Figure 15.7 Correspondence between circular motion at constant speed and simple harmonic motion for (*a*) an object suspended from a spring and (*b*) a pendulum.

15.3 Fourier's theorem

Simple harmonic motion is important because, as Figure 15.3 suggests, it is very common. Another reason it is important is that, according to a rule known as **Fourier's theorem,*** any periodic function can be written as a sum of sinusoidal functions of frequency $f_n = n/T$, where $n \geq 1$ is an integer and T is the period of the function. This means that *any* periodic motion can be treated as a superposition of simple harmonic motions. So, if we understand simple harmonic motion, we can deal with any other type of periodic motion by breaking it down into its simple harmonic components. Because any motion that is nonrepetitive can be thought of as periodic motion that has an infinitely long period, Fourier's theorem has broad implications: The time-dependent motion of *any* system can be expressed in terms of sinusoidal functions.

Consider, for example, the periodic motion represented by the nonsinusoidal curve in **Figure 15.8*a*** on the next page. Although very different from simple harmonic motion, this motion can be expressed as the sum of a few simple harmonic components, shown in the sinusoidal curves of Figure 15.8*b*. The first component has the same frequency $f_1 = 1/T$ as the original periodic function; this frequency, the lowest in the sum, is called the **fundamental frequency** or **first harmonic.** All other components, called **higher harmonics,** are at integer multiples of the fundamental frequency: $f_n = nf_1 = n/T$.† When these higher harmonics are added to the first harmonic, the shape of the resulting periodic function is not sinusoidal, but the period remains the same (Figure 15.8*c*). By adjusting the amplitude of each harmonic, we can make the sum of harmonics fit the original periodic function.

The breaking down of a function into harmonic components is called *Fourier analysis,* and the resulting sum of sinusoidal functions is called a *Fourier series*. **Figure 15.9** on the next page shows one way of graphically representing the Fourier series: The amplitudes A_n of all the harmonics are plotted against the frequencies of the harmonics. As you saw in Checkpoint 15.4, the energy of a simple harmonic oscillator is proportional to the square of the amplitude. For this reason, it is customary to plot A_n^2 as a function of frequency, as shown in Figure 15.9*c*; such a plot is called the **spectrum** of the periodic function.

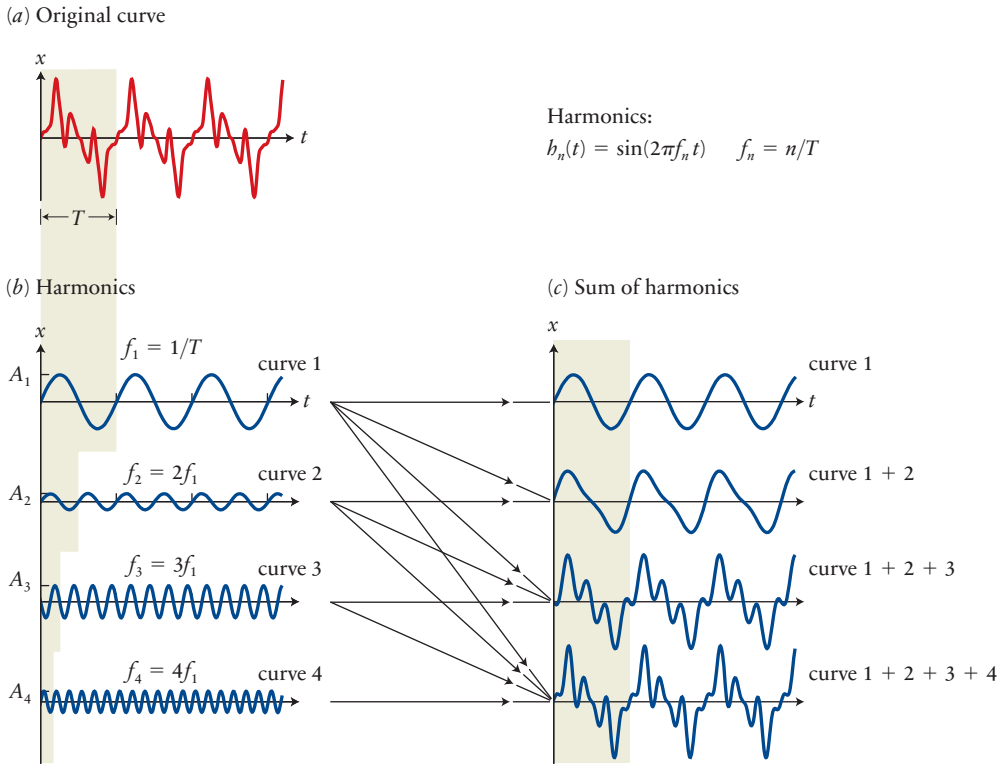
The spectrum shows the contribution of each harmonic to the original periodic function. A similar type of visual display of frequency content is found on some stereophonic components. Displays such as the one

CONCEPTS

*After the French mathematician Jean-Baptiste Joseph Fourier (1768–1830).

†In general, an infinite sum of sines and cosines is required to break down arbitrary periodic functions. Only periodic functions for which $f(t) = -f(-t)$ (that is, they are odd in t, such as the one shown in Figure 15.8) can be analyzed with only sines (which are also odd in t).

Figure 15.8 Fourier analysis of a periodic function into sinusoidal functions. The period of each function is indicated by the shading. (*a*) Original periodic function. (*b*) The first through fourth harmonics used to describe the function in (*a*). (*c*) Successive sum of those harmonics, showing an increasingly improving match to the original periodic function.



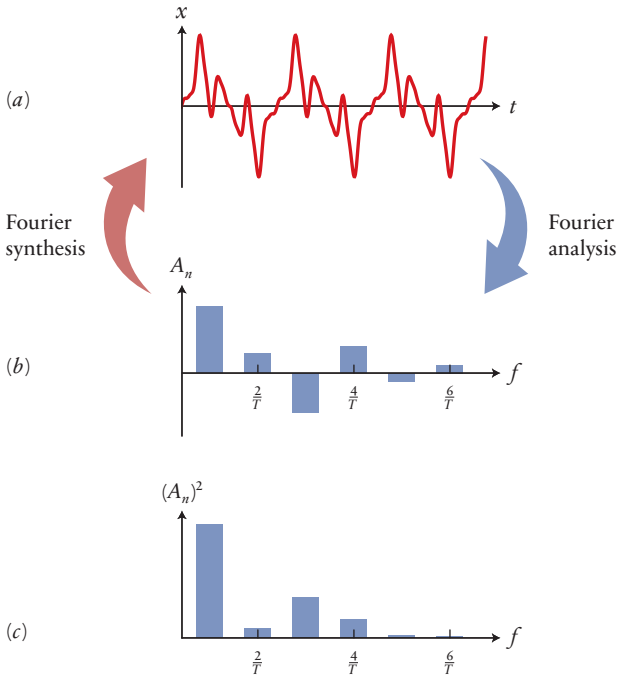


Figure 15.9 (*a*) Periodic function and (*b*) amplitudes of the harmonic functions in the Fourier series of the function shown in part *a*. (*c*) Spectrum of the periodic function, obtained by plotting the squares of the amplitudes.

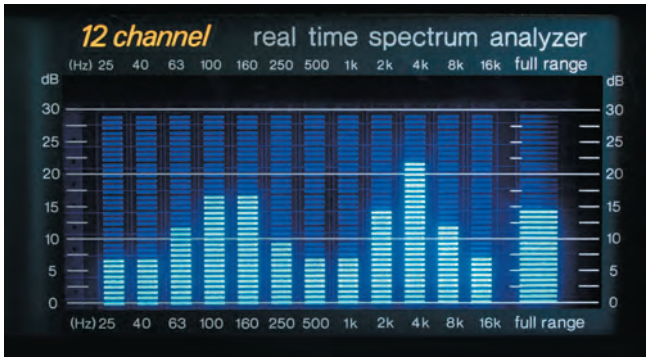
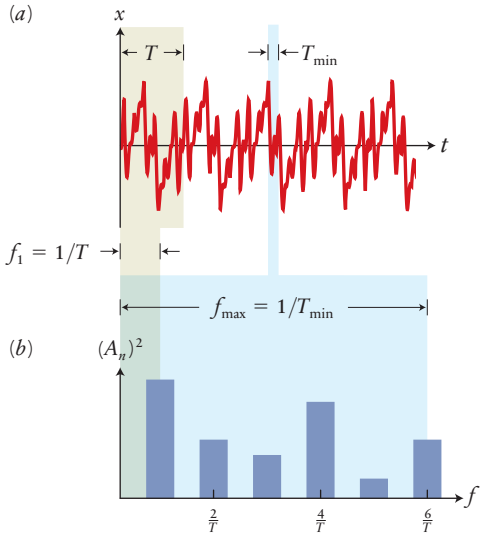


shown in **Figure 15.10** provide a visual representation of the frequency content of the sound being played.

Figure 15.11 shows some important relationships between a periodic function and its spectrum. The period T of the function determines the frequency of the first harmonic. In other words, the duration of the slowest component of the function determines the lowest frequency in the spectrum. Conversely, the duration T_{min} of the fastest component in the function determines the highest frequency in the spectrum.



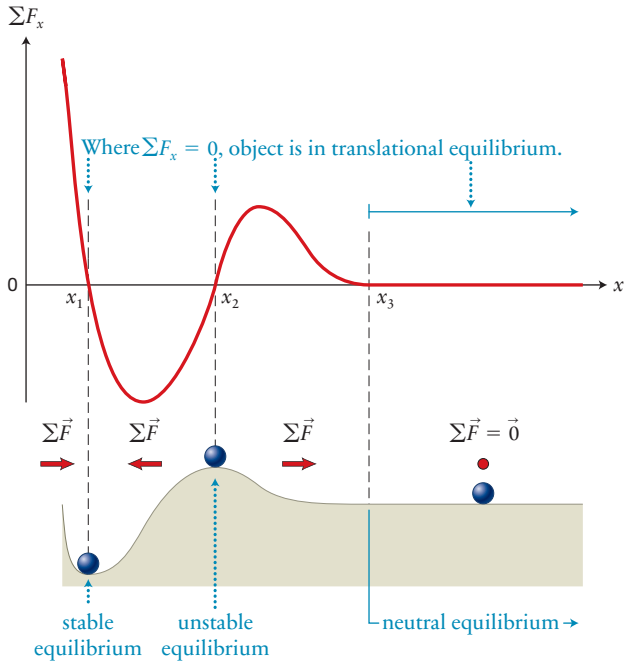
Fourier analysis has many applications, ranging from electronic signal processing to chemical analysis

Figure 15.10 Spectrum analyzer display on a stereo component.

CONCEPTS

Figure 15.11 Relationship between a periodic function and its spectrum.

and voice recognition. The ear functions as a Fourier analyzer because the inner ear breaks down the oscillations produced by sound into simple harmonic components, each producing a nerve impulse proportional to the amplitude of that component.



The inverse of Fourier analysis—the creation of periodic functions by adding sinusoidal functions together—is called *Fourier synthesis*. A musician's electronic synthesizer, for example, produces a sum of harmonics that add up to produce different periodic functions. When the amplitudes of the different harmonics are adjusted so that they match the frequency content of real instruments, the synthesizer simulates the sounds of many musical instruments.

15.6 (*a*) What does the spectrum of a single sinusoidal function of period T look like? (*b*) As T is increased, what change occurs in the spectrum?

15.4 Restoring forces in simple harmonic motion

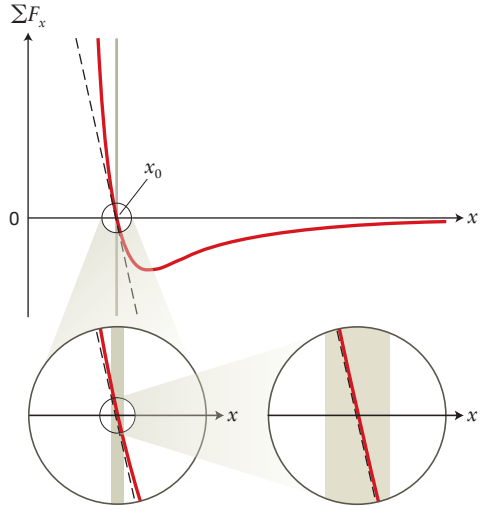
Periodic motion takes place about a position of translational or rotational equilibrium (see Section 12.5) and requires a restoring force that tends to return the object to the equilibrium position. Consider, for example, an object moving along an x axis and subject to the vector sum of forces whose x component is shown graphically in **Figure 15.12**. The object is in translational equilibrium at each position where the vector sum is zero: at x_1, x_2, and all values of $x > x_3$. Can the object oscillate about any of these positions? From the graph we see that ΣF_x is positive to the left of x_1, and so the vector sum $\Sigma\vec{F}$ points toward x_1. To the right of x_1, ΣF_x is negative, and so the vector sum of forces

Figure 15.12 Whenever the vector sum of the forces exerted on an object is zero, the object is in translational equilibrium. This graph shows stable, unstable, and neutral equilibria.

again points toward x_1. The forces exerted on the object tend to return the object to x_1 whenever it moves away from x_1. Around x_1 the vector sum of forces "restores" the translational equilibrium so that the object can oscillate around x_1.

