximum potential differences can be found from the maximum current (using Eqs. 32.6, 32.13, and 32.24). Rounding off to two significant digits, you have $V_R = IR = 1.6 \times 10^2$ V, $V_L = I\omega L = 3.1 \times 10^2$ V, and $V_C = I/\omega C = 3.1 \times 10^2$ V.

(*b*) No. $(V_R + V_L + V_C) \gg \mathscr{E}_{max}$ because the potential differences are not in phase and are never simultaneously at their maxima.

32.16 Changing L or C while keeping R constant changes the resonant angular frequency (unless both L and C are changed in such a way that their product remains constant) and can change the shape of the $I(\omega)$ curve. Increasing C while keeping L fixed broadens the curve, and increasing L while keeping C fixed sharpens the curve. Because it depends only on R and on the applied emf, the amplitude of the current at resonance is not affected by the values of L or C.

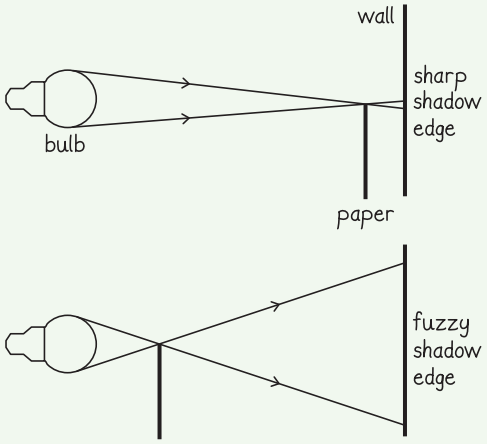
32.17 Above, because when $V_L > V_C$, the inductor dominates the reactance.



32.18 We substitute the answers from Example 32.10 into Eq. 32.52:

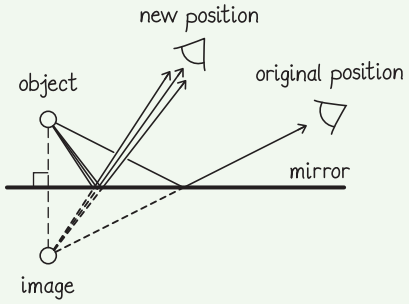
$$P_{av} = I_{rms}^2 R = \frac{I^2}{(\sqrt{2})^2} R = \frac{(3.2\text{ A})^2(50\ \Omega)}{2} = 2.6 \times 10^2\text{ W}.$$

Chapter 33



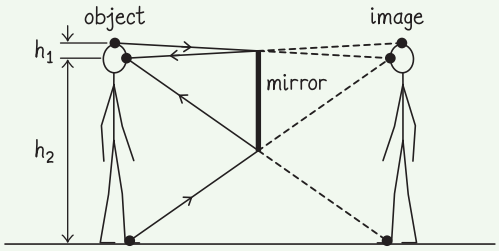
33.1 (*a*) See Figure S33.1. In considering whether the brightness of any location on the screen has changed, note that the distribution of light from the first bulb has not changed, which means the brightness of a particular location changes only if additional light is cast on that location by the second bulb. If the second bulb does not cast light on a particular location, the brightness does not change. (The fact that a given location would be shadowed if it were illuminated by only the second bulb does not decrease the brightness of the light from the first bulb.) The brightness of the spot created by the first bulb does not change because no light from the second bulb strikes this spot. (*b*) Locations P and Q are now brighter than before because some light from the second bulb strikes them. Locations R and S are unaffected because no light from the second bulb reaches them.

Figure S33.1



33.2 See Figure S33.2. The shadow edges become sharper as you move the paper farther from the bulb and fuzzier as you move the paper closer to the bulb. This happens because the bulb is not a point source of light. Rays from different parts of the bulb's surface pass by the edge of the paper at slightly different angles. When the paper is farther from the bulb, the difference in these angles is less and so the edge of the shadow is sharper. When the paper is close to the bulb, the angular size of the filament (as seen from the edge) is greater, which makes the edge of the shadow fuzzier.

Figure S33.2

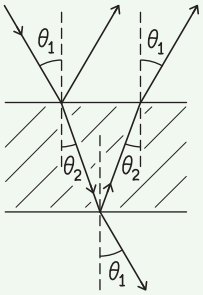


33.3 No. Figure S33.3 shows the reflected rays that reach the observer in the two locations. Because the angle of incidence always equals the angle of reflection when the reflecting surface is smooth, any ray from the object that reflects anywhere on the mirror can be traced back through the mirror to a location directly behind the object. Moving the observer changes only which subset of the reflected rays the observer sees and not where the rays appear to come from.

Figure S33.3

33.4 No. Figure S33.4 shows the rays that reflect into the person's eye from the highest and lowest points on his body. These rays strike the mirror at a height midway between where they originate on the person and the person's eye. So the mirror needs to extend only from halfway between the person's eye and the highest point on the person's body to halfway between the person's eye and the lowest point on the person's body. The ray from the highest point strikes the mirror at a height midway between the height h_1 in Figure S33.4 at which the ray originates and the height at which it strikes the eye, and the same is true for the ray from the lowest point. So the top of the mirror can be at a height that is half the height h_1 above the height of the eye, and the bottom of the mirror can be at a height that is half the height h_2 below the height of the eye. Because $h_1 + h_2$ is the person's height, this means the mirror needs to be only half this height. (However, the mirror must be positioned at the right height.)

Figure S33.4



33.5 The wavefronts arrive at a given location in the glass at the same frequency that they arrive at any location in vacuum. However, they travel only two-thirds as fast in the glass as in vacuum. Sequential wavefronts arrive at the glass surface at instants separated by the period T of the wave ($T = 1/f$). If the wave traveled at the same speed in glass as it does in vacuum, then during one period, one wavefront would travel a distance into the glass equal to the vacuum wavelength (400 nm) before the next wavefront arrived at the surface of the glass, and the wavefronts would be separated by 400 nm. However, because the wavefronts travel at only two-thirds the speed of light in vacuum, the spacing between wavefronts in the glass must be two-thirds of the vacuum wavelength, or 267 nm.

33.6 The propagation of the wavefronts is exactly like that shown in Figure 33.16*a* with the direction of propagation reversed. Consequently, because the angle of incidence equals θ_2, the angle of refraction must equal θ_1.

33.7 The angle between the ray reflected from the bottom surface and the normal is θ_2, as shown in Figure S33.7. This ray is now incident at the top surface and refracted as it emerges into the air. This is equivalent to the situation shown in Figure 33.17*b*, in which the ray originates in the glass and is refracted in the air. Therefore, as discussed in Example 33.3, in air the angle this refracted ray makes with the normal is θ_1. Note in Figure S33.7 that this refracted ray is shifted sideways relative to the ray *reflected* from the top surface.

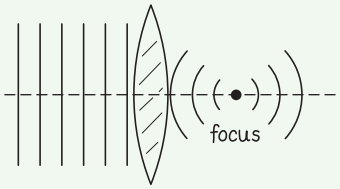


Figure S33.7

33.8 The critical angle corresponds to the angle of incidence for which the angle of refraction is 90°. When entering the medium, to obtain a given angle of refraction, the angle of incidence of a violet ray must be greater than that of a red ray; therefore the critical angle is smaller for a violet ray than for a red ray.

33.9 See Figure S33.9. The wavefronts are perpendicular to the light rays everywhere.

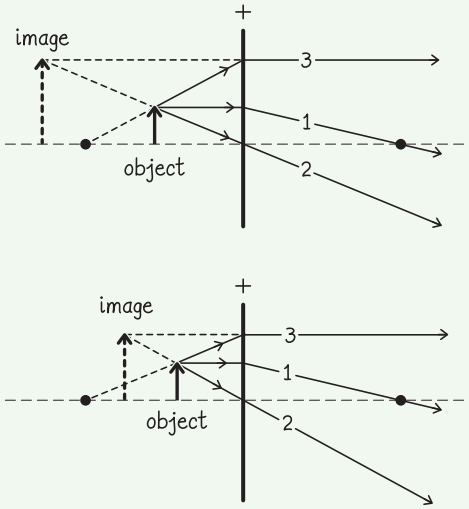

Figure S33.9

33.10 No. The image location can be found with any two of the three principal rays. Because all three intersect at one point, any two of them indicate the point of intersection and therefore the image location. It is, however, useful to draw all three rays in order to check that you have made no mistakes.

33.11 Decrease. See Figure S33.11. As the object moves closer to the lens, ray 3 makes a smaller angle with the lens axis and thus intercepts the lens closer to the axis. Ray 1 remains the same, and ray 2 makes a greater angle with the axis in order to pass through the center of the lens. As a result, the image point—the virtual intersection of the rays—is closer to the axis (as well as the lens), making the image smaller.

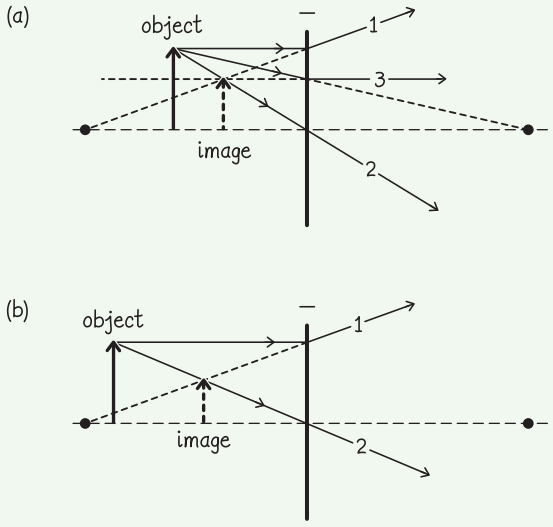

Figure S33.11

33.12 Virtual, because the rays do not actually intersect anywhere on the image. They merely appear to originate from a common point on the virtual image.

33.13 (*a*) See Figure S33.13*a*. You draw ray 3 by first drawing a line connecting the point of interest on the object with the focus on the side of the lens opposite the object. Run ray 3 along this line from the object to the lens surface; then change the ray direction so that it emerges parallel to the lens axis. (*b*) There is no position for which the image is larger than the object. To see why, all you need to consider is principal rays 1 and 2. When the object is moved, the direction of ray 1 does not change—only ray 2 changes direction. When the object is moved to the left, as in Figure S33.13*b*, ray 2 now intersects ray 1 closer to the lens axis and the image is smaller. Moving the object right, toward the lens, makes the image larger, but it cannot become larger than the object because, on the left side of the lens where the image forms, ray 1 is always below the tip of the object. As shown in Figure 33.33, placing the object beyond the object-side focus also produces an image that is smaller than the object. (*c*) It is not possible to form a real image with a diverging lens because rays diverge when they go through it.

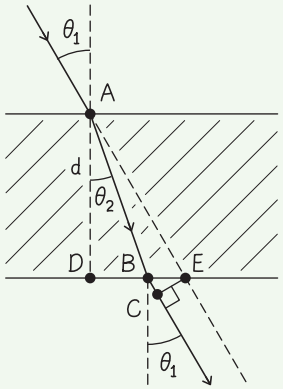

Figure S33.13

33.14 See Figure S33.14. (*a*) You need to determine the distance CE in terms of the angle of incidence θ_1, slab thickness d = AD, and slab index of refraction n_2. Angle CBE = $90° - \theta_1$, and so angle BEC = θ_1. Therefore CE = BE cos θ_1. To determine the distance BE, you can say DB + BE = DE, DE = d tan θ_1, and DB = d tan θ_2.

Substituting the second and third expressions in the first, you obtain d tan θ_2 + BE = d tan θ_1, which can be solved for BE:

Figure S33.14

$$\text{BE} = d(\tan\theta_1 - \tan\theta_2) = d\left(\frac{\sin\theta_1}{\cos\theta_1} - \frac{\sin\theta_2}{\cos\theta_2}\right). \qquad (1)$$

Applying Snel's law (Eq. 33.7) to this case and solving Eq. 33.7 for $\sin\theta_2$ gives you $\sin\theta_2 = n_1 \sin\theta_1/n_2$. Next you can use the identity $\sin^2\theta + \cos^2\theta = 1$ to get an expression for $\cos\theta_2$:

$$\cos\theta_2 = \sqrt{1 - \sin^2\theta_2} = \sqrt{1 - \left(\frac{n_1 \sin\theta_1}{n_2}\right)^2}.$$

You can substitute these expressions for $\sin\theta_2$ and $\cos\theta_2$ into Eq. 1:

$$\text{BE} = d\left[\frac{\sin\theta_1}{\cos\theta_1} - \frac{n_1 \sin\theta_1}{n_2\sqrt{1 - \left(\frac{n_1 \sin\theta_1}{n_2}\right)^2}}\right],$$

which simplifies to

$$\text{BE} = d\sin\theta_1\left(\frac{1}{\cos\theta_1} - \frac{n_1}{\sqrt{n_2^2 - n_1^2\sin^2\theta_1}}\right).$$

From this you can determine the distance CE:

$$\text{CE} = \text{BE}\cos\theta_1 = d\sin\theta_1\left(1 - \frac{n_1\cos\theta_1}{\sqrt{n_2^2 - n_1^2\sin^2\theta_1}}\right).$$

$$(b)\ \text{CE} = (0.010\text{ m})(0.50)\left(1 - \frac{(1)(0.87)}{\sqrt{(1.5)^2 - (1)^2(0.5)^2}}\right)$$

$$= 0.0019\text{ m}.$$

Thus, at an angle of incidence of 30°, in passing through a glass slab that is 10 mm thick (about three times the thickness of a typical windowpane), a light ray is shifted sideways by 2 mm (20% of the thickness of the slab).

33.15 (*a*) f is negative (lens is diverging), so $f = -80$ mm; o is positive (object is on same side as illumination), so $o = 100$ mm. Substituting these values into Eq. 33.16 gives

$$\frac{1}{i} = \frac{1}{-80\text{ mm}} - \frac{1}{100\text{ mm}} = -0.0225\text{ mm}^{-1},$$

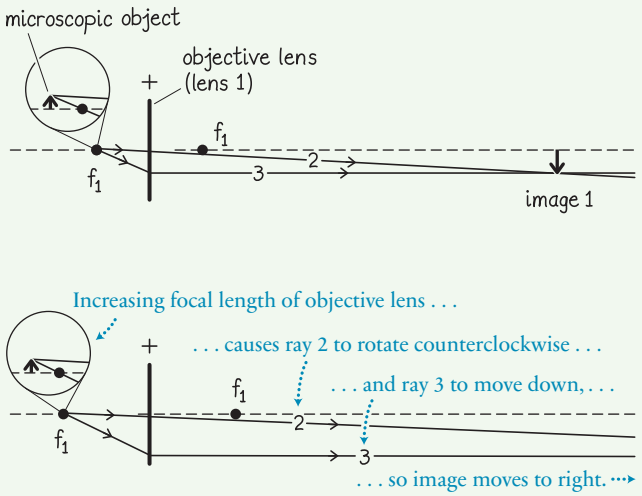
and solving for i gives $i = -44$ mm. The value of i is negative, as it should be for a virtual image, and the absolute value of i is less than o, which is consistent with Figure 33.33.

(*b*) Equation 33.17 gives

$$M = \frac{h_i}{h_o} = \frac{-i}{o} = \frac{-(-44\text{ mm})}{100\text{ mm}} = 0.44.$$

The image height is 44% of the object height.

33.16 (*a*) Solving Eq. 33.21 for f gives $f = (0.25\text{ m})/M_\theta$, and substituting this result into Eq. 33.22 gives $d = 4M_\theta$. For $M_\theta = 8$, you have $d = +32$ diopters.



(*b*) $f = (0.25\text{ m})/M_\theta = (0.25\text{ m})/8 = 0.031\text{ m} = 31\text{ mm}$.

33.17 (*a*) The image moves farther from the objective lens. This can be seen either by constructing a ray diagram (Figure S33.17) or by considering the relationship among object distance, image distance, and focal length (Eq. 33.16). Solving Eq. 33.16 for i_1 gives

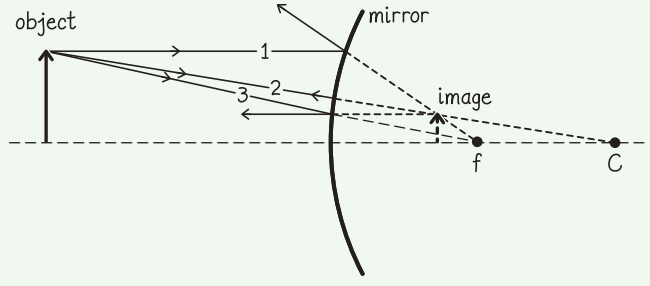
$$\frac{1}{i_1} = \frac{1}{f_1} - \frac{1}{o_1} = \frac{o_1 - f_1}{o_1 f_1} \text{ or } i_1 = \frac{o_1 f_1}{o_1 - f_1}.$$

Increasing both o_1 and f_1 will increase the numerator of the expression for i_1; keeping the sample "just outside the focal point" of the lens implies that the distance between the sample and the lens, $o_1 - f_1$, is kept at least roughly the same, so increasing the numerator while keeping the denominator constant increases i_1. (Practical limitations on the construction of lenses actually allow the distance $o_1 - f_1$ to be smaller for shorter-focal-length lenses, so in fact, the denominator also increases as the focal length increases. However, this last effect is not a consequence of the simple thin-lens treatment but of ways that lenses are not ideal that are beyond the scope of this text.)