Because the vector sum of the forces always pushes the object back to x_1, this equilibrium position is said to be *stable*. You can visualize this position by imagining a ball at the bottom of a bowl: When the ball is displaced in any direction, a restoring force accelerates it back toward the bottom.

On either side of equilibrium position x_2, the direction of the vector sum of the forces is such that the object accelerates away from the equilibrium position. Such an equilibrium position is called *unstable* because the forces tend to amplify any disturbance from equilibrium. Imagine balancing a ball on top of a hill: The slightest displacement of the ball in any direction is enough to make it accelerate away from the equilibrium position.



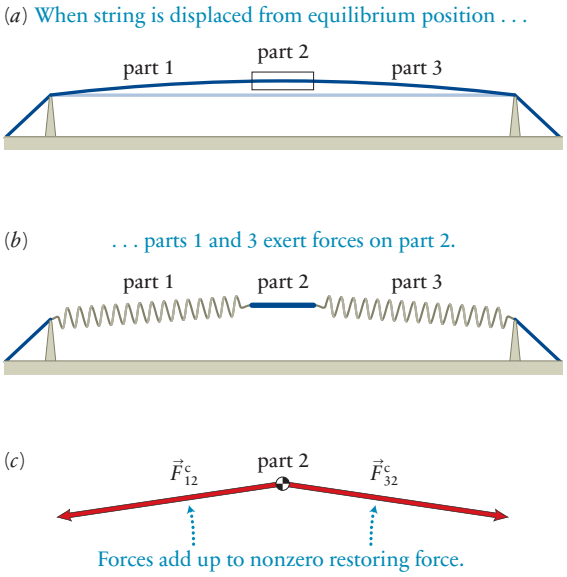
Positions for which $x > x_3$ represent a *neutral* equilibrium: Moving the ball in any direction has no effect on its subsequent acceleration.

What all this tells us is that objects tend to oscillate about *stable* equilibrium positions because the forces about such positions tend to restore the equilibrium. A consequence of the restoring forces about stable equilibrium positions is:

In the absence of friction, a small displacement of a system from a position of stable equilibrium causes the system to oscillate.

CONCEPTS

Figure 15.13 For sufficiently small displacements near a stable equilibrium position, the restoring force is linear in the displacement.



15.7 (*a*) Are there any equilibrium positions in the sum-of-forces-versus-distance graph in **Figure 15.13**? If so, is the equilibrium stable, unstable, or neutral? (*b*) Compare the magnitude of the restoring force for equal displacements on either side of x_0 in Figure 15.13.

Figure 15.13 shows why so many systems move in simple harmonic motion. As we saw in Section 15.2, simple harmonic motion requires *linear* restoring forces—that is, forces that are linearly proportional to the displacement from the equilibrium position. In Checkpoint 15.7*b* you saw that the restoring force about the stable equilibrium position x_0 in Figure 15.13 is not linear. However, as illustrated by the successive enlargements in Figure 15.13, the curve, which gives the relationship between force and position, becomes indistinguishable from a straight line for small displacements from the equilibrium position x_0 (say, within the shaded region). In other words:

For sufficiently small displacements away from the equilibrium position, restoring forces are always linearly proportional to the displacement. Consequently, for small displacements, objects execute simple harmonic motion about any stable equilibrium position.

The restoring forces in the examples in Figure 15.3 fall into two categories: elastic (*b*, *d*) and gravitational (*a*, *c*). We saw in Chapter 8 that, for small displacements from the equilibrium position, the elastic restoring force of a spring is linearly proportional to the displacement. The same is true for other elastic restoring forces. **Figure 15.14**, for example, shows a string displaced from its equilibrium position. Each part of the stretched string is subject to elastic (contact) forces

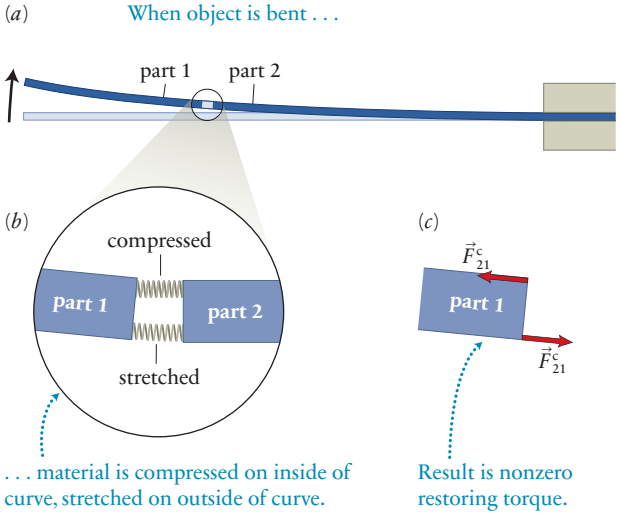


Figure 15.14 Cause of the restoring force for a taut string displaced from equilibrium.

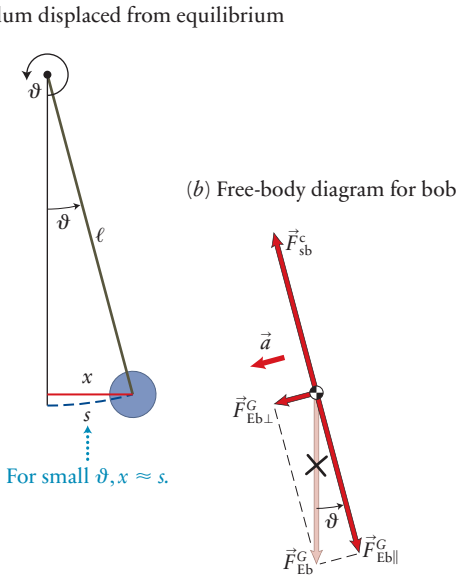
exerted by the parts immediately adjacent to it. Part 2 in the middle of the string in Figure 15.14*b*, for instance, is subject to a force exerted by part 1 and a force exerted by part 3. In the equilibrium position, when the string is straight, the elastic forces exerted by parts 1 and 3 on part 2 add to zero. As the string is displaced, however, the elastic forces exerted by the two neighboring parts no longer line up (Figure 15.14*c*) and their vector sum provides a restoring force that tends to return the string to its equilibrium position. For small displacements, as we just saw, this restoring force is linearly proportional to the displacement from the equilibrium position.

The same line of reasoning applies to the restoring forces that arise when materials are twisted or bent. **Figure 15.15** shows that bending an object compresses

Figure 15.15 Cause of the restoring torque on a beam bent away from its equilibrium shape.

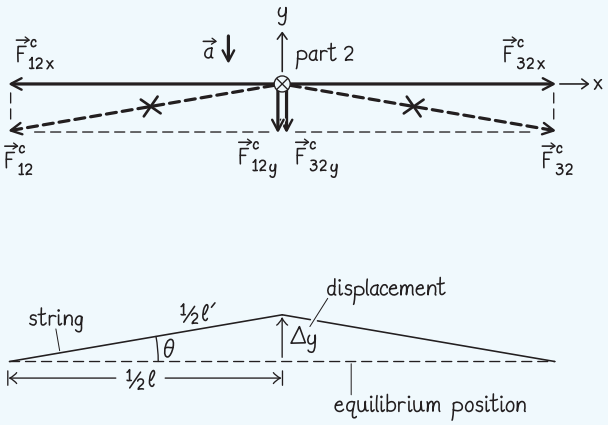


CONCEPTS

the material that lies on the inside of the curve and stretches the material that lies on the outside of the curve. The resulting internal elastic forces cause torques on each part of the object, torques that tend to return the object to its equilibrium shape. For small displacements, the internal elastic forces are linearly proportional to the displacement, and consequently the restoring torque, too, is linearly proportional to the (rotational) displacement.

Let us next examine a pendulum, where the restoring force is due to gravity. **Figure 15.16*a*** shows a pendulum bob of mass m suspended from a string of length ℓ. If the bob is much more massive and much smaller than the string that supports the bob, we can ignore the mass of the string and treat the bob as a particle. Such a pendulum is called a *simple pendulum*. The bob is pulled back over an arc of length s. As the free-body diagram in Figure 15.16*b* shows, the bob is subject to two forces: a contact force exerted by the string and a gravitational force. The restoring force is provided by the component of the gravitational force perpendicular to the string, $\vec{F}^G_{\text{Eb}\perp}$. From Figure 15.16*b*, we see that the magnitude of $\vec{F}^G_{\text{Eb}\perp}$ is equal to $mg\sin\vartheta$ and from Figure 15.16*a* that $\sin\vartheta = x/\ell$, and so the magnitude of the restoring force exerted on the bob is $mg\sin\vartheta = (mg/\ell)x$. Provided the rotational displacement is small, the bob's displacement from its equilibrium position along the circular arc s is approximately equal to the bob's horizontal displacement x, $s \approx x$. For small angles, therefore, the restoring force is linearly proportional to the bob's displacement.

Figure 15.16 For small angles the horizontal displacement x of a pendulum is almost the same as the length of the arc s along which it is displaced.



EXAMPLE 15.1 Displaced string

Show that for small displacements the restoring force exerted on part 2 of the displaced string in Figure 15.14 is linearly proportional to the displacement of that part from its equilibrium position.

❶ **GETTING STARTED** Figure 15.14*c* shows the forces exerted by parts 1 and 3 on part 2 when the string is displaced from its equilibrium position. I'll assume that these forces are much greater than the force of gravity exerted on part 2 so that I can ignore gravity in this problem. The force that pulls the string away from the equilibrium position is not shown, which means the string has been released after being pulled away from the equilibrium position.

I begin by making a free-body diagram and choosing a set of axes (**Figure 15.17**). The x components of the forces $\vec{F}^c_{12}$ and $\vec{F}^c_{32}$ cancel; the sum of the y components is the restoring force. The magnitude of the y components is determined by the angle θ between the x axis and either $\vec{F}^c_{12}$ or $\vec{F}^c_{32}$.

Figure 15.17

I also make a sketch of the displaced string, showing the displacement Δy of part 2 from its equilibrium position. I denote the length of the string in its equilibrium position by ℓ and the length of the displaced string by ℓ'.

❷ **DEVISE PLAN** The forces $\vec{F}^c_{12}$ and $\vec{F}^c_{32}$ are equal in magnitude and their y components are determined by $\sin\theta$, which is equal to $\Delta y/\left(\frac{1}{2}\ell'\right)$. If the displacement is small, I can assume that the length of the string doesn't change much from its equilibrium value, so that $\ell \approx \ell'$. Because the forces $\vec{F}^c_{12}$ and $\vec{F}^c_{32}$ are proportional to the tension in the string, I can also consider these forces to be constant. Using this information, I can express the restoring force in terms of the displacement Δy.

❸ **EXECUTE PLAN** From my sketch I see that the restoring force is $F^c_{12y} + F^c_{32y}$. Because $\vec{F}^c_{12}$ and $\vec{F}^c_{32}$ are equal in magnitude, I can write the sum of the y components as $2F^c_{12y} = 2F^c_{12}\sin\theta$. I also know that $\sin\theta = \Delta y/\left(\frac{1}{2}\ell'\right) \approx \Delta y/\left(\frac{1}{2}\ell\right)$. Combining these two relationships, I obtain for the magnitude of the restoring force: $F_{\text{restoring}} = 2F^c_{12y} \approx (4F^c_{12}/\ell)\Delta y$. For small displacements, the term in parentheses is constant and so the restoring force is, indeed, proportional to the displacement Δy. ✔

(Continued)

CONCEPTS

4 EVALUATE RESULT I made two assumptions to derive my answer. The first is that gravity can be ignored. Indeed, taut strings tend to be straight, indicating that gravity (which would make the strings sag) doesn't play an appreciable role. The other assumption I made was that the length of the string doesn't change much when it is displaced from its equilibrium position. This assumption is also justified because the displacement of a string tends to be several orders of magnitude smaller than the string length.