Figure S33.17

(*b*) Shorter focal lengths give a more compact microscope, because the first image must fall close to the focal point of the eyepiece lens, and thus the distance between the two lenses is roughly $i_1 + f_2$. From part *a* we know that i_1 depends on f_1, and so decreasing f_1 decreases i_1.

33.18 (*a*) Using the result of Example 33.9 gives you $f_1 = M_\theta f_2 = (22)(0.0400\text{ m}) = 0.88$ m.



(*b*) The length of the telescope is roughly the sum of the focal lengths of the two lenses (see Figure 33.50): 0.88 m + 0.04 m = 0.92 m. Because the eyepiece lens is by design a short-focal-length lens, the length of the telescope is determined primarily by the focal length of the objective lens.

33.19 (*a*) The ray diagram in Figure S33.19 shows that the image is behind the mirror and virtual. You calculate the image distance with Eq. 33.24. The focal length is half the radius of curvature, C = 1.0 m, and is negative because it is a virtual focus:

$$i = \left(\frac{1}{f} - \frac{1}{o}\right)^{-1} = \left(\frac{1}{-0.50} - \frac{1}{1.0}\right)^{-1} = -0.33\text{ m}.$$

The negative value for i tells you that the image is located 0.33 m behind the mirror.

Figure S33.19

(*b*) $h_i = -\dfrac{h_o i}{o} = -\dfrac{(0.30\text{ m})(-0.33\text{ m})}{(1.0\text{ m})} = 0.10\text{ m}.$

The image is smaller than the object, and the positive value for h tells you that the image is upright.

33.20 The only change to the physics behind the derivation of the lensmaker's formula is that Eq. 33.25 becomes $n_1 \sin\theta_i = n_2 \sin\theta_r$. In the paraxial approximation, this result can be written as $(n_1/n_2)\theta_i = \theta_r$. Comparing this with Eq. 33.26, you see that the effect of submerging the lens is to substitute (n_1/n_2) for n. Once you make this change in the remainder of the derivation, the lensmaker's formula becomes $\frac{1}{f} = \left(\frac{n_1}{n_2} - 1\right)\left(\frac{1}{R_1} + \frac{1}{R_2}\right)$.

Chapter 34

34.1 Once the fronts reach P, the intensity at P is the same as the intensity at any point on any of the wavefronts. For any point R above or below the ray through P, you can locate a corresponding point R′ for which the distance R′P is exactly half a wavelength greater than the distance RP. Those points therefore do not contribute to the intensity at P. Only the point exactly on the ray (dashed line) contributes.

34.2 If you identify pairs of points that radiate in phase at P, then, for each pair, there exists another pair that is exactly 180° out of phase with the first pair and thus cancels the radiation from the first pair.

34.3 (*a*) The spacing between fringes decreases as the separation between the slits increases because $\sin\theta$ is proportional to $1/d$. (*b*) The spacing between fringes increases as the wavelength increases because $\sin\theta$ is proportional to λ.

34.4 No. Two of the waves cancel each other perfectly, but the third wave is not canceled. The intensity observed on the screen, at angles given by $d \sin\theta = \pm(n - \frac{1}{2})\lambda$, is the intensity of one of the three waves.

34.5 Fringe brightness is determined by the intensity (power/area) that strikes the screen. Increasing the number of slits increases the amount of power that travels through the slits to the screen. In addition, increasing the number of slits causes the fringes to sharpen, with the result that the power that reaches the screen is concentrated into narrower fringes, decreasing the area and thus increasing the brightness further.

34.6 (*a*) As you found in Checkpoint 34.3, the angle of the fringes increases with wavelength, and so the angle is less for violet light than for red. White light is thus dispersed into a rainbow, with the violet end of the spectrum at smaller angles than the red. (*b*) Each rainbow corresponds to the fringes of a particular order for all colors, or said another way, each order produces its own rainbow.

34.7 (*a*) The spacing between fringes in a two-slit interference pattern increases with increasing wavelength and with decreasing distance between slits (see Checkpoint 34.3). The same is true for diffraction gratings: The separation distance between adjacent fringes is increased by decreasing the separation distance between adjacent slits. Therefore the distance between adjacent slits should be decreased if your aim is to increase the diffraction grating's ability to separate close wavelengths. (*b*) No, as long as the slits are very narrow. The fringe spacing is determined entirely by the separation distance between adjacent slits. (Slit width does, however, affect the brightness of the pattern by determining how much light gets through the diffraction grating.)

34.8 Yes. The diffracted x rays interfere constructively at all angles for which the difference in path length is either zero (as it is for $\theta' = \theta$) or an integer multiple of λ. The diffracted beam at $\theta' = \theta$ corresponds to the zeroth-order maximum; other beams correspond to higher orders and are much weaker.

34.9 From Figure 34.20*b* you can see that $2\theta + 2\alpha = \pi$, so $\theta = -\alpha + \frac{\pi}{2}$. Using trigonometry, I get $\cos\theta = \cos(-\alpha + \frac{\pi}{2}) = -\sin(-\alpha) = \sin\alpha$. Substituting this into the Bragg condition yields $2d \sin\alpha = m\lambda$.

34.10 Crystal B. Spots closer together correspond to greater distances between crystal planes and hence greater atomic spacing.

34.11 It decreases, because the spacing between spots is proportional to the wavelength.

34.12 If the electrons travel more slowly, their wavelength increases, and the diffraction spots spread farther apart.

34.13 You could perform the experiment shown in Figure 34.6 with a light source so weak that the light "particles" pass through the pair of slits only one at a time. If light indeed has particle properties, a source this weak would give you a pattern that initially is like the one in Figure 34.25*a*, showing where individual particles of light hit the screen.

34.14 The maximum probability is at the locations of greatest intensity in the interference pattern; these locations are at angles θ for which $\sin\theta$ is a multiple of λ/d.

34.15 Although the maximum time-averaged intensity is greater than the sum of the intensities of the original two beams, averaging this time-averaged intensity over the entire area filled by the bright and dark bands of the interference pattern gives just the sum of the intensities of the original two beams, $2S_{0,av}$ (because the average of the cosine squared is one-half).

34.16 No, because the higher-order bright fringes exist only as long as $m\lambda/d < 1$. For values of m such that $m\lambda/d > 1$, there are no bright fringes because these correspond to $\sin\theta_m > 1$, for which there is no angle θ_m.

34.17 The oil forms a thin film that causes thin-film interference. The thickness of the oil layer determines for which wavelength constructive interference occurs. If the thickness of the film varies spatially, different wavelengths interfere constructively at different locations.

34.18 (*a*) If $a < \lambda$, there are no dark fringes because that would require $\sin\theta > 1$. This indicates that no minimum exists, and the light coming through an aperture with a diameter less than the wavelength acts as a true point source as assumed in our original discussion of multiple-slit interference. When $a < \lambda$, the slit acts as a point source with the wavelets spreading out spherically from the slit. (*b*) For $a \gg \lambda$, the first dark fringe occurs very close to $\theta = 0$. This means there is essentially no diffraction, and the beam just propagates straight ahead. This illustrates that single-slit diffraction is observed primarily with slits from a few wavelengths wide to tens of wavelengths wide.

34.19 Resolution is determined by wavelength and the ratio f/d: $y_r = 1.22\,\lambda f/d$. For a given wavelength, the greater f/d is, the larger the Airy disk. For the three lenses, f/d is (*i*) 1.3, (*ii*) 1.5, and (*iii*) 1.1. (*a*) The highest resolution is obtained with the smallest Airy disk, produced by lens *iii*. (*b*) The lowest resolution is obtained with the largest Airy disk, produced by lens *ii*. (The wavelength determines the exact size of the Airy disk; the comparisons made here assume the same wavelength for all three lenses.)

34.20 (*a*) The stopping potential difference V_{stop} is proportional to the frequency (Figure 34.48*b*) of the incident photons, and the maximum kinetic energy K_{max} of the ejected electrons is proportional to V_{stop} (Eq. 34.34). Therefore, K_{max} must be proportional to the frequency of the incident photons. (*b*) The minimum frequency the light can have and be able to eject electrons. Lower-frequency light does not eject electrons.

34.21 (*a*) The photon slows down because the speed of light is less in a medium that has an index of refraction of 1.5 than in air (index of refraction 1). (*b*) The frequency remains unchanged, as discussed in Chapter 33. (*c*) The wavelength decreases because the wavefronts travel less far in a given time interval. (*d*) The photon's energy does not change because the medium does not take away any energy. This is why photon energy must be expressed in terms of frequency rather than wavelength, because neither frequency nor energy depends on the medium, whereas wavelength does.

Index

A

Absolute temperature, 686
Absolute time, 26
Absolute zero, 708
Absorbed light, 1166–1169
Acceleration, 87–115
  average, 87, 96, 104
  of car, 92, 98–99, 104
  centripetal, 427–428, 434
  of closed system, 231–232
  collision and, avoiding, 99
  constant, motion with, 90, 96–99
  definition of, 87
  direction of, 87
  displacement and, 89–90, 105–106
  due to gravity, 88–90, 99–100, 102
  in electric field, 820, 822
  in electric potential energy, 879–880
  free-fall equations, 99–102
  in Galilean transformation equations, 190
  on inclined planes, 102–103
  instantaneous, 103–106, 318–319
  interactions and, 228
  magnitude of, 87, 88
  motion diagrams, 92–94
  nonzero, 92, 131, 822
  of object in free fall, 89–91
  projectile motion and, 90–92
  in rolling motion, 406–407
  symbol for, 87
  translational equilibrium and, 251–252
  unit of, 87
  velocity and, changes in, 87–88
  x components of
    average acceleration and, 87, 96, 104
    constant acceleration and, 96
    curvature of *x(t)* curve related to, 88
    due to gravity, 90, 100
    inclined planes and, 102–103
    instantaneous acceleration and, 104–105
    in projectile motion, 92
Acceleration-*versus*-time graphs, 131
AC circuits, 1124–1128
  power in, 1150–1152
  with two resistors, 1137
AC source, 1124
Action at a distance, 814, 820
Addition
  significant digits in, 37
  of vectors, 69, 317
Adhesive forces, 632
Adiabatic processes, 703, 717
Adiabats, 717
Airy, Sir George, 1231
Airy disk, 1231–1233
Alternating currents, 1122–1124
Altimeter, 636
Ammeter, 1101, 1151
Ampère, Marie, 987
Ampère's law, 987–990
Ampèrian paths, 983–985
Amplitude, 1136
  of waves in one dimension, 559, 569
  of waves in two and three dimensions, 583, 589, 592
AND gate, 1134
Andromeda Galaxy, 463
Angle of incidence, 1166–1173, 1180–1182
Angle of reflection, 1166–1167, 1169, 1171, 1173
Angle of refraction, 1170–1172, 1180–1181
Angular coordinate, 326
Angular momentum, 367–372
  conservation of, 400–404, 434
  gravity and, 431–434
  torque and, 389–392
Angular momentum law, 402
Antennas, 1049–1053
Antineutrino, 793
Antinodes, 562
Aphelion, 429
Apparently weightless, 437
Apparent weight, 437
Archimedes' principle, 623
Area, 71
Area vector, 858
Assumptions, hidden, 21
Atmospheres, pressure given in, 635
Atmospheric pressure, 635–636, 641–642
Atom, 24
  core of, 1128
  substitute, 1129
  valence electrons, 1128–1130
Atomic potential difference, 891–892
Attractive interactions, 212
Attributes, 222
Audible frequency range, 585
Automobile battery, 918
Average acceleration, 87, 96, 104
Average power, 567
Average speed, 59–62
Average velocity, 59–62
Avogadro's number, 33
Axial vectors, 398

B

Balances, 435
Barometer, 640–641
Base, 1132
Batteries, in charge separation and storage, 917–919
Beat frequency, 601
Beating, 599–601
Bernoulli effect, 627
Bernoulli's equation, 644–647
Beta decay, 792–793
Bias potential difference (or bias), 1133–1134
Binomial series expansion, 827
Blood flow, 650
Boltzmann constant, 686
Boulder-Earth system, 216
Boundary effects, 550–554
Bragg angle, 1215–1216
Bragg condition, 1216
Brahe, Tycho, 433
Brayton cycle, 757–759, 770–772
Breakdown threshold, 913–914
Broken chemical bonds, 221
Brownian motion, 665–666
Bulk stress, 617, 618, 619
Buoyancy, fluids and, 622–624

C

Calculus, to determine displacement, 106
Calibrating graphs, 55–56
Candela, 33
Capacitance, 921–924
Capacitors, 911–915
  in charge separation and storage, 911–915
  coaxial, 923–924
  definition of, 911
  with dielectrics, 930–931
  fully charged, 912
  isolated, 912
  magnetic field in, 1057–1058
  metal-slab, 914–915
  parallel-plate, 911–914, 922
  power of, 1070–1071
  spherical, 924
Capillary rise, 633
Capillary tube, 632–633
Carnot, Sadi, 757
Carnot cycle, 757–759, 768–770
Cartesian coordinate system, 317, 326, 898
Causal relationship, 26
Cavendish, Henry, 442–443
Celestial mechanics, 446–451
Cell potential difference, 918
Celsius scale, 708, 709
Center of mass, 193–197
  importance of, 196
  position of, 195–196
  reference frames and, 193–194
  velocity and, 195
Center-of-mass velocity, 195
Central electric force, 799
Centripetal acceleration, 427–428, 434
Change, time and, 26
Chapter summary, overview of, 30
Charge carriers, 785
  force exerted by distributions of, 800–803
  mobility of, 788–793
Charged conducting objects, 854–856
Charge distribution, continuous
  electric field of, 897–899
  electrostatic potentials of, 895–897
Charged particles
  in cavity, 855–856
  in electric field, 824–825
  in electric fields, 958–963, 1046–1049
  in magnetic fields, 996–999
  in motion, magnetic fields of, 976–1010
    Ampère's law, 987–990
    Ampèrian paths, 983–985

Charged particles (*continued*)
current loops and spin magnetism, 978–980
magnetic dipole moment and torque, 980–983
magnetic field of moving charged particle, 996–999
magnetic fields due to currents, 993–996
solenoids, 990–991
source of magnetic field, 977–978
toroids, 991–992
trajectory, 820–821
Charge flow, magnetism and, 946–949
Charge polarization, 793–794
Charge-separating devices, 918
Charge separation and storage, 909–940
batteries in, 917–919
capacitance and, 921–924
capacitors and, 911–915
dielectric constant and, 928–931
dielectrics and, 915–917
Gauss's law in, 931–933
in electric field energy, 925–928
emf and, 926
in Van de Graaff generators, 910–911, 913, 917, 927
in voltic cells, 917–919
Charging by induction, 794
Checkpoints, overview of, 30
Chemical bonds, broken, 221
Chemical energy, 156, 219, 221
Circuit diagram, 1082
Circuit element
definition of, 1080
resistance of, 1084
Circuits. *See* Electric circuits
Circular apertures, 1231–1234
Circular motion, 352–387
angular momentum, 367–372
at constant speed, 352–356
forces and, 356–358
rotational inertia, 358–360
of extended objects, 372–377
rotational kinematics, 362–367
Circular symmetry, 977–978
Classical mechanics, 21
Clocks
desynchronization of twins, 472
synchronizing, 462, 464–465
Closed path, 446
Closed surfaces, 849–851
Closed-system approach, 296
Closed systems, 156–158
acceleration of, 231–232
conservation of energy in, 164–166
definition of, 156
Coaxial capacitor, 923–924
Coefficients
of friction, 336–340
of restitution, 163–164
Coherent deformation, 216–218
Coherent (or mechanical) energy, 217–220, 221, 237
Coherent sources, 589–592
Cohesive forces, 628–629
Collector, 1132, 1235
Collisions
classification of, 150–151
elastic, 150, 160–162
inelastic, 150, 163–164
totally inelastic, 150–155, 163, 164, 166
momentum
conservation of momentum and, 135–140
friction and, 117–122
inertial standard and, 127–128
in isolated systems, 133
momentum changes and, 129–130
in two dimensions, 330–331
Color charge, 226
Commutator, 982
Component vectors, 326–327
Compression, 584
Compressional wave, 584
Compressive stress, 617, 618, 619
Concepts, definition of, 24
Condenser, 759
Conducting objects, charged, 854–856
Conducting plate, 866
Conduction, 790
Conductivity, 1093–1094
Conductors
capacitance of, calculating, 921
electric fields in, 1088–1090
moving, in magnetic fields, 1012–1014
Configuration state, 216
Conic sections, 447–448
Conservation
of charge, principle of, 792
of energy, 164–166
law of, 150, 153
special relativity and, 492–496
laws, 26
energy, 150, 153
for interacting objects, 181–184
momentum, 152, 201, 261
relativity and, 201–202
of momentum
angular, 400–404, 434
in collisions, 129–130
in interactions, 135–140
law of, 152
special relativity and, 488–492
in reference frames, 177
in inertial reference frames, 180–181
in interacting objects, 181–184
relativity and, 201–202
in zero-momentum reference frames, 186
Constant acceleration, motion with, 96–99
Constant velocity, 87, 88, 90, 96, 98, 179
Constrained quasistatic processes, 717
Constraints, on systems, 123–124
Constructive interference, 549
Contact angle, 632
Contact forces, 250, 253
Context-rich (CR) problems, 30
Continuity equation, 645
Continuous charge distribution
electric field of, 897–899
electrostatic potentials of, 895–897
Contraction, length, 484–488
Converging lens, 1173–1177, 1183–1186
Conversion factors, 34–35
Convertible kinetic energy, 198–201
Converting energy, 743–746
Convex surface, 1173
Coordinates, in motion, 316
Coulomb (C), 797–798
Coulomb, Charles, 796, 797
Coulomb's law, 796–800, 801, 824, 827, 846, 860
Counting numbers, 37
Creation
to change value of extensive quantity, 123–124
of momentum, 135, 137
Critical angle, 1171–1172, 1181
Crossed wires, 985
Crystal lattice, 1214
Crystalline, 1214
Crystal monochromator, 1216
Current-carrying rods, 949
Current-carrying wire, 947–948, 977–978, 980, 983–985, 988–989, 993–996
Current density, 1093–1094
Current loops, spin magnetism and, 978–980
Current loop torque, 981–982
Currents
alternating, 1122–1124
magnetic fields due to, 993–996
magnetism and, 954–956
resistance and, 1082–1084
Curvature, radius of, 630–631
Curve up/curve down, 88
Cutoff angular frequency, 1144
Cycle, 745
Cycloid, 405
Cylindrical symmetry, 853–854