15.8 Using a calculator, determine the percent error in the approximation $\sin\theta \approx \theta$ for polar angles of 1°, 5°, 10°, and 20°. (Note: For this "small-angle" approximation, θ must be expressed in radians.)

In Section 15.1, I showed how oscillations arise from a continuous conversion between kinetic energy and potential energy. Another way to look at oscillations is to say:

Oscillations arise from an interplay between inertia and a restoring force.

When an object that is subject to a restoring force is displaced from its equilibrium position, the restoring force accelerates it back toward the equilibrium position. Once it gets there, however, it has a nonzero velocity, and its inertia causes it to overshoot the equilibrium position.

This picture of an interplay between inertia and restoring force allows us to make some qualitative predictions about the period of an oscillator. The greater the mass of the oscillating object, the harder it is to accelerate and so the longer the period.* Increasing the restoring force has the opposite effect: The greater the restoring force, the greater the object's acceleration and the shorter the period—a stiff spring causes a much more rapid oscillation than a soft, sloppy one.

The period of an oscillating object increases when its mass is increased and decreases when the magnitude of the restoring force is increased.

This relationship does not hold for pendulums, however, because for a pendulum the restoring force and mass are proportional to each other. Increasing the mass of a pendulum bob makes the pendulum harder to accelerate but increases the magnitude of the gravitational force exerted on the pendulum bob—the restoring force—in proportion (see Figure 15.16*b*). The two effects cancel, and so:

The period of a pendulum is independent of the mass of the pendulum.

15.9 (*a*) What effect, if any, does increasing the length ℓ of a simple pendulum have on its period? (*b*) A pendulum and an object suspended from a spring are taken to the Moon, where the acceleration due to gravity is smaller than that on Earth. How does the period of the pendulum on the Moon compare with its period on Earth? (*c*) How does the period of the suspended object on the Moon compare with its period on Earth?

*You can demonstrate this as follows: Position a plastic or thin wooden ruler on a table so that about half its length overhangs the edge of the table. While pressing the ruler down on the table, pull the free end down and release, noting the rapid oscillations. Next attach an eraser or other small object on top of the overhanging part of the ruler and repeat the experiment. Because of the increased mass, the period is now much longer.

CONCEPTS

Self-quiz

1. Is an oscillating object in translational equilibrium?
2. A pendulum bob swings through a circular arc defined by positions A and D in **Figure 15.18**. (*a*) At A, B, and C, what are the possible directions of the velocity of the bob and of the restoring force exerted on it? (*b*) What is the direction of the bob's acceleration at A and C?
3. The cart-spring system shown in **Figure 15.19** is undergoing simple harmonic motion. (*a*) Is the cart's speed greater at A or at B? (*b*) At which of these two positions is the restoring force acting on the cart greater? (*c*) At which of these two positions is the cart's acceleration greater?

Figure 15.18

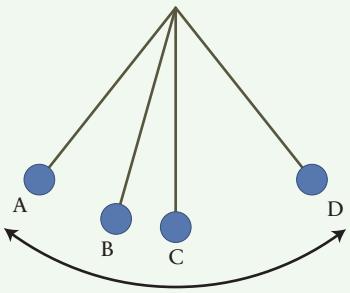


Figure 15.19

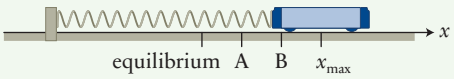

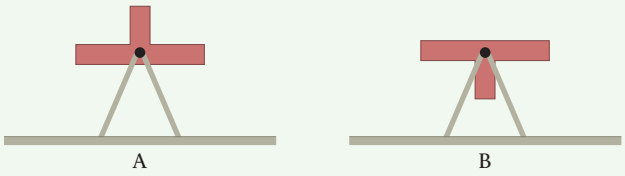

Figure 15.20

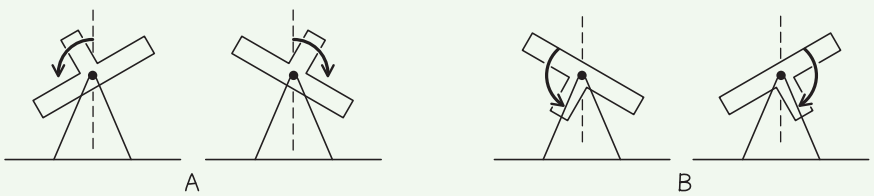


4. A T-shaped wooden structure is balanced on a pivot in the two configurations shown in **Figure 15.20**. Which configuration is in stable equilibrium? Which configuration is likely to oscillate?

Answers

1. No. When an object is in translational equilibrium, the sum of the forces exerted on it is zero. An oscillating object is subject to a variable force that accelerates the object back and forth.
2. (*a*) The velocity is always tangent to the bob's trajectory; the restoring force always points along the arc toward the equilibrium position C. At A, the bob reaches its maximum displacement, so its velocity must be zero; the restoring force points along the arc toward C. At B, the velocity can be in either direction along the arc as the bob swings back and forth, but the restoring force always points along the arc towards C. At C, the velocity can be to the right or left, but the restoring force is zero because this is the equilibrium position. (*b*) At A, the acceleration is tangent along the arc toward C. At C, the bob does have a centripetal radial acceleration directed vertically upward, but no tangential acceleration.
3. (*a*) Once released from the stretched position shown, the cart speeds up as it moves left toward the equilibrium position, so its speed is greater at A than at B. (*b*) The restoring force is proportional to the displacement from the equilibrium position, so it is greater at B than at A. (*c*) The acceleration is proportional to the restoring force, so it, too, is greater at B.
4. If the structure in configuration A is tipped slightly to the left as shown in **Figure 15.21**, the gravitational force exerted on the part to the left of the vertical line through the pivot is greater than that exerted on the part to the right of the pivot, and so the torques caused by these forces make it tip farther in the same direction, away from the equilibrium position. Conversely, if it is tipped to the right, it tips farther to the right. This configuration is unstable, and so the structure does not oscillate. If the structure in configuration B is tipped slightly either way, the torques caused by gravitational forces exerted on the parts on either side of the pivot cause it to move in the opposite direction, back toward the equilibrium position. Configuration B is stable, and so the structure oscillates.

Figure 15.21

15.5 Energy of a simple harmonic oscillator

In Section 15.2, you saw that there is a correspondence between simple harmonic motion and circular motion at constant speed. We begin our quantitative description of simple harmonic motion by exploiting this correspondence.

Figure 15.22 shows a sinusoidally varying, time-dependent function describing some simple harmonic motion represented by a rotating arrow of length A whose tip traces out a circle. The circle is called a **reference circle,** and the arrow is called a **phasor.** The phasor rotates in a counterclockwise direction with a constant rotational speed ω. The vertical component of the phasor varies sinusoidally with time (see Figures 15.6 and 15.7).

Let us first establish a relationship between the rotational speed of the phasor and the frequency f of the corresponding simple harmonic motion. If the phasor completes one revolution in a period T, its rotational speed is

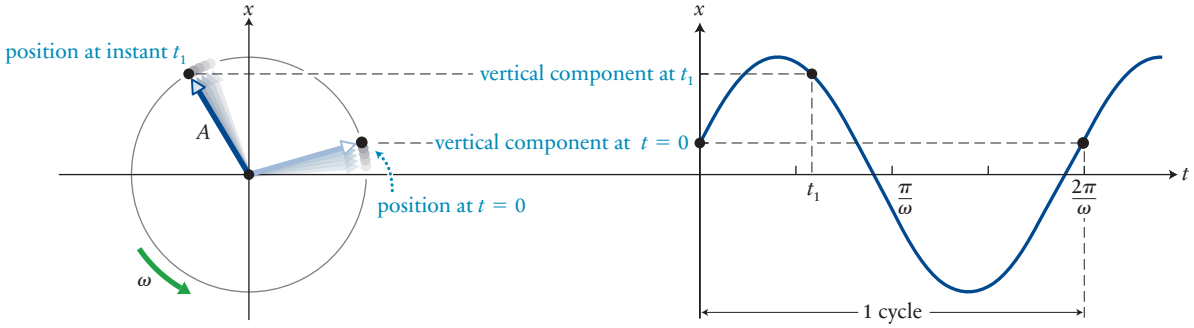
$$\omega \equiv \frac{\Delta\vartheta}{\Delta t} = \frac{2\pi}{T}, \tag{15.1}$$

and the frequency of the corresponding simple harmonic motion is, as noted in Section 15.1,

$$f \equiv \frac{1}{T}. \tag{15.2}$$

The derived SI unit of frequency is the **hertz** (Hz) after the 19th-century German physicist Heinrich Hertz, who produced the first radio waves:

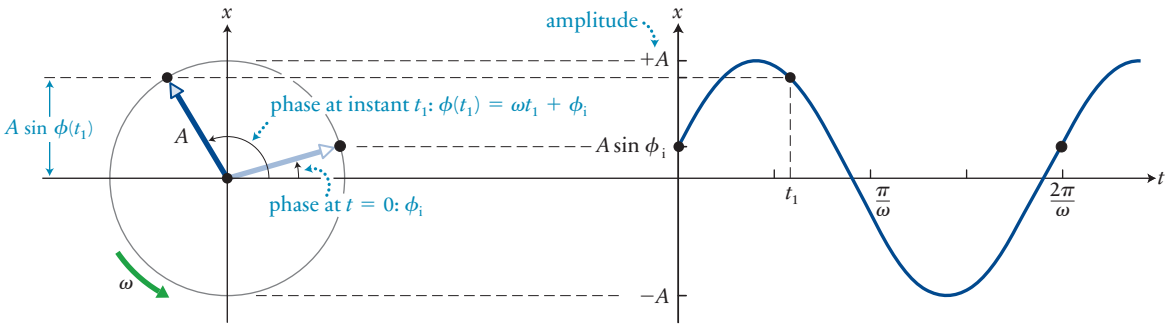
$$1\ \text{Hz} \equiv 1\ \text{s}^{-1}. \tag{15.3}$$



Substituting $1/T$ from Eq. 15.2 into Eq. 15.1, we find

$$\omega = 2\pi f. \tag{15.4}$$

So the rotational speed ω of the phasor is greater than the frequency f of the simple harmonic motion by a factor of 2π. The reason for this factor is that ω measures the change in rotational position per unit time, and in one revolution the rotational position ϑ changes by 2π. Frequency, on the other hand, measures the number of cycles per unit time, and one revolution on the reference circle corresponds to one oscillation cycle (Figure 15.22).



In the context of oscillations, ω is often called the **angular frequency** because it has the same unit (s^{-1} or inverse second) as the frequency f. Keep in mind, however, that the frequency f and the angular frequency ω are not equal (see Eq. 15.4). To facilitate remembering the distinction between the two, we use the SI unit hertz for f and the SI unit s^{-1} for ω.

Figure 15.22 Reference circle and $x(t)$ curve for a simple harmonic oscillator.

QUANTITATIVE TOOLS

Figure 15.23 The phase of a simple harmonic oscillator at any instant is given by the angle between the phasor and the positive horizontal axis measured in the counterclockwise direction.

The rotational position of the tip of the phasor relative to the positive horizontal axis is called the **phase** of the motion (**Figure 15.23**). The phase is represented by the symbol $\phi(t)$. For constant angular frequency, the phase increases linearly with time:

$$\phi(t) = \omega t + \phi_i \quad \text{(constant angular frequency)}, \qquad (15.5)$$

where the constant ϕ_i is the *initial phase* at $t = 0$. The phase $\phi(t)$ tells us at what point in the cycle the motion is; the initial phase ϕ_i is the phase at $t = 0$. Because rotational position is a unitless number, the phase is unitless too. You determine the phase by expressing the angle between the phasor and the positive horizontal axis in radians and dividing by 1 rad.

The vertical component of A in Figure 15.23 can now be written in the form

$$x(t) = A\sin\phi(t) = A\sin(\omega t + \phi_i) \quad \text{(simple harmonic motion)}, \quad (15.6)$$

where the **amplitude** A of the oscillation is equal to the length of the phasor. Equation 15.6 gives a general expression for the position of a simple harmonic oscillator as a function of time when the equilibrium position is at $x = 0$—a pendulum bob, an object suspended from a spring, a taut string. Because the motion is periodic, $x(t)$ has the same value each time the phase increases by 2π. For a crest (where $x(t) = A$ and the sine function in Eq. 15.6 has the value 1), the phase could be $\frac{\pi}{2}$, or $\frac{\pi}{2}$ plus an integer multiple of 2π; for a trough (where $x(t) = -A$ and the sine function in Eq. 15.6 has the value -1), the phase could be $\frac{3\pi}{2}$, or $\frac{3\pi}{2}$ plus an integer multiple of 2π.

EXERCISE 15.2 Oscillation phases

Consider the spring-cart system of Figure 15.1 again. The cart is pulled away from its equilibrium position in the positive x direction and then released at $t = 0$. (*a*) What is the initial phase of the cart's oscillation? What is the phase of the cart's oscillation (*b*) half a period later and (*c*) one period later? What are the cart's initial phases in the following two situations? (*d*) The cart is at its equilibrium position when, at $t = 0$, it is given a sharp blow in the negative x direction so that it starts oscillating. (*e*) The cart is first pulled back a distance d in the positive x direction, and then at $t = 0$ it is given a sharp blow, also in the positive x direction, so that it carries out an oscillation of amplitude $A = 2d$.

SOLUTION (*a*) The cart starts at maximum amplitude in the positive x direction, so the phasor is pointing straight up and the initial phase of the cart's oscillation is $\phi_i = (90°)(2\pi \text{ rad}/360°)/(1 \text{ rad}) = \pi/2$. ✔

(Continued)

QUANTITATIVE TOOLS

(*b*) In one period, the phasor completes a full cycle, so half a period later the phasor has traversed half a cycle (180°). The angle between the phasor and the horizontal axis is thus 90° + 180° = 270°, and thus $\phi(t) = (270°)(2\pi \text{ rad}/360°)/(1 \text{ rad}) = 3\pi/2$. ✔

(*c*) In one period the phasor has completed a full cycle, so the phase is equal to the initial phase $\phi_i + 2\pi = \frac{\pi}{2} + 2\pi = \frac{5\pi}{2}$. ✔

(*d*) If the cart is in the equilibrium position, the phasor must be parallel to the horizontal axis and so the phasor is at 0° or 180°. When the phasor is at 0°, the cart moves in the positive x direction; when it is at 180°, the cart moves in the negative x direction, so the initial phase is $\phi_i = (180°)(2\pi \text{ rad}/360°)/(1 \text{ rad}) = \pi$. ✔

(*e*) The displacement of the cart is given by Eq. 15.6. At $t = 0$: $x(0) = A \sin \phi_i$. I am given that $x(0) = +d$ and $A = 2d$, so $+d = 2d \sin \phi_i$, or $\sin \phi_i = \frac{1}{2}$, and so $\phi_i = \pi/6$ or $5\pi/6$. Because the cart moves in the positive x direction at $t = 0$, the initial phase must be $\phi_i = \pi/6$. ✔

By differentiating Eq. 15.6 with respect to time, we can obtain general expressions for the x components of the velocity and acceleration of a harmonic oscillator:

$$v_x \equiv \frac{dx}{dt} = \omega A \cos(\omega t + \phi_i) \quad \text{(simple harmonic motion)} \tag{15.7}$$

$$a_x \equiv \frac{d^2x}{dt^2} = -\omega^2 A \sin(\omega t + \phi_i) \quad \text{(simple harmonic motion).} \tag{15.8}$$

Equations 15.6–15.8 are the basic kinematic equations for simple harmonic motion. We derived them without considering any particular system—everything followed from the fact that simple harmonic motion corresponds to the projection onto a screen of some object moving in circular motion at constant speed.

15.10 (*a*) What are the algebraic signs of x, v_x, and a_x when the phase $\phi(t) = \omega t + \phi_i$ is between 0 and $\frac{\pi}{2}$? (*b*) Repeat for $\pi < \phi(t) < \frac{3\pi}{2}$.

Substituting Eq. 15.6 into Eq. 15.8, we find that the x component of the acceleration of an object in simple harmonic motion is proportional to the displacement and points in the direction opposite the displacement (that is, toward the equilibrium position):

$$a_x = -\omega^2 x \quad \text{(simple harmonic motion).} \tag{15.9}$$

Substituting the definition of the acceleration into Eq. 15.9, we obtain a second-order differential equation in the variable x:

$$\frac{d^2x}{dt^2} = -\omega^2 x \quad \text{(simple harmonic motion).} \tag{15.10}$$

This equation is called the **simple harmonic oscillator equation** because any system that satisfies this equation undergoes simple harmonic motion. As we shall see in the next two sections, the symbols may take on different meanings for different types of simple harmonic motion, but the mathematical form is always that given in Eq. 15.10.

Multiplying both sides of Eq. 15.9 by the mass of the oscillating object, we have

$$ma_x = -m\omega^2 x \quad \text{(simple harmonic motion).} \tag{15.11}$$

The left side of Eq. 15.11 is equal to the x component of the vector sum of the forces acting on the oscillating object, $ma_x = \Sigma F_x$, and so

$$\Sigma F_x = -m\omega^2 x \quad \text{(simple harmonic motion)}. \tag{15.12}$$

Because m and ω are positive constants, Eq. 15.12 tells us that an object in simple harmonic motion is subject to a force that always points in a direction opposite the object's displacement x from the equilibrium position and is linearly proportional to x—in other words, a *linear restoring force* as we already concluded in Section 15.4.

Let us next examine the mechanical energy of a simple harmonic oscillator, using kinematic Equations 15.6–15.8. The work done by the forces exerted on the oscillating object when it is moving from the equilibrium position to position x is found by integrating the x component of the position-dependent force exerted on the oscillator (Eq. 9.22):

$$W = \int_{x_0}^{x} \Sigma F_x(x)\,dx = -\int_{x_0}^{x} m\omega^2 x\,dx, \tag{15.13}$$

where we have substituted the restoring force given in Eq. 15.12. This work causes the kinetic energy of the oscillating object to change, and so Eq. 15.13 gives us the change in kinetic energy ΔK. Working out the integration thus yields

$$\Delta K = -m\omega^2 \int_{x_0}^{x} x dx = -m\omega^2 [\tfrac{1}{2}x^2]_{x_0}^{x} = \tfrac{1}{2}m\omega^2 x_0^2 - \tfrac{1}{2}m\omega^2 x^2. \tag{15.14}$$

Because the interaction that causes the oscillation is reversible, this change in kinetic energy must be provided by some form of potential energy. (In the examples we discussed, the energy was provided by gravitational potential energy or the elastic potential energy of a spring.) If we include the object that causes the oscillation in our system, the system must be closed, so $\Delta E = \Delta K + \Delta U = 0$. Therefore the change in potential energy of the (closed) system is $\Delta U = -\Delta K$, or, substituting Eq. 15.14,

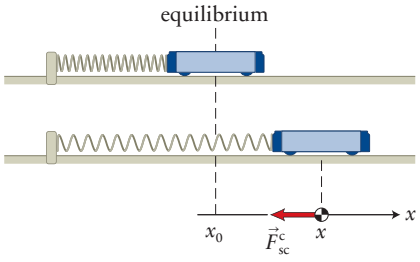
$$\Delta U = U(x) - U(x_0) = \tfrac{1}{2}m\omega^2 x^2 - \tfrac{1}{2}m\omega^2 x_0^2. \tag{15.15}$$

If we let the potential energy at the equilibrium position be zero, $U(x_0) = 0$, then we see that the potential energy of the oscillating system is $U(x) = \frac{1}{2}m\omega^2 x^2$, and so the mechanical energy is

$$E = K + U = \tfrac{1}{2}mv^2 + \tfrac{1}{2}m\omega^2 x^2 \tag{15.16}$$

or, substituting for x from Eq. 15.6 and for v_x from Eq. 15.7,

$$\begin{aligned} E &= \tfrac{1}{2}m\omega^2 A^2 \cos^2(\omega t + \phi_i) + \tfrac{1}{2}m\omega^2 A^2 \sin^2(\omega t + \phi_i) \\ &= \tfrac{1}{2}\,m\omega^2 A^2 \quad \text{(simple harmonic motion)}, \end{aligned} \tag{15.17}$$



where we have used the fact that $\cos^2\phi + \sin^2\phi = 1$ for all ϕ. Equation 15.17 shows that the mechanical energy of a simple harmonic oscillator is constant and proportional to the square of the amplitude, as we concluded earlier.

15.11 (*a*) Use Eq. 15.15 to determine the maximum potential energy of a simple harmonic oscillator. (*b*) Does your answer to part *a* agree with Eq. 15.17?

15.6 Simple harmonic motion and springs

Figure 15.24 Restoring force exerted by spring on cart when cart is displaced from its equilibrium position x_0.

Whenever an object undergoes reversible deformation as a result of stretching, compressing, bending, or twisting, it exerts an elastic restoring force. Consider, for example, the spring-cart system in **Figure 15.24**. The spring exerts on the oscillating cart a force $F^{c}_{scx} = -k(x - x_0)$ (Eq. 8.20), where k is the spring constant and $x - x_0$ is the displacement of the cart from its equilibrium position at x_0, where the spring is relaxed.

We can use this information about the restoring force to obtain an equation for the cart's motion in terms of the amplitude, angular frequency, and phase of the motion. If we let the origin be at the equilibrium position, $x_0 = 0$ and so

$$F^{c}_{scx} = -kx. \tag{15.18}$$

The equation of motion for the cart in the horizontal direction is then

$$\Sigma F_{cx} = ma_x = -kx, \tag{15.19}$$

where m is the cart's mass, or

$$ma_x = m\frac{d^2x}{dt^2} = -kx \tag{15.20}$$

or

$$\frac{d^2x}{dt^2} = -\frac{k}{m}x. \tag{15.21}$$

The solution to this simple harmonic oscillator equation is a sinusoidal function $x(t)$, and comparison with Eq. 15.10 tells us that $k/m = \omega^2$. Therefore the angular frequency of the oscillation is

$$\omega = +\sqrt{\frac{k}{m}}. \tag{15.22}$$

The plus sign in front of the square root means that we must take the positive square root because ω is always positive.

The motion of the cart is given by Eq. 15.6:

$$x(t) = A\sin\left(\sqrt{\frac{k}{m}}t + \phi_i\right). \tag{15.23}$$

Figure 15.25 Four of the infinite number of solutions that satisfy Eq. 15.21.

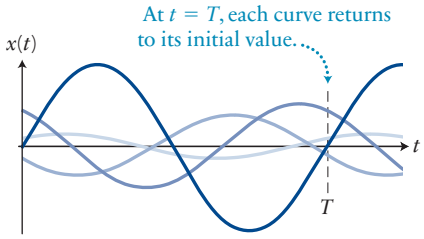


Figure 15.25 shows a number of different sinusoidal functions of the form given by Eq. 15.23 that satisfy Eq. 15.21. All of the functions $x(t)$ shown in Figure 15.25 complete one cycle in a period T, and so they all have the same angular frequency ω, whose value is fixed by properties of the system—the spring constant k and the cart's mass m (Eq. 15.22). However, the peak heights tell you that the curves do not all have the same amplitude A, and the fact that each curve reaches its maximum at a different instant tells you that they have different initial phases ϕ_i. Without information in addition to the values of k and m, we cannot determine the amplitude A and initial phase ϕ_i.

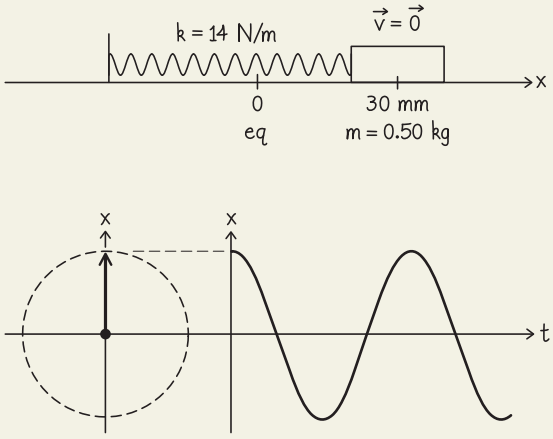
In order to determine A and ϕ_i, we have to know the position and x component of the velocity at some instant. The next examples illustrate how to determine these quantities for some specific situations.



QUANTITATIVE TOOLS

EXAMPLE 15.3 Cart pulled away and released from rest

A cart of mass $m = 0.50$ kg fastened to a spring of spring constant $k = 14$ N/m is pulled 30 mm away from its equilibrium position and then released with zero initial velocity. What are the cart's position and the x component of velocity 2.0 s after being released?