D

Damped oscillations, 527–529
Damping, 506
Damping coefficient, 528
Damping force, 527–528
DC circuits, 1136
De Broglie, Louis, 1218
De Broglie wavelength, 1218
Deceleration, 87
Decimal places, 37
Decomposition
of forces, 319–322
of vectors, 317–319
Deductive reasoning, 22
Deformable objects, 271
Deformation
coherent and incoherent, 216–218
elastic restoring force and, 520
force and, 251, 256
in fluids, 617
friction and, 323
of macro-sized objects, 271
pressure and, 640
in simple harmonic motion, 520, 568
of spring scale, 435
Degree of freedom, 710
Degrees Celsius, 708
Degrees Fahrenheit, 708
Demagnetized clip, 943
Density, 33
Depletion zone, 1130
Destruction

to change value of extensive quantity, 123–124
of momentum, 135, 137
Destructive interference, 549
Desynchronization of twin clocks, 472
Diagrams, electric field, 816–817
Dielectric constant, 928–931
Dielectrics
capacitor with, 930–931
in charge separation and storage, 915–917
Gauss's law in, 931–932
properties of, 928
Diffraction, 592–594
of light, 1208–1210
at single-slit barrier, 1229–1231
X-ray, 1213–1217
Diffraction gratings, 1210–1213, 1226–1227
Diffraction limit, 1233
Dilation, time, 479–484
Diodes, 1130–1132
Diopters, 1186
Dipole, 832–835
charge, 825–826
electrostatic potential and electric field due to, 899
field, 825–827
flux of, 851
induced, 834
moment, 821–822, 826–827, 833–835
oscillating, 1049–1053
permanent, 821, 822
right-hand dipole rule, 980
separation, 825–826
Dipole antenna, 1053
Direct current, 1122
Direct integration, 863
Direction
of current, 947, 1097
of time, 26
Discharged strip, 786
Dispersion, 1172
Displaced volume of fluid, 623, 639
Displacement, 55–57
calculus to determine, 106
distance traveled and, 57–61, 66, 68
magnitude of, 89–90
in motion in a plane
vectors in a plane, 316–319
work and friction, 324
work as product of two vectors, 331–335
of waves, 541–544, 546–550
in one dimension, 541–544, 546–550
in two and three dimensions, 581, 585–592
working with, 67–68
x component of, 56–57
Displacement current, in changing electric fields, 1055–1059
Displacement curve, 542
Displacement vector, 55–57, 66–70
Dissipative interactions, 216–219, 220, 221, 235–238
Distance, definition of, 66
Distance traveled, 57–61, 66, 68
Distributed forces, 300–303
Diverging lens, 1176–1177
Division, significant digits in, 37
Dopants, 1129
Doppler effect, 474, 602–607
Dozen, 33
Drag force, 528
Drain, 1133
Drift speed, 1093
Drift velocity, 1092–1093
Drude, P. K., 1092
Drude model, 1092

E

Earth
centripetal acceleration and, 426
gravitational force of, 426–430, 450
intensity of Sun's radiation on surface of, 1069–1070
North pole, pole attracted to, 942
orbit of, 426–427
satellites orbiting, 446–447
solar system data relative to, 430
surface of
gravitational potential energy near, 444–445
potential energy near, 232–234
weighing, 443
Earth-boulder system, 216
Earth reference frame, 177
center of mass and, 193–194
convertible kinetic energy and, 198–199
definition of, 177
Galilean relativity and, 190, 191
inertial reference frames and, 179–181
principle of relativity and, 182–184, 186
relativity of motion and, 177–179
zero-momentum reference frame and, 186–187
Eddy currents, 1019
Effective weight, 437
Einstein, Albert, 177, 462
Elastic collision, 150, 154, 160–162
Elastic limit, 255
Elastic potential energy, 216
Elastic range, 255
Elastic restoring force, 520
Electrical breakdown, 913
Electrical charge, 225, 785–788
Electrical charge symmetry, 24
Electrical conductors, 790
Electrical insulator, 789
Electrical measuring instruments, 1101
Electric circuits, 1079–1120
AC, 1124–1128, 1150–1152
basic circuit, 1080–1082
current and resistance, 1082–1084
electric fields in conductors, 1088–1090
energy conversion in, 1080–1084, 1098, 1106–1108
junctions and, 1084–1087
multiloop circuits, 1084–1087, 1101–1106
power in, 1106–1108, 1150–1152
RC series, 1141–1145, 1147–1148
resistance and Ohm's law, 1092–1096
RLC series, 1145–1146, 1148
single-loop circuits, 1096–1101
Electric constant, 860
Electric dipole. *See* Dipole
Electric field diagrams, 816–817
Electric field energy
charge separation and storage in, 925–928
emf and, 926
Electric field lines, 846–848
density of, 848–849
field line flux, 850–852
field strength from, 849
of infinite charged plate, 847
properties of, 849
Electric field model, 814–816
Electric fields, 813–844. *See also* Gauss's law
acceleration in, 820
accompanying changing magnetic field, 1015–1016, 1025–1027
calculating, using Gauss's law, 864
changing, 1042–1071

  interactions in, 132–133
  momentum of, 130, 132–133
Isothermal processes, 717, 724–727
Isotherms, 714–715

J

Joule (J), 283
Joules per coulomb (J/C), 889
Junctions, electric circuits and, 1084–1087

K

Kelvin scale, 708, 709
Kepler, Johannes, 426, 428, 432–433
Kepler's laws of planetary motion, 433
Kilogram, 32, 127
Kinematics, 54. *See also* Motion
  definition of, 54
  graphs for motion types, 98
  rotational, 362–367
Kinetic energy, 151–153
  closed-system approach to determine, 296
  conservation of energy and, 164–166
  convertible, 198–201
  definition of, 151, 217
  in Earth reference frames, 198–199
  in elastic collisions, 161–162, 183
  in explosive separations, 166–167
  in inertial reference frames, 183–185, 201–202
  internal energy and, 153–156
  open-system approach to determine, 296
  relativity and, 198–201
  thermal energy converted to, 157
  translational, 198–200
  in zero momentum reference frames, 186
  zero/nonzero, 177
Kinetic friction, 323
  coefficient of, 340

L

Laminar flow, 626–627, 644–650
Laplace's law, 631, 653
Latent heat, 713
Law
  of angular momentum, 402
  definition of, 20
  of gravity, Newton's, 426–429
    Coulomb's law and, 797
    field model and, 814–815
    Kepler's laws of planetary motion and, 432–433
  of inertia, 261
  of motion, Newton's, 261
    first, 261
    second, 261
    third, 261, 262
LC circuit, 1122
Lead-acid cell, 918
Leading zeros, 36
Leads, 1090
Length
  contraction, 474, 484–488
  definition of, 24
  in Galilean transformation equations, 190
  measurements at high speeds, 486
  object's proper, 473
  relaxed, 255
  standard unit for, 24
Length contraction, 474, 484–488
Lens, 1173
  converging, 1173–1177, 1183–1186
  diverging, 1176
  magnification of, 1184–1190
  simplified ray diagrams for, 1175
  strength, 1186
  thin, 1183–1186
Lensmaker's formula, 1193–1195
Lenz's law, 1016–1019
Light
  absorbed, 1166–1169
  diffracted, 1208–1210
  dispersed, 1172
  reflected, 1166–1169
  refracted, 1169–1172
  speed of, 466–467, 469, 474, 483–484
  transmitted, 1166–1169
Light clock, 469
Like charges, 786
Limiting process, 76
Linear charge density, 828
Linear mass density, 553, 565–566, 568–570
Linear restoring force, 264, 512–513, 519
Line integrals, 983–984
Logic gates, 1134
Longitudinal waves, 543
Long-range interactions, 222–223
Loop rule, 1097–1098
Loops
  definition of, 1080
  in multiloop circuits, 1084–1087, 1101–1106
  in single-loop circuits, 1096–1101
Lorentz factor, 480
Lorentz transformation equations, 488
Loudness, 585

M

Mach number, 609
Macrostates, entropy and, 673–676
Magnetic constant, 987
Magnetic dipole moment, torque and, 980–983
Magnetic energy
  in changing magnetic fields, 1029–1031
  in square toroid, 1031
Magnetic field meter, 955–956
Magnetic fields, 944–946, 955
  Ampère's law for calculating, 987
  in capacitors, 1057–1058
  changing, 1011–1041
    electric field accompanying changing magnetic field, 1015–1016, 1025–1027
    Faraday's law, 1014–1015
    induced currents in, 1012–1019, 1022–123, 1025, 1027
    induced emf, 1021–1025
    inductance, 1027–1029
    Lenz's law, 1016–1019
    magnetic energy in, 1029–1031
    moving conductors in magnetic fields, 1012–1014
  of charged particles in motion, 976–1010
    Ampère's law, 987–990
    Ampèrian paths, 983–985
    current loops and spin magnetism, 978–980
    magnetic dipole moment and torque, 980–983
    magnetic field of moving charged particle, 996–999
    magnetic fields due to currents, 993–996
    solenoids, 990–991
    source of the magnetic field, 977–978
    toroids, 991–992
  of current-carrying wire, 977–978, 980, 983–985, 988–989, 993–996
  due to currents, 993–996
  generating
    by circular arc of current-carrying wire, 995
    by a large current-carrying sheet, 989
    by long straight current-carrying wire, 988, 994
    by moving electron, 997
  line integrals of, 983–984
  moving particles in, 958–963
Magnetic flux, 956–958
Magnetic interactions, 941–975
  magnetic fields, 944–946
  magnetic flux, 956–958
Magnetic materials, 943
Magnetic monopoles, 943
Magnetic poles, 942–943
Magnetism
  charge flow and, 946–949
  current and, 954–956
  definition of, 942
  electricity unified with, 963–965
  Gauss's law for, 957, 983
  Hall effect, 962–963
  as relativistic effect, 950
  relativity and, 949–952
  spin, current loops and, 978–980
Magnification, 1184–1190
Magnitude
  of acceleration, 87, 88
  of displacement, 89–90
  of drift velocity, 1093
  of electric fields, 848
  of electrostatic force, 797
  of gravitational field, 816
  sign for, 65
  of vector product, 412
  of velocity, 87, 88, 91
Manometer, 640
Many-particle systems, work on, 296–299
Mass
  center of, 193–197 (*See* Center of mass)
  definition of, 127
  densities, 34, 624
  of electrons, 961–962
  of energy, 476–477
  gravitational interactions and, 224
  gravity and, 429
  measuring, 566
  of the object, 428
  reduced, 199
  spring, 476–477
Mass density, 34, 624
Mass spectrometer, 960–961
Mathematics in physics, 35–38
Matter, 24–25
  classifying, 222
  clustering of, 25
  energy and, 474–477
  properties of, defined, 222
  relative size of, 25
  states of, 713 (*See also* States)

Matter waves, 1217–1218
Maxwell, James Clerk, 1056
Maxwell-Ampère law, 1056
Maxwell's equations, 1059–1062
Measuring instruments, electrical, 1101
Mechanical (or coherent) energy, 217–220, 221, 237
Mechanical equilibrium, 402
Mechanical waves, 540
Mechanics, celestial, 446–451
Melting, specific transformation energy for, 713, 714
Meniscus, 632–633
Metal-slab capacitor, 914–915
Meter, 24
Meters cubed per second (m^3/s), 645
Meters per second (m/s), 32
Michelson, A. A., 466
Mirrors, spherical, 1190–1193
Mobility of charge carriers, 788–793
Model
  definition of, 21
  in developing hypothesis, 21
  of real-world happening, 55
Moiré pattern, 587–588
Mole, 33
Momentum, 128–148
  angular (*See* Angular momentum)
  bounce and, 137
  change in, 129–130
  in collisions, 129–130
    conservation of momentum and, 135–140
    friction and, 117–122
    inertial standard and, 127–128
    in isolated systems, 133
    momentum changes and, 129–130
  conservation law and, 152, 201
  conservation of
    in collisions, 129–130
    in interactions, 135–140
    law of, 152, 201, 261
    special relativity and, 488–492
  creation of, 135, 137
  definition of, 128–130
  destruction of, 135, 137
  force and, 247–248
  impulse and, 137
  inertia and, 128–130
  input or output of, 132, 137
  in interactions, 132–133
  interactions in, 132–133
  of isolated systems, 130, 132–133
  photon energy, 1234–1238
  symbol for, 128
  of systems, 128–130
  time rate of change in, 247–248, 252, 259, 261, 269
  translational equilibrium and, 251–252
  in two dimensions, 330–331
  units of, 128
  as vector, 128
  velocity and, 128–129
  x component of, 128–129, 135, 138
Momentum law, 137–138
Momentum-*versus*-time graphs, 136, 140, 186
Monatomic ideal gas
  entropy of, 690–691
  properties of, 687–689
Monochromatic, 1216
Moon
  centripetal acceleration and, 427
  gravitational force of, 426–430, 450
  orbit of, 426–427
Morley, E. W., 466
Motion
  in a circle (*See* Circular motion)
  with constant acceleration, 96–99
  coordinates in, 316
  equation of, 259–262
  gravity for determining, 91
  horizontal component of, 316
  Kepler's laws of planetary, 433
  kinematics graphs for, 98
  Newton's laws of, 261
  in one dimension, 54–85
    average speed and average velocity, 59–62
    instantaneous velocity, 73–74
    motion at constant velocity, 71–73
    position and displacement vector, 55–57, 66–70
    from reality to model, 54–55
    representing motion, 57–59
    scalar and vector, 64–66
    velocity as a vector, 70–71
  orbital, 426
  phase of, 517
  in a plane, 315–350
    coefficients of friction, 336–340
    collisions and momentum in two dimensions, 330–331
    decomposition of forces, 319–322
    friction and, 322–324
    projectile motion in two dimensions, 328–330
    straight as a relative term, 315–316
    vector algebra, 326–328
    vectors in, 316–319
    work as product of two vectors, 331–335
  projectile, in two dimensions, 328–330
  at rest, 87, 92, 98
  rolling, 404–409
  rotational equation of, 400
  translational, 393, 395–396, 404–405
  types
    acceleration-*versus*-time, 131
    kinematics graphs for, 98
    momentum-*versus*-time, 136, 140, 186
    velocity *versus* time, 96, 98, 104
  vertical component of, 316
  of waves, 541
Motion, relativity of, 177–179
Motion diagrams, 92–94, 98
Moving conductors, in magnetic fields, 1012–1014
Multiloop circuits, 1084–1087, 1101–1106
Multimeter, 1101
Multiple-slit interference, 1222–1227
Multiplication
  significant digits in, 37
  of vectors, 70

N

Natural philosophy, 20
Nearsightedness, 1186
Negative charge, 787
Negative electrical charge, 225
Negative work, 284–286
Net force, 248
Neutral buoyancy, 640
Neutral equilibrium position, 511
Neutrons, 24
Newton (N), 259–260
Newton, Isaac
  law of gravity, 426–429
    Coulomb's law and, 797
    field model and, 814–815
    Kepler's laws of planetary motion and, 432–433
  laws of motion, 261
    first, 261
    second, 261
    third, 261, 262
  newton (N) in honor of, 259
  on time and change, 26
Node, 550
Nonconvertible kinetic energy, 198–199
Nondissipative processes, 220, 221, 229–232
Nonelectrostatic, 918
Noninertial reference frames, 181
Nonmechanical waves, 540
Nonparaxial rays, 1175
Nonpolar dielectric, 915
Nonrelativistic speeds, 480
Non-SI units, 34–35
Non-SI units of measure, 32, 34–35
Nonuniform electric field, 820, 821–822
Nonviscous fluids, 625–626, 644–647
Nonzero acceleration, 92, 131, 822
Normal components, 320–321
North pole, Earth's, 942
North pole of magnet, 942
Npn-type bipolar transistor, 1132–1133
N-type silicon, 1132–1133
N-type wells, 1133–1134
Nuclear energy, 219
Number density, 33