1 GETTING STARTED I begin by making a sketch of the initial condition and representing the oscillation by a reference circle and a graph of position versus time (**Figure 15.26**). I choose the positive x axis to be in the same direction as the cart's initial displacement, with the origin of the axis at the equilibrium position. Because the cart is released with zero initial velocity, its initial kinetic energy at $x = +30$ mm is $K = 0$, and so each time it returns to that position it again has $K = 0$. This tells me that the cart's initial displacement is also its maximum displacement, and so $A = 30$ mm. Because the cart begins at its maximum positive displacement, I know that the oscillation begins with the phasor straight up, and so the initial phase is $\phi_i = +\pi/2$.

Figure 15.26

2 DEVISE PLAN To determine the position of the cart at $t = 2.0$ s, I can use Eq. 15.6. This equation contains the angular frequency ω, which I can determine from Eq. 15.22, and the amplitude A and initial phase ϕ_i, which I already determined. To calculate the x component of the cart's velocity, I can use Eq. 15.7.

3 EXECUTE PLAN From Eq. 15.22, I get for the angular frequency of the oscillation:

$$\omega = \sqrt{\frac{k}{m}} = \sqrt{\frac{14\ \text{N/m}}{0.50\ \text{kg}}} = \sqrt{28\ \text{s}^{-2}} = 5.3\ \text{s}^{-1}.$$

Substituting this angular frequency, $t = 2.0$ s, $A = 30$ mm, and $\phi_i = +\pi/2$ into Eq. 15.6, I obtain for the cart's position at $t = 2.0$ s:

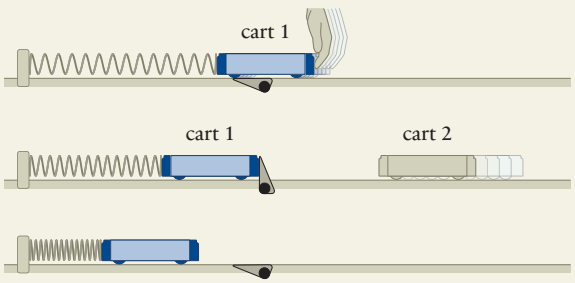
$$x(2.0\ \text{s}) = (30\ \text{mm})\sin\left[(5.3\ \text{s}^{-1})(2.0\ \text{s}) + \frac{\pi}{2}\right]$$

$$= -12\ \text{mm}. \checkmark$$

Substituting the same values into Eq. 15.7, I obtain for the x component of the cart's velocity:

$$v_x(2.0\ \text{s}) = (5.3\ \text{s}^{-1})(30\ \text{mm})\cos\left[(5.3\ \text{s}^{-1})(2.0\ \text{s}) + \frac{\pi}{2}\right]$$

$$= +1.5 \times 10^2\ \text{mm/s}. \checkmark$$



4 EVALUATE RESULT The magnitude of the value I obtained for x is smaller than the amplitude, as it should be. The phase at $t = 2.0$ s is $\phi(t) = (5.3\ \text{s}^{-1})(2.0\ \text{s}) + \pi/2 = 12$, which corresponds to $12/(2\pi) = 1.9$ cycles, so the phasor is in the fourth quadrant, which confirms that x should be negative. The cart moves a distance of $4A = 0.12$ m in one cycle, which takes $2\pi/\omega = 1.2$ s, and so the cart's average speed is $(0.12\ \text{m})/(1.2\ \text{s}) = 0.10$ m/s, indicating that the magnitude of the velocity component I obtain is reasonable. Because the cart is moving in the positive x direction when the phasor is in the fourth quadrant, the x component of the velocity should be positive, as I found.

15.12 (*a*) In Example 15.3 is the initial condition that $v_x = 0$ satisfied by Eq. 15.7? (*b*) Is it correct to say that the x component of the velocity given by Eq. 15.7 must be positive whenever x is negative so as to make sure that the cart moves back to its equilibrium position?

EXAMPLE 15.4 Cart struck with spring already compressed

Cart 1 of mass $m = 0.50$ kg fastened to a spring of spring constant $k = 14$ N/m is pushed 15 mm in from its equilibrium position and held in place by a ratchet (**Figure 15.27**). An identical cart 2 is launched at a speed of 0.10 m/s toward cart 1. The carts collide elastically, releasing the ratchet and setting cart 1 in motion. After the collision, cart 2 is immediately removed from the track. (*a*) What is the maximum compression of the spring? (*b*) How many seconds elapse between the instant the carts collide and the instant the spring reaches maximum compression?

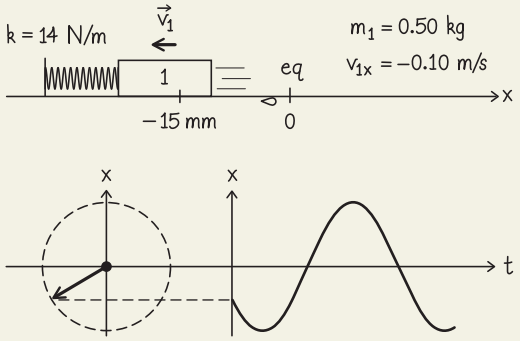


Figure 15.27 Example 15.4.

(Continued)

1 GETTING STARTED If I ignore the effect of the spring during the collision, I can say that the elastic collision interchanges the velocities of the two carts. I make a sketch of the initial condition of cart 1 just before the collision, choosing the positive x axis to the right, the equilibrium position at $x = 0$, and the initial displacement of the cart 15 mm to the left of $x = 0$. I also draw a reference circle and sketch the oscillation resulting from the collision (**Figure 15.28**). With this choice of axis, the x component of the initial velocity of cart 1 is $v_{x,i} = -0.10$ m/s. Because m and k are the same as in Example 15.3, the angular frequency is again $\omega = 5.3\ \text{s}^{-1}$.

Figure 15.28

In contrast to the situation in Example 15.3, the initial displacement of cart 1 is not equal to the amplitude of the oscillation because the collision increases the cart's displacement from the equilibrium position. In other words, cart 1 moves leftward immediately after the collision. It continues moving in this direction until the elastic restoring force building up in the compressing spring causes the cart to stop. This maximum-compression position gives the amplitude of the oscillation.

2 DEVISE PLAN I can determine the value of the amplitude from the mechanical energy of the cart-spring system, which is the sum of the initial potential energy in the spring and the initial kinetic energy of the cart. The potential energy in the spring is given by Eq. 9.23; because the equilibrium position x_0 is at the origin, this equation reduces to $U_{\text{spring}} = \frac{1}{2}kx^2$. The kinetic energy is given by $K = \frac{1}{2}mv^2$. At the position of maximum compression, all of the mechanical energy is stored in the spring, $x = -A$, and so $E_{\text{mech}} = U_{\text{spring}} = \frac{1}{2}kA^2$.

Once I know A, I can determine the initial phase from Eq. 15.6. I can then use that same equation to solve for t at the position of maximum compression, where $x = -A$.

3 EXECUTE PLAN (*a*) The initial kinetic and potential energies of the cart-spring system are

$$K = \tfrac{1}{2}(0.50\ \text{kg})(-0.10\ \text{m/s})^2 = 0.0025\ \text{J}$$

$$U = \tfrac{1}{2}kx^2 = \tfrac{1}{2}(14\ \text{N/m})(-15\ \text{mm})^2\left(\frac{1.0\ \text{m}}{1000\ \text{mm}}\right)^2 = 0.0016\ \text{J}$$

so

$$E_{\text{mech}} = K + U = (0.0025\ \text{J}) + (0.0016\ \text{J}) = 0.0041\ \text{J}.$$

At the position of maximum compression, all of this energy is stored in the spring, and so $\frac{1}{2}kA^2 = 0.0041$ J, or with the k value given,

$$A = \sqrt{\frac{2(0.0041\ \text{J})}{14\ \text{N/m}}} = 0.024\ \text{m} = 24\ \text{mm}. \checkmark$$

(*b*) Substituting the value for A determined in part *a* and the initial condition $x_i = -15$ mm at $t = 0$ into Eq. 15.6, I obtain

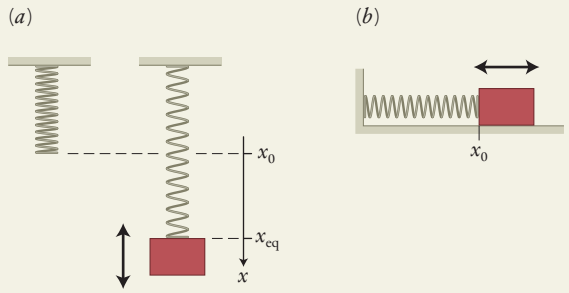
$$x(0) = A\sin(0 + \phi_i) = (24\ \text{mm})\sin\phi_i = -15\ \text{mm}$$

$$\sin\phi_i = \frac{-15\ \text{mm}}{24\ \text{mm}} = -0.63 \quad \text{or} \quad \phi_i = \sin^{-1}(-0.63).$$

Two initial phases satisfy this relationship, $\phi_i = -0.68$ and $\phi_i = -\pi + 0.68 = -2.5$, but only the latter gives a negative x component of the velocity (see Eq. 15.7), as required by the initial condition.

At the first instant of maximum compression, $\sin(\omega t + \phi_i) = -1$, which means $\omega t + \phi_i = -\frac{1}{2}\pi$. Solving for t yields $t = \left(-\frac{1}{2}\pi - \phi_i\right)/\omega = \left[-\frac{1}{2}\pi - (-2.5)\right]/(5.3\ \text{s}^{-1}) = 0.17$ s. ✔

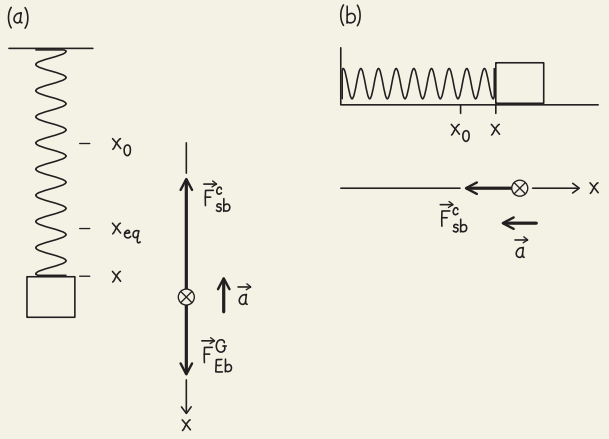
4 EVALUATE RESULT At 24 mm, the amplitude is greater than the 15-mm initial displacement from the equilibrium position, as I would expect. From the reference circle part of my sketch I see that it takes about one-eighth of a cycle to go from the position of impact to the position of maximum compression. From Eq. 15.1 I see that the number of seconds needed to complete one cycle is $T = 2\pi/\omega = 2\pi/(5.3\ \text{s}^{-1}) = 1.2$ s, and so the 0.17-s value I obtained for seconds elapsed between collision and maximum compression is indeed close to one-eighth of a cycle. The assumption that the influence of the spring can be ignored during the collision is justified because the force exerted by the spring is small relative to the force of the impact: At a compression of 15 mm, the magnitude of the force exerted by the spring is $(14\ \text{N/m})(0.015\ \text{m}) = 0.21$ N. The force of impact is given by the time rate of change in the cart's momentum, $\Delta\vec{p}/\Delta t$. The magnitude of the momentum change is $\Delta p = m\Delta v = (0.50\ \text{kg})(0.10\ \text{m/s}) = 0.050\ \text{kg}\cdot\text{m/s}$. If the collision takes place in, say, 20 ms, the magnitude of the force of impact is $(0.050\ \text{kg}\cdot\text{m/s})/(0.020\ \text{s}) = 2.5$ N, which is more than 10 times greater than the magnitude of the force exerted by the spring.



QUANTITATIVE TOOLS

15.13 Suppose cart 2 were not removed from the track of Figure 15.27 immediately after the collision but instead were left stationary at the collision point. (*a*) At what instant do the two carts collide again? (*b*) Describe the motion of the two carts after this second collision.

EXAMPLE 15.5 Vertical oscillations



A block of mass $m = 0.50$ kg is suspended from a spring of spring constant $k = 100$ N/m. (*a*) How far below the end of the relaxed spring at x_0 is the equilibrium position x_{eq} of the suspended block (**Figure 15.29a**)? (*b*) Is the frequency f with which the block oscillates about this equilibrium position x_{eq} greater than, smaller than, or equal to that of an identical system that oscillates horizontally about x_0 on a surface for which friction can be ignored (Figure 15.29*b*)?