O

Object distance, 1183
Objects
  charged conducting, 854–856
  deformable, 271
  escape speed of, 451
  interacting
    conservation in, 181–184
    force in, 267–271
  mass of, 428
  in mechanical equilibrium, 402
  proper length of, 473
  shape factor of, 407
  in translational equilibrium, 402
  vector sum of forces exerted on, 393
Observer, 177
Ohmmeter, 1101
Ohm's law, 1092–1096
Ohm Ω, 1095
Open-system approach, 296

Opposite charges, 786
Optical instruments, 1186–1190
Orbital motion, 426
Orbits
  elliptical, 448
  escape speed and, 451
  hyperbolic, 448
  parabolic, 448
  planetary, 427–430
  satellite, 446–450
Order of magnitude, 24
Order-of-magnitude estimates, 42–45
Order-of-magnitude rounding, 24
Origin, 54

  definition of, 177
  inertial, 179–181
  noninertial, 181
  simultaneous events in, 465
  subscript operations for, 192
  zero-momentum, 186–187
Reflected light, 1166–1169
Reflected pulse, 550
Reflection
  angle of, 1166–1167, 1169, 1171, 1173
  total internal, 1171–1172, 1181
  of wave pulse, 551–554
Reflection symmetry, 22–23
Refraction, 1169–1172
  angle of, 1170–1172, 1180–1181
Relative speed, 150
Relativistic speeds, 480
Relativity, 177–210
  center of mass, 193–197
  conservation laws and, 201–202
  convertible kinetic energy, 198–201
  Einstein's theories of, 177
  Galilean relativity, 189–193
  inertial reference frames, 179–181
  magnetism and, 949–952
  of motion, 177–179
  principle of, 181–186
  zero-momentum reference frame, 186–187
Relativity of simultaneity, 468, 474
Relaxed length, 255
Representations, 27–29
  visual, 27–29
Repulsive forces, 628
Repulsive interactions, 212
Residual electromagnetic interactions, 225, 226
Residual strong interactions, 226
Resistance
  current and, 1082–1084
  internal, 1100
  Ohm's law and, 1092–1096
Resistance, of circuit element, 1084
Resistor, 1090
Resolution, 1226
Resolution, limits of, 1231–1234
Resonance, 1148–1149
Resonance curve, 1149
Resonant angular frequency, 1149
Restitution, coefficient of, 163–164
Restoring forces, 255, 264, 512–513
Reversible interactions, 220, 221, 229–232
Reversible processes, 153
Right-hand current rule, 947–948, 955, 980
Right-hand dipole rule, 980
Right-hand force rule, 948, 980
Right-hand rule, 396–397
RLC series circuit, 1145–1146, 1148
Rolling motion, 404–409
  acceleration in, 406–407
  angular momentum and, 367–372
  dynamics of, 406–407
  rotational inertia and, 400–404
  static friction and, 407
  velocity in, 404–406
  without slipping, 405–406
Root-mean-square values, 1069
Rotation
  about a fixed axis, 392, 404
  free, 392–393
  vectorial nature of, 395–398
Rotational equation of motion, 400
Rotational impulse, 402
Rotational impulse equation, 402
Rotational inertia, 358–360
  of extended objects, 372–377
  rolling motion and, 400–404
Rotational kinematics, 362–367
Rotational motion, 352. *See also* Circular motion
Rotational symmetry, 22–23
Rotational velocity vectors, 398

S

Satellite orbits, 446–450
Scalar, 64–66
Scalar field, 816
Scalar product, 333–334
Scales, time, 26–27
Scientific method, 20–21
  definition of, 20
  hypothesis in, 20–21
  significant digits and, 35–38
Second, 26
Secondary maxima, 1212–1213, 1225
Second derivative, 104
Second law of thermodynamics, 676
Self-quiz, overview of, 30
Semiconductors, 1128–1130
Shape factor of objects, 407
Shear stress, 617, 618–619, 625, 647
Shock waves, 607–609
Short circuit, 1086–1087
Short-range interactions, 223
Signal delay, 463
Significant digits, 35–38
Simple harmonic motion
  definition of, 505
  energy of simple harmonic oscillator, 516–519
  linear restoring force and, 508
  periodic motion and, 508
  restoring forces in, 511–514
  springs and, 520–524
Simple harmonic oscillator, 507, 516–519
Simple harmonic oscillator equation, 518–519
Simple pendulum, 513, 526, 527
Simultaneity detector, 465
Simultaneous as relative term, 465–469
Single-loop circuits, 1096–1101
Single particle, work on, 293–296
Single-slit barrier, diffraction at, 1229–1231
Single-variable integration, 859
Sinusoidal curves, 507
Sinusoidal electromagnetic waves, 1069–1070
Sinusoidal waves, 546, 547, 561, 571
SI units, 32–35. *See also* Units of measure

physical quantities for, 32
prefixes for, 32
SI, 32–35
significant digits and, 35–38
Unit vector, 65
Unit vector notation, 65
Universal gravity, 426–431
Universe
definition of, 24
matter and, 24–25
structure and size scales of, 24–25
time scales in, 26–27
Unpaired charge, 788
Unstable equilibrium position, 511
Upgrading energy, 754

V

Vacuum, 635
Vacuum gauge, 640
Valence electrons, 1128–1130
Van de Graaff, Robert J., 910
Van de Graaff energy, 927
Van de Graaff generators, 910–911, 913, 917, 927, 1122
Vaporization, specific transformation energy for, 713, 714
Variable force, 300–303
Vector algebra, 326–328
Vector bosons, 225
Vector field, 816
Vectorial nature of rotation, 395–398
Vector product, 411–413
Vectors
addition of, 69, 317
algebra, 326–328
axial, 398
bosons, 225
component, 326–327
decomposing, 317–319
displacement, 55–57, 66–70
momentum as, 128
multiplication of, 70
in a plane, 316–319
polar, 398
position, 55–57, 66–70
Poynting, 1069–1071
product, 411–413
rotational velocity, 398
rotation of, 395–398
scalar and, 64–66
scalar product of two, 333–334
subtraction of, 69–70, 317
unit, 65
velocity as, 70–71
work as product of two, 331–335
x component of, 65–66
zero, 67
Vector sum of forces
definition of, 248
in equation of motion, 259–261
exerted on an object, 393
free-body diagrams, 252–254, 255, 256
in impulse equation, 266–267
in Newton's law of motion, 261
in systems of many interacting objects, 269, 271
in systems of two interacting objects, 268
translational equilibrium and, 251–252
Vector sum of horizontal displacement, 316–317
Velocity
average, 59–62, 71
center-of-mass, 195
changes in
acceleration and, 87–88
linear, 91
x component of, 105
constant, 87, 88, 90, 96, 98, 179
inertia and, 120, 121–122
instantaneous, 73–74, 318–319
magnitude of, 87, 88, 91
momentum and, 128–129
motion at constant, 71–73
in rolling motion, 404–406
as a vector, 70–71
x component of, 119–120, 121, 128, 135, 138
of zero-momentum reference frame, 186
Velocity gradient, 648
Velocity selector, 961
Velocity-*versus*-time graphs, 131, 140
for acceleration, 104, 131
for classification of collisions, 150
for explosive separation, 167
for friction, 117
for inertia, 118, 119, 120, 121
for momentum, 136, 140
for motion in one dimension, 62
for principal of relativity, 182
VENUS mnemonic, 40
Vertical component of motion, 316
Vertical oscillations, 523
Vibration, 505
Viscosity of fluids, 618, 625, 647–651
Visual representations, 27–29
Volt (V), 889
Volta, Alessandro, 889
Voltic cells, charge separation and storage in, 917–919
Voltmeter, 889–890, 1101, 1151
Volume
entropy and, 678–683
order-of-magnitude estimate of, 42–44
Volume charge density, 828
Volume flow rate, 645
Vortices, 625

W

Watt (W), 303
Wave equation, 569–571
Wavefronts, 581–583
Wave function of the wave, 581
Wavelength, 547
Wavelet, 592
Wave number of motion, 560
Wave propagation, 544–548
medium for, 540
Wave pulse, 1048
Waves

in one dimension, 539–579
amplitude of, 559, 569
boundary effects, 550–554
definition of, 540
displacement of, 541–544, 546–550
energy transport in waves, 567–569
harmonic, 546
interference and, 549
longitudinal, 543
mechanical, 540, 543
motion of, 541
nonmechanical, 540
out of phase, 562–563
periodic, 546–547
in phase, 562–563, 587
pulse of, 550–554
representing waves graphically, 540–543
sinusoidal, 546, 547, 561, 571
speed of, 541
standing waves, 562–564
superposition of waves, 548–550
transverse, 543
traveling, 558–559
wave equation, 569–571
wave functions, 556–562
wave propagation, 540, 544–548
wave speed, 564–566
polarization of, 1053
in two and three dimensions, 580–615
amplitude of, 583, 589, 592
beat frequency, 601
beating, 599–601
coherent sources, 589–592
compressions and rarefactions in longitudinal waves, 586
difference between, 583
diffraction, 592–594
displacement of, 581, 585–592
Doppler effect, 602–607
energy of sound, 596–597
intensity, 596–599
interference, 587–592
shock waves, 607–609
sound, 584–587, 596–597
spherical waves, 582
wavefronts, 581–583
wave function of the wave, 581
Waves, particle optics and, 1207–1246
circular apertures and limits of resolution, 1231–1234
diffraction
gratings, 1210–1213, 1226–1227
of light, 1208–1210
at single-slit barrier, 1229–1231
X-ray, 1213–1217
matter waves, 1217–1218
multiple-slit interference, 1222–1227
photons, 1218–1220
energy and momentum of, 1234–1238
thin-film interference, 1227–1229
Weak charge, 225
Weak interactions, 224, 225–226
Weber, Wilhelm, 956
Weighing devices, 435
Weight
of Earth, 443
gravitational force and, 434–437
notation of, 437
Wheatstone bridge, 1105–1106
Work, 283–313
concept of, 283
electrostatic, 880–882
energy diagrams, 286–289
equation for particles, 294–295
force displacement, 283–284, 294
friction and, 323–324
gravity and, 295
on many-particle system, 296–299
positive and negative, 284–286
power, 303–305
as product of two vectors, 331–335
on single particle, 293–296
system choice, 289–291
thermal energy transfer and, 719–721
variable and distributed forces, 300–303
Work function, 1237

X

X axis, 54–55
X component
of acceleration
average acceleration and, 87, 96, 104
constant acceleration and, 96
curvature of *x(t)* curve related to, 88
due to gravity, 90, 100
inclined planes and, 102–103
instantaneous acceleration and, 104–105
in projectile motion, 92
algebraic sign of, 57, 65–66
definition of, 56
of displacement, 56–57
in graphs, 56–57
of momentum, 128–129, 135, 138
of position, 69, 75
symbols, 75
of vector, 65–66
of velocity, 119–120, 121, 128, 135, 138
X coordinates, 54–55, 316
X-ray crystallography, 1217
X-ray diffraction, 1216
X(t) curve, 59

Y

Y coordinate, 316

Z

Zero gravitational force, 796
Zero-momentum reference frames, 186–187
Zeros
leading, 36
trailing, 38
without units, 38
Zeroth-order bright fringe, 1210
Zero vector, 67

SI Units, Useful Data, and Unit Conversion Factors

The seven base SI units		
Unit	**Abbreviation**	**Physical quantity**
meter	m	length
kilogram	kg	mass
second	s	time
ampere	A	electric current
kelvin	K	thermodynamic temperature
mole	mol	amount of substance
candela	cd	luminous intensity

Some derived SI units			
Unit	**Abbreviation**	**Physical quantity**	**In terms of base units**
newton	N	force	$kg \cdot m/s^2$
joule	J	energy	$kg \cdot m^2/s^2$
watt	W	power	$kg \cdot m^2/s^3$
pascal	Pa	pressure	$kg/m \cdot s^2$
hertz	Hz	frequency	s^{-1}
coulomb	C	electric charge	$A \cdot s$
volt	V	electric potential	$kg \cdot m^2/(A \cdot s^3)$
ohm	Ω	electric resistance	$kg \cdot m^2/(A^2 \cdot s^3)$
farad	F	capacitance	$A^2 \cdot s^4/(kg \cdot m^2)$
tesla	T	magnetic field	$kg/(A \cdot s^2)$
weber	Wb	magnetic flux	$kg \cdot m^2/(A \cdot s^2)$
henry	H	inductance	$kg \cdot m^2/(A^2 \cdot s^2)$

SI Prefixes					
10^n	**Prefix**	**Abbreviation**	10^n	**Prefix**	**Abbreviation**
10^0	—	—			
10^3	kilo-	k	10^{-3}	milli-	m
10^6	mega-	M	10^{-6}	micro-	μ
10^9	giga-	G	10^{-9}	nano-	n
10^{12}	tera-	T	10^{-12}	pico-	p
10^{15}	peta-	P	10^{-15}	femto-	f
10^{18}	exa-	E	10^{-18}	atto-	a
10^{21}	zetta-	Z	10^{-21}	zepto-	z
10^{24}	yotta-	Y	10^{-24}	yocto-	y

Values of fundamental constants

Quantity	Symbol	Value
Speed of light in vacuum	c_0	3.00×10^{8} m/s
Gravitational constant	G	6.6738×10^{-11} N · m^2/kg^2
Avogadro's number	N_A	$6.02214076 \times 10^{23}$ mol^{-1}
Boltzmann's constant	k_B	1.381×10^{-23} J/K
Charge on electron	e	1.60×10^{-19} C
Permittivity constant	ϵ_0	$8.85418782 \times 10^{-12}$ C^2/(N · m^2)
Permeability constant	μ_0	$4\pi \times 10^{-7}$ T · m/A
Planck's constant	h	6.626×10^{-34} J · s
Electron mass	m_e	9.11×10^{-31} kg
Proton mass	m_p	1.6726×10^{-27} kg
Neutron mass	m_n	1.6749×10^{-27} kg
Atomic mass unit	amu	1.6605×10^{-27} kg

Other useful numbers

Number or quantity	Value
π	3.1415927
e	2.7182818
1 radian	57.2957795°
Absolute zero ($T = 0$)	−273.15°C
Average acceleration g due to gravity near Earth's surface	9.8 m/s^2
Speed of sound in air at 20 °C	343 m/s
Density of dry air at atmospheric pressure and 20 °C	1.29 kg/m^3
Earth's mass	5.97×10^{24} kg
Earth's radius (mean)	6.38×10^{6} m
Earth–Moon distance (mean)	3.84×10^{8} m

Unit conversion factors

Length

1 in. = 2.54 cm (defined)

1 cm = 0.3937 in.

1 ft = 30.48 cm

1 m = 39.37 in. = 3.281 ft

1 mi = 5280 ft = 1.609 km

1 km = 0.6214 mi

1 nautical mile (U.S.) = 1.151 mi = 6076 ft = 1.852 km

1 fermi = 1 femtometer (fm) = 10^{-15} m

1 angstrom (Å) = 10^{-10} m = 0.1 nm

1 light − year (ly) = 9.461×10^{15} m

1 parsec = 3.26 ly = 3.09×10^{16} m

Volume

1 liter (L) = 1000 mL = 1000 cm^3 = 1.0×10^{-3} m^3
=1.057 qt (U.S.) = 61.02 $in.^3$

1 gal (U.S.) = 4 qt (U.S.) = 231 $in.^3$ = 3.785 L = 0.8327 gal (British)

1 quart (U.S.) = 2 pints (U.S.) = 946 mL

1 pint (British) = 1.20 pints (U.S.) = 568 mL

1 m^3 = 35.31 ft^3

Speed

1 mi/h = 1.4667 ft/s = 1.6093 km/h = 0.4470 m/s

1 km/h = 0.2778 m/s = 0.6214 mi/h

1 ft/s = 0.3048 m/s = 0.6818 mi/h = 1.0973 km/h

1 m/s = 3.281 ft/s = 3.600 km/h = 2.237 mi/h

1 knot = 1.151 mi/h = 0.5144 m/s

Angle

1 radian (rad) = 57.30° = 57°18'

1° = 0.01745 rad

1 rev/min (rpm) = 0.1047 rad/s

Time

1 day = 8.640×10^4 s

1 year = 365.242 days = 3.156×10^7 s

Mass

1 atomic mass unit (u) = 1.6605×10^{-27} kg

1 kg = 0.06852 slug

1 metric ton = 1000 kg

1 long ton = 2240 lbs = 1016 kg

1 short ton = 2000 lbs = 909.1 kg

1 kg has a weight of 2.20 lb where g = 9.80 m/s^2

Force

1 lb = 4.44822 N

1 N = 10^5 dyne = 0.2248 lb

Energy and work

1 J = 10^7 ergs = 0.7376 ft · lb

1 ft · lb = 1.356 J = 1.29×10^{-3} Btu = 3.24×10^{-4} kcal

1 kcal = 4.19×10^3 J = 3.97 Btu

1 eV = 1.6022×10^{-19} J

1 kWh = 3.600×10^6 J = 860 kcal

1 Btu = 1.056×10^3 J

Power

1 W = 1 J/s = 0.7376 ft · lb/s = 3.41 Btu/h

1 hp = 550 ft · lb/s = 746 W

1 kWh/day = 41.667 W

Pressure

1 atm = 1.01325 bar = 1.01325×10^5 N/m^2 = 14.7 $lb/in.^2$ = 760 torr

1 $lb/in.^2$ = 6.895×10^3 N/m^2

1 Pa = 1 N/m^2 = 1.450×10^{-4} $lb/in.^2$

Periodic Table of the Elements