Figure 15.29 Example 15.5.

❶ **GETTING STARTED** I begin by making a free-body diagram for the suspended block, choosing the positive x axis pointing downward. Two forces are exerted on the block: an upward force $\vec{F}^{c}_{sb}$ exerted by the spring and a downward gravitational force $\vec{F}^{G}_{Eb}$ exerted by Earth (**Figure 15.30a**). When the suspended block is in translational equilibrium at x_{eq} (which lies below x_0), the vector sum of these forces must be zero. With the block at x_{eq}, the spring is stretched such that the end attached to the block is also at x_{eq}. When the block is below x_{eq}, the spring is stretched farther, causing the magnitude of $\vec{F}^{c}_{sb}$ to increase, and so now the vector sum of the forces exerted on the block points upward. When the block is above x_{eq} (but below the position x_0 of the end of the spring when it is relaxed), the spring is stretched less than when the block is at x_{eq}, causing the magnitude of $\vec{F}^{c}_{sb}$ to decrease, and so the vector sum of the forces exerted on the block points downward. The vector sum of $\vec{F}^{c}_{sb}$ and $\vec{F}^{G}_{Eb}$ thus serves as a restoring force.

Figure 15.30

I also make a free-body diagram for the horizontal arrangement (Figure 15.30*b*), showing only the horizontal forces (the force of gravity and the normal force exerted by the surface cancel out). I let the positive x axis point to the right. In this case, the restoring force is $\vec{F}^{c}_{sb}$ only.

❷ **DEVISE PLAN** In translational equilibrium, the vector sum of the forces exerted on the suspended block is zero, and so I can determine the magnitude of the force exerted by the spring. I can then use Hooke's law (Eq. 8.20) to determine the distance between the equilibrium position and x_0. To compare the oscillation frequencies of the two systems, I should write the simple harmonic oscillator equation for each system in the form given by Eq. 15.12.

❸ **EXECUTE PLAN** (*a*) For translational equilibrium, I have

$$\Sigma F_x = F^{c}_{sbx} + F^{G}_{Ebx} = -k(x_{eq} - x_0) + mg = 0,$$

where $x_{eq} - x_0$ is the displacement of the spring's end from its relaxed position. Solving for $x_{eq} - x_0$, I obtain

$$x_{eq} - x_0 = \frac{mg}{k} = \frac{(0.50\text{ kg})(9.8\text{ m/s}^2)}{100\text{ N/m}} = 0.049\text{ m}. \checkmark$$

(*b*) For the horizontal arrangement, I have in the situation depicted in my sketch (Figure 15.30*b*)

$$\Sigma F_x = F^{c}_{sbx} = -k(x - x_0), \qquad (1)$$

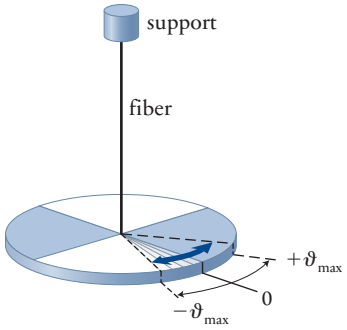
so if I let the origin of my x axis be at the position of the end of the relaxed spring, $x_0 = 0$, the rightmost factor in Eq. 1 reduces to $-kx$ and thus $\Sigma F_x = -kx$. Next I turn to the vertical arrangement. In the position illustrated in Figure 15.30*a*, the x component of the upward force exerted by the spring is

$$F^{c}_{sbx} = -k(x - x_0) = -k(x - x_{eq}) - k(x_{eq} - x_0). \quad (2)$$

From part *a* I know that $k(x_{eq} - x_0)$ is equal to mg. The x component of the vector sum of the forces exerted on the block at position x is thus

$$\Sigma F_x = F^{G}_{Ebx} + F^{c}_{sbx} = mg - k(x - x_{eq}) - mg$$

$$= -k(x - x_{eq}).$$



If, as usual, I let the origin be at the equilibrium position, $x_{eq} = 0$, then this result for ΣF_x is identical to Eq. 1. Comparing these results to Eq. 15.12, I see that in both cases $k = m\omega^2$ and so the oscillation frequencies $f = \omega/2\pi$ of the two systems are the same: $f_{vert} = f_{hor}$. ✔

❹ **EVALUATE RESULT** The two oscillations take place about different equilibrium positions (x_0 for the horizontal case, x_{eq} for the vertical case), but the effect of the combined gravitational and elastic forces in the vertical arrangement is the same as that of just the elastic force in the horizontal arrangement because the force exerted by the spring is linear in the displacement.

15.14 Convince yourself that the argument presented in the solution to Example 15.5 is also valid for displacements of the block above x_{eq}.

15.7 Restoring torques

Figure 15.31 Torsional oscillator.

Some simple harmonic oscillators involve rotational rather than translational displacements. As an example, consider the disk suspended from a thin fiber shown in **Figure 15.31**. Such a setup is called a *torsional oscillator*. If the disk is rotated in the horizontal plane over an angle ϑ_{max}, the fiber is twisted, and elastic potential energy is stored in the fiber. When the disk is released, it oscillates as energy is converted back and forth between the elastic potential energy in the fiber and the rotational kinetic energy of the disk. Translational oscillations, as in our simple pendulum and block-spring setup, are due to the interplay between a restoring force and inertia; rotational oscillations are due to an interplay between a restoring torque and rotational inertia.

For a quantitative description of the disk's oscillation, we use the rotational form of the equation of motion for the disk, which relates the sum of the torques caused by the forces acting on the disk to its rotational acceleration α_ϑ (Eq. 12.10):

$$\Sigma\tau_\vartheta = I\alpha_\vartheta, \tag{15.24}$$

where I is the rotational inertia of the disk.

To complete the description, we must relate the torque to the rotational displacement—just as we related force to translational displacement for translational oscillations. In the case of the rotating disk, the torque is caused by the twisted fiber: A clockwise rotation of the fiber causes a counterclockwise torque, and vice versa; greater rotational displacements of the disk cause greater torques. For small rotational displacements, we might expect that the relationship between rotational displacement and torque is linear:

$$\tau_\vartheta = -\kappa(\vartheta - \vartheta_0). \tag{15.25}$$

The minus sign indicates that the direction of the torque is opposite the direction of the rotational displacement: The torque tends to rotate the disk back toward its equilibrium position. This rotational Form of Hooke's law is found to hold for a wide variety of materials. The constant κ (the Greek letter kappa), called the *torsional constant*, depends on the properties of the material being twisted. Just as stiff springs have large spring constants, stiff materials have large torsional constants.

If we let the rotational position at equilibrium be zero, $\vartheta_0 = 0$, we can combine Eqs. 15.24 and 15.25, yielding

$$I\alpha_\vartheta = I\frac{d^2\vartheta}{dt^2} = -\kappa\vartheta \tag{15.26}$$

or

$$\frac{d^2\vartheta}{dt^2} = -\frac{\kappa}{I}\vartheta. \tag{15.27}$$

Notice the similarity between this equation and two earlier ones: Eq. 15.10 for a generic harmonic oscillator and Eq. 15.21 for a mass oscillating on a spring. The meaning of the symbols is different, but the mathematical form is identical. The disk therefore executes simple harmonic motion, and the rotational position $\vartheta(t)$ is a sinusoidal function of time.

To find the position as a function of time, we exploit the correspondence between Eqs. 15.21 and 15.27, substituting rotational displacement ϑ for translational displacement x in Eq. 15.23 and rotational inertia I for mass m and the torsional constant κ for the spring constant k in Eq. 15.22:

$$\vartheta = \vartheta_{\max} \sin(\omega t + \phi_i) \tag{15.28}$$

$$\omega = \sqrt{\frac{\kappa}{I}} \quad \text{(torsional oscillator)}, \tag{15.29}$$

where $\vartheta_{\max}$ in Eq. 15.28 is the maximum rotational displacement (the amplitude of the rotational oscillation). Note that the ω in Eq. 15.29 represents the angular frequency of the torsional oscillator, not its rotational speed.

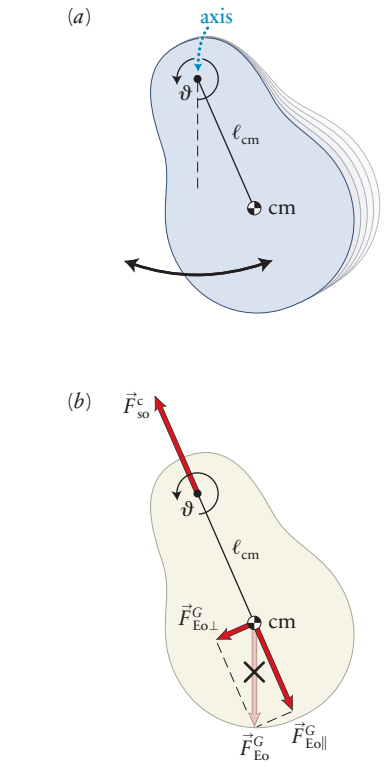
15.15 For the torsional oscillator shown in Figure 15.31, what effect, if any, does a decrease in the radius of the disk have on the oscillation frequency f? Assume the disk's mass is kept the same.

The pendulum is another example of a rotational oscillator. For a pendulum, however, the restoring torque is not caused by an elastic force, and so we cannot use Eq. 15.25. Instead, we must write an expression for the restoring torque due to gravity and relate the magnitude of this torque to the rotational displacement of the pendulum. Consider an object suspended about a rotation axis located a distance ℓ_{cm} from the object's center of mass, as illustrated in **Figure 15.32a**. The restoring torque is provided by the component of the force of gravity perpendicular to ℓ_{cm}: $F^G_{Eo\perp} = -mg \sin\vartheta$ (Figure 15.32*b*). The lever arm of this force relative to the rotation axis is ℓ_{cm}, and so for a rotational displacement ϑ, the torque caused by the force of gravity about the axis is

$$\tau_\vartheta = -\ell_{cm}(mg \sin\vartheta), \tag{15.30}$$

where m is the object's mass. For small rotational displacements, $\sin\vartheta \approx \vartheta$, and so once again we obtain a restoring torque that is linearly proportional to the rotational displacement:

$$\tau_\vartheta = -(m\ell_{cm}\, g)\vartheta. \tag{15.31}$$



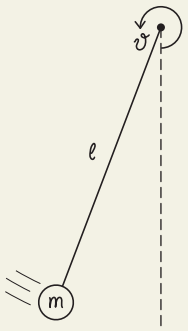
After $\tau_\vartheta = I\alpha_\vartheta = Id^2\vartheta/dt^2$ is substituted for the left side of Eq. 15.31, we get

$$\frac{d^2\vartheta}{dt^2} = -\frac{m\ell_{cm}\, g}{I}\vartheta, \tag{15.32}$$

and so the angular frequency of oscillation is

$$\omega = \sqrt{\frac{m\ell_{cm}\, g}{I}} \quad \text{(pendulum)}. \tag{15.33}$$

Figure 15.32 (*a*) Oscillating pendulum. (*b*) Extended free-body diagram for the pendulum.



EXAMPLE 15.6 The simple pendulum

Suppose a simple pendulum consisting of a bob of mass m suspended from a string of length ℓ is pulled back and released. What is the period of oscillation of the bob?

1 GETTING STARTED I begin by making a sketch of the simple pendulum (**Figure 15.33**), indicating the equilibrium position by a vertical dashed line.

Figure 15.33

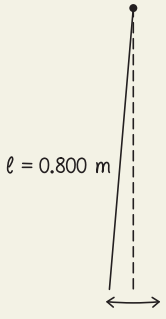
2 DEVISE PLAN The period of the pendulum is related to the angular frequency (Eq. 15.1). To calculate the angular frequency, I can use Eq. 15.33 with $\ell_{cm} = \ell$. If I treat the bob as a particle, I can use Eq. 11.30, $I = mr^2$, with $r = \ell$ to calculate the bob's rotational inertia about the point of suspension.

3 EXECUTE PLAN Substituting the bob's rotational inertia into Eq. 15.33, I get

$$\omega = \sqrt{\frac{m\ell g}{m\ell^2}} = \sqrt{\frac{g}{\ell}},$$

so, from Eq. 15.1, $\omega = 2\pi/T$, I obtain

$$T = \frac{2\pi}{\omega} = 2\pi\sqrt{\frac{\ell}{g}}. \checkmark$$



4 EVALUATE RESULT My result says that T is independent of the mass m of the bob, in agreement with what is stated in Section 15.4. Increasing g decreases the period as it should: A greater g means a greater restoring force, and so the bob is pulled back to the equilibrium position faster. It also makes sense that increasing ℓ increases the period: As my sketch shows, for greater ℓ the bob has to move a greater distance to return to the equilibrium position.

EXAMPLE 15.7 Measuring *g*

The oscillations of a thin rod can be used to determine the value of the acceleration due to gravity. A rod that is 0.800 m long and suspended from one end is observed to complete 100 oscillations in 147 s. What is the value of g at the location of this experiment?

1 GETTING STARTED I begin by making a sketch of the situation. To simplify the problem, I assume that the rod pivots about the fixed end (**Figure 15.34**).

Figure 15.34

2 DEVISE PLAN I calculated the rotational inertia of a thin rod about one end in Example 11.11: $I = \frac{1}{3}m\ell^2$, where m is the rod's mass and ℓ its length. I can use this equation and Eq. 15.33 to solve for g, noting that ℓ_{cm} in Eq. 15.33 is half the length of the rod $\left(\ell_{cm} = \frac{1}{2}\ell\right)$.

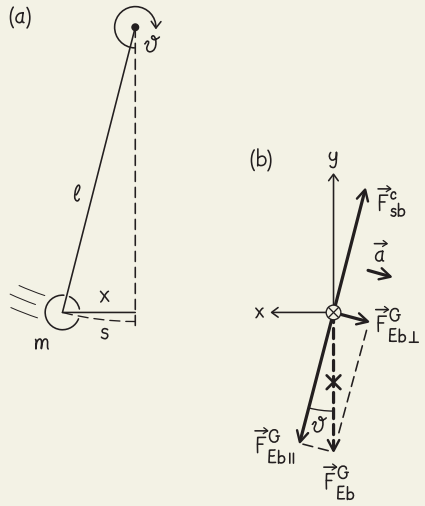
3 EXECUTE PLAN Substituting the rod's rotational inertia and the center-of-mass distance $\ell_{cm} = \frac{1}{2}\ell$ into Eq. 15.33, I get

$$\omega = \sqrt{\frac{m\frac{1}{2}\ell g}{\frac{1}{3}m\ell^2}} = \sqrt{\frac{3g}{2\ell}}.$$

Solving for g yields $g = \frac{2}{3}\omega^2\ell$. The period of the rod is $(147\text{ s})/(100) = 1.47\text{ s}$, and the angular frequency is $\omega = 2\pi f = 2\pi(1/T) = 2\pi/(1.47\text{ s}) = 4.27\text{ s}^{-1}$. Substituting this information into the expression for g yields $g = \frac{2}{3}(4.27\text{ s}^{-1})^2(0.800\text{ m}) = 9.74\text{ m/s}^2$. ✔

4 EVALUATE RESULT I note that the rod's mass does not appear in my expression for ω. Because ω is proportional to $1/T$, this again confirms what Section 15.4 says about the period of a pendulum being independent of the pendulum's mass because the restoring force is proportional to the pendulum's mass. The value I obtained, 9.74 m/s^2, is reasonably close to the acceleration due to gravity near Earth's surface, giving me confidence in my solution.

15.16 Can you use the experiment described in Example 15.7 to measure the gravitational constant G?



QUANTITATIVE TOOLS

EXAMPLE 15.8 The simple pendulum as a one-dimensional oscillator

The angular frequency ω of a simple pendulum can be calculated by treating the pendulum as a one-dimensional oscillator. In Section 15.4, we used this approach to analyze the restoring force exerted on a pendulum, considering the effect of the force of gravity on the horizontal displacement of the bob and ignoring the slight difference between the horizontal displacement x and the arc length s along which the bob swings. Show that this treatment yields for ω the same expression I obtained in Example 15.6, $\omega = \sqrt{g/\ell}$.

❶ **GETTING STARTED** I make a sketch of the pendulum, showing the bob displaced a horizontal distance x from its equilibrium position, the distance I must concentrate on in this problem (**Figure 15.35*a***). I also draw a free-body diagram for the bob (Figure 15.35*b*), showing $\vec{F}^G_{Eb\parallel}$ and $\vec{F}^G_{Eb\perp}$, with the component vectors of $\vec{F}^G_{Eb}$ parallel to and perpendicular to the string in its displaced orientation.

Figure 15.35

❷ **DEVISE PLAN** The component of the gravitational force perpendicular to the string in its displaced orientation, $\vec{F}^G_{Eb\perp}$, provides the restoring force. For small displacements, this component is nearly parallel to the x axis, and so I can take $F^G_{Eb\perp}$ to be the restoring force in the x direction. This expression will permit me to use the simple harmonic oscillator equation (Eq. 15.10) to obtain an express for ω.

❸ **EXECUTE PLAN** From my free-body diagram, I see that

$$F^G_{Eb\perp} = -mg\sin\theta = -mg\frac{x}{\ell},$$

The x component of the force exerted on the bob is equal to $F^G_{Eb\perp}\cos\theta$. In the small-angle approximation, $F^G_{Eb\perp}\cos\theta \approx F^G_{Eb\perp}$. Thus I can write Eq. 15.11 as

$$ma_x \approx -\frac{mg}{\ell}x,$$

or

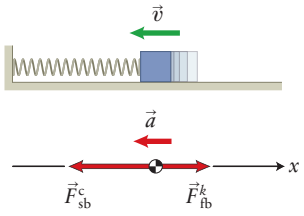
$$a_x \equiv \frac{d^2x}{dt^2} \approx -\frac{g}{\ell}x.$$

Comparing this result with Eq. 15.10, $d^2x/dt^2 = -\omega^2 x$, tells me that $-\omega^2 x = -(g/\ell)x$, an equality that yields the same angular frequency of oscillation as in Example 15.6: $\omega = \sqrt{g/\ell}$. ✔

❹ **EVALUATE RESULT** Given that my result is the same as that obtained using a different method, I feel confident that it is correct.

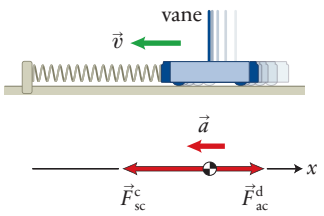
15.17 Imagine placing a pendulum in an elevator. While the elevator accelerates upward, is the frequency f of the pendulum greater than, smaller than, or equal to the frequency when the elevator is at rest?

15.8 Damped oscillations



Up to this point, we have ignored any dissipation of energy in simple harmonic motion. Mechanical oscillations always involve some friction, however, and so the energy of the oscillation is slowly converted to thermal energy. As this conversion takes place, the oscillating object slows down. The general term for this slowing down because of energy dissipation is *damping*, and the system is said to execute a **damped oscillation.**

Consider, for example, the two systems in **Figure 15.36**. Figure 15.36*a* shows a block oscillating under the action of a spring. In Figure 15.36*b* the block is replaced by a cart with a vane on top. As the block oscillates, it rubs against the floor, and its motion is slowed down by friction with the floor. The motion of the cart is hindered by air drag caused by the vane.



The figure also shows the free-body diagrams for the block and the cart. Each object is subject to two forces in the horizontal direction: a restoring force exerted by the spring and a *damping force*—a force due to friction or drag that dissipates the energy of the oscillation. Damping forces can take

Figure 15.36 Damped oscillating systems.

(*a*) Oscillating block is slowed by friction

(*b*) Oscillating cart is slowed by air drag on vane

QUANTITATIVE TOOLS

many forms. For the oscillating block rubbing on the floor, the magnitude of the force of kinetic friction is $F_{\text{fb}}^{k} = \mu_k(mg)$, with μ_k the coefficient of kinetic friction. The direction of this force is always opposite the direction of motion (that is, in the direction opposite the direction of the velocity vector).

Drag forces exerted by air (or other gases) or liquids at low speeds tend to be proportional to the velocity of the object: The faster you ride your bicycle, for instance, the greater the drag force exerted on you by the air. So

$$\vec{F}_{\text{ac}}^{\text{d}} = -b\vec{v} \quad \text{(low speed)}, \tag{15.34}$$

where the coefficient b, called the *damping coefficient,* depends on the shape of the object on which the drag force acts and on the properties of the gas or liquid exerting the force. The SI units of the damping coefficient are kg/s. The minus sign tells you that the direction of the drag force is opposite the direction of the velocity.

For most oscillators, velocity-dependent drag forces are the main cause of energy dissipation. In the presence of drag, the equation of motion for the cart in Figure 15.36 becomes

$$\Sigma F_x = F_{\text{sc}x}^{\text{c}} + F_{\text{ac}x}^{\text{d}} = -kx - bv_x = ma_x, \tag{15.35}$$

where k is the spring constant and m the mass of the cart. When we write the x components of the velocity and the acceleration as time derivatives of x, Eq. 15.35 can be written in the form

$$m\frac{d^2x}{dt^2} + b\frac{dx}{dt} + kx = 0. \tag{15.36}$$

As long as the damping is not too great, the solution to this differential equation is a sinusoidally varying function whose amplitude decreases with time. The solution, given here without proof, is

$$x(t) = Ae^{-bt/2m}\sin(\omega_{\text{d}}t + \phi_{\text{i}}), \tag{15.37}$$

where the angular frequency ω_{d} of the damped oscillator is given by

$$\omega_{\text{d}} = \sqrt{\frac{k}{m} - \frac{b^2}{4m^2}} = \sqrt{\omega^2 - \left(\frac{b}{2m}\right)^2}. \tag{15.38}$$

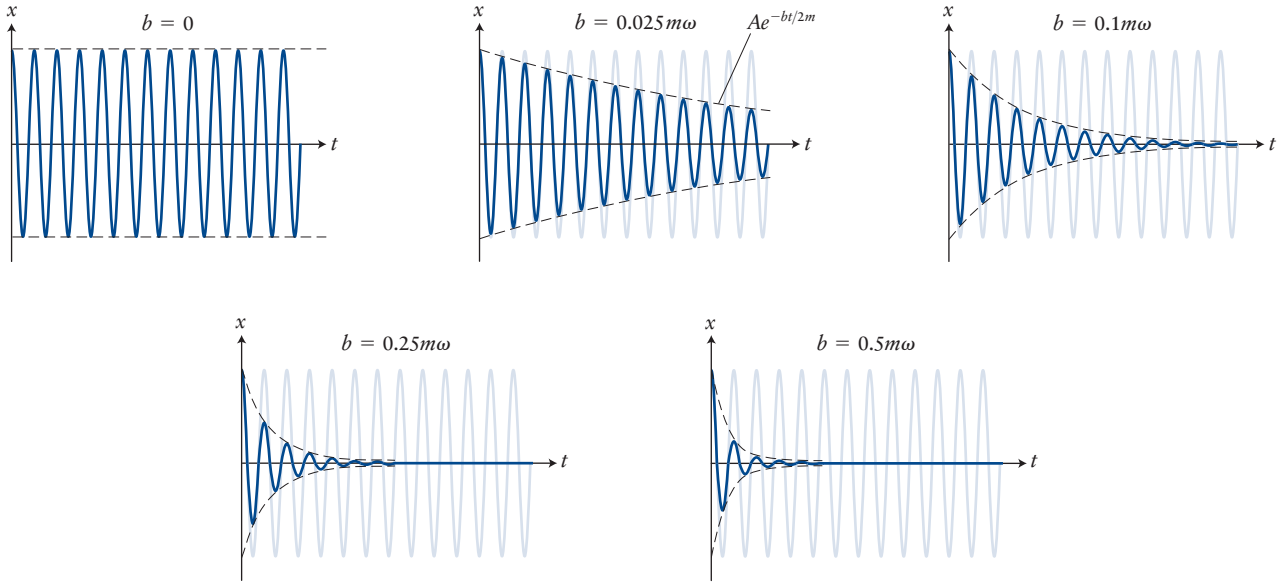


Figure 15.37 shows oscillations for various values of the damping coefficient b. For $b = 0$, there is no damping, which means $\omega_{\text{d}} = \omega$ and $e^{-bt/2m} = 1$. In this case, Eq. 15.37 is identical to Eq. 15.6, the equation for the position of an undamped simple harmonic oscillator. For light damping (small b), the second term in the square root in Eq. 15.38 is negligible, and the damping does not affect the angular frequency of the oscillation: $\omega_{\text{d}} \approx \omega_0$. As Figure 15.37 shows, however, damping decreases the amplitude of the oscillation with each swing. Mathematically, this is expressed by the exponential (see Appendix B) factor $e^{-bt/2m}$ in Eq. 15.37, which makes the amplitude at any given instant equal to $x_{\text{max}} = Ae^{-bt/2m}$, where x_{max} is the time-dependent amplitude of the damped oscillator and A is the (constant) amplitude of the undamped system. In the figure, this decreasing amplitude x_{max} is indicated by the dashed exponential curves, called the *envelope* of the oscillation. The stronger the damping, the faster the amplitude decreases. For very large damping, oscillations cease to occur and the system just returns to the equilibrium position. Such a system is said to be *overdamped*.

The ratio m/b has units of time, and it is customary to call this ratio the **time constant** $\tau \equiv m/b$. (Even though the symbol for the time constant is the same as that for torque, there is no relationship between the two.) With this simplification, the decreasing amplitude can be written as

$$x_{\text{max}}(t) = Ae^{-t/2\tau}. \tag{15.39}$$

QUANTITATIVE TOOLS

Figure 15.37 Damped simple harmonic motion for various values of the damping coefficient b not so great as to prevent oscillations.

The mechanical energy of the oscillator, which is proportional to the square of the amplitude (Eq. 15.17), thus decreases as

$$E(t) = \tfrac{1}{2}m\omega^2 x_{\max}^2 = (\tfrac{1}{2}m\omega^2 A^2)e^{-t/\tau} = E_0 e^{-t/\tau}, \qquad (15.40)$$

where $E_0 = \frac{1}{2}m\omega^2 A_0^2$ is the initial mechanical energy. Equation 15.40 shows that after a time interval equal to the time constant, so that $t = \tau$, the energy has decreased to $e^{-\tau/\tau} = e^{-1} \approx 0.37$ of its initial value; only about one-third of the initial energy remains. During each time interval of duration τ, the energy again decreases by the factor e^{-1}. After two time constants, for instance, only about 10% of the initial energy remains.

Because oscillation periods vary widely, it is often convenient to express the time constant τ in terms of the period T so that we know after how many *cycles* (rather than seconds) the energy has decreased by a certain factor. In terms of cycles, the decay of the oscillation can be characterized by the *quality factor,* defined as

$$Q \equiv \omega\tau = 2\pi\frac{\tau}{T}. \qquad (15.41)$$

The quality factor is a unitless ratio similar to the rotational coordinate ϑ—if $Q = 2\pi$, then $\tau = T$, and so the energy decays by a factor of e^{-1} in one cycle. When $Q = 1000(2\pi)$, it takes 1000 cycles for the energy to decay by a factor of e^{-1}. A large Q implies that $\omega_d \approx \omega_0$. For mechanical oscillators with low friction (piano strings, tuning forks), Q can be as large as a few thousand, meaning the oscillator executes thousands of oscillations before its energy decreases by a factor of e^{-1}. A bell with a large Q rings for a longer time interval than one with a small Q.

15.18 A tuning fork that sounds the tone musicians call middle C oscillates at frequency $f = 262$ Hz. If the amplitude of the fork's oscillation decreases by a factor of 3 in 4.0 s, what are (*a*) the time constant of the oscillation and (*b*) the quality factor?

Chapter Summary

Fundamental characteristics of periodic motion (Sections 15.1, 15.5)

Concepts **Periodic motion** is any motion that repeats itself at regular time intervals. **Oscillation** (or **vibration**) is back-and-forth periodic motion.

The *period* T is the minimum time interval in which periodic motion repeats, and the **amplitude** A of the motion is the magnitude of the maximum displacement of the moving object from its equilibrium position.

Quantitative Tools The **frequency** f of periodic motion is the number of cycles per second and is defined as

$$f \equiv \frac{1}{T}. \tag{15.2}$$

The SI unit of frequency is the **hertz** (Hz):

$$1 \text{ Hz} \equiv 1 \text{ s}^{-1}. \tag{15.3}$$

Simple harmonic motion (Sections 15.2, 15.4, 15.5)

Concepts **Simple harmonic motion** is periodic motion in which the displacement of a system from its equilibrium position varies sinusoidally with time. A system moving in this way is called a *simple harmonic oscillator*.

A restoring force that is linearly proportional to displacement tends to return a simple harmonic oscillator to its equilibrium position. For small displacements, restoring forces are generally proportional to the displacement and therefore cause objects to execute simple harmonic motion about any stable equilibrium position.

A **phasor** is a rotating arrow whose component on a vertical axis traces out simple harmonic motion. The **reference circle** is the circle traced out by the tip of the phasor, and the length of the phasor is equal to the amplitude A of the simple harmonic motion.

Quantitative Tools The **angular frequency** ω of oscillation is equal to the rotational speed of a rotating phasor whose vertical component oscillates with a frequency f. Angular frequency is measured in s^{-1} and is related to the frequency (measured in Hz) by

$$\omega = 2\pi f. \tag{15.4}$$

For a simple harmonic oscillator of amplitude A, the displacement x as a function of time is

$$x(t) = A \sin(\omega t + \phi_i), \tag{15.6}$$

where the sine argument is the **phase** $\phi(t)$ of the periodic motion,

$$\phi(t) = \omega t + \phi_i, \tag{15.5}$$

and ϕ_i is the *initial phase* at $t = 0$.

The x components of the velocity and acceleration of a simple harmonic oscillator are

$$v_x \equiv \frac{dx}{dt} = \omega A \cos(\omega t + \phi_i) \tag{15.7}$$

$$a_x \equiv \frac{d^2x}{dt^2} = -\omega^2 A \sin(\omega t + \phi_i). \tag{15.8}$$

Any object that undergoes simple harmonic motion obeys the **simple harmonic oscillator equation:**

$$\frac{d^2x}{dt^2} = -\omega^2 x, \tag{15.10}$$

where x is the object's displacement from its equilibrium position.

The mechanical energy E of an object of mass m undergoing simple harmonic motion is

$$E = \tfrac{1}{2} m\omega^2 A^2. \tag{15.17}$$

Fourier series (Section 15.3)

Concepts **Fourier's theorem** says that any periodic function with period T can be written as a sum of sinusoidal simple harmonic functions of frequency $f_n = n/T$, where n is an integer. The $n = 1$ term is the **fundamental frequency** or **first harmonic,** and the other components are **higher harmonics.**

Oscillating springs (Section 15.6)

Quantitative Tools For an object attached to a light spring of spring constant k, the simple harmonic oscillator equation takes the form

$$\frac{d^2x}{dt^2} = -\frac{k}{m}x, \tag{15.21}$$

and the angular frequency of the oscillation is

$$\omega = +\sqrt{\frac{k}{m}}. \tag{15.22}$$

The motion of the object is described by

$$x(t) = A\sin\left(\sqrt{\frac{k}{m}}t + \phi_i\right). \tag{15.23}$$

Rotational oscillations (Section 15.7)

Concepts A horizontal disk suspended at its center by a thin fiber forms a type of *torsional oscillator*.

A pendulum is any object that swings about a pivot. A *simple pendulum* consists of a small object (the bob) attached to a very light wire or rod.

Quantitative Tools If a torsional oscillator of rotational inertia I is twisted through a small angle from its equilibrium position ϑ_0 to position ϑ, the restoring torque τ_ϑ is

$$\tau_\vartheta = -\kappa(\vartheta - \vartheta_0), \tag{15.25}$$

where κ is the *torsional constant*. When $\vartheta_0 = 0$, the simple harmonic oscillator equation for the torsional oscillator is

$$\frac{d^2\vartheta}{dt^2} = -\frac{\kappa}{I}\vartheta. \tag{15.27}$$

The rotational position ϑ of the torsional oscillator at instant t is given by

$$\vartheta = \vartheta_{max}\sin(\omega t + \phi_i), \tag{15.28}$$

where ϑ_{max} is the maximum rotational displacement and

$$\omega = \sqrt{\frac{\kappa}{I}}. \tag{15.29}$$

For small rotational displacements, the simple harmonic oscillator equation of a pendulum is

$$\frac{d^2\vartheta}{dt^2} = -\frac{m\ell_{cm}g}{I}\vartheta \tag{15.32}$$

and its angular frequency is

$$\omega = \sqrt{\frac{m\ell_{cm}g}{I}}, \tag{15.33}$$

where ℓ_{cm} is the distance from the center of mass of the pendulum to the pivot.

The period of a simple pendulum is $T = 2\pi\sqrt{\frac{\ell}{g}}$.

Damped oscillations (Section 15.8)

Concepts In **damped oscillation,** the amplitude decreases over time due to energy dissipation. The cause of the dissipation is a *damping force* due to friction, air drag, or water drag.

A damped oscillator that has a large *quality factor* Q keeps oscillating for many periods.

Quantitative Tools At low speeds, the damping force $\vec{F}^{\,\mathrm{d}}_{\mathrm{ao}}$ tends to be proportional to the velocity of the object:

$$\vec{F}^{\,\mathrm{d}}_{\mathrm{ao}} = -b\vec{v}, \tag{15.34}$$

where b, the *damping coefficient,* has units of kilograms per second.

For small damping, the position $x(t)$ of a damped spring is

$$x(t) = Ae^{-bt/2m}\sin(\omega_{\mathrm{d}}t + \phi_{\mathrm{i}}), \tag{15.37}$$

and its angular frequency ω_{d} is

$$\omega_{\mathrm{d}} = \sqrt{\frac{k}{m} - \frac{b^2}{4m^2}} = \sqrt{\omega^2 - \left(\frac{b}{2m}\right)^2}. \tag{15.38}$$

The **time constant** τ for a damped system is $\tau = m/b$. In one time constant, the energy of a damped simple harmonic oscillator is reduced by a factor of $1/e$.

The amplitude $x_{\max}(t)$ and energy $E(t)$ of a damped oscillation of initial amplitude A and initial energy E_0 decrease exponentially with time:

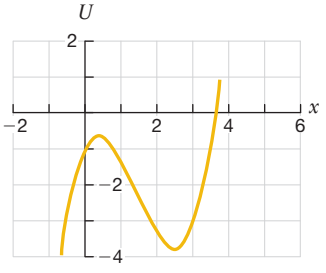
$$x_{\max}(t) = Ae^{-t/2\tau} \tag{15.39}$$

$$E(t) = E_0e^{-t/\tau}. \tag{15.40}$$

The *quality factor* Q of a damped system is

$$Q = 2\pi\frac{\tau}{T}. \tag{15.41}$$

Questions and Problems



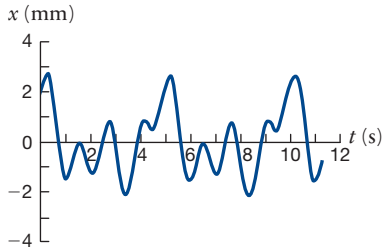
For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy,* •• = *intermediate,* ••• = *hard;* CR = *context-rich problem.*

15.1 Periodic motion and energy

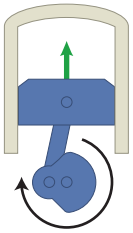
1. If you photograph a flock of birds taking off from ground level, some of the wings will be blurred in the photograph even though the bodies are in focus. In which wing positions are the wings least blurry? •
2. Plot kinetic energy and potential energy as a function of time for the cart in Figure 15.2. •
3. Based on the energy diagrams in Figure 15.2, sketch a graph showing velocity as a function of position for the cart represented in the figure. ••
4. (*a*) At what displacement (expressed as a fraction of the amplitude of the motion) is the kinetic energy of the cart in Figure 15.2 half its maximum value? (*b*) What is the velocity (expressed as a fraction of the maximum velocity) at this displacement? ••
5. Figure P15.5 shows a graph of the potential energy U of a moving object as a function of its position x. What is the maximum range of x values possible for periodic motion in this system? ••

Figure P15.5



15.2 Simple harmonic motion

6. An object attached to one end of a spring makes 25 complete oscillations in 5.0 seconds. What are its period and frequency? •

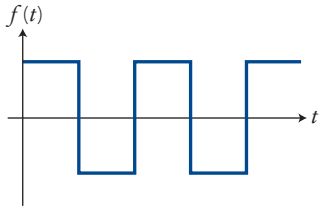


7. What is the period of the motion represented by the curve in Figure P15.7? •

Figure P15.7

8. (*a*) Explain why the motion of the engine piston in Figure P15.8 is only approximately simple harmonic motion. (*b*) What must you do to the length of the connecting rod if you want to make the motion more nearly simple harmonic motion? ••

Figure P15.8

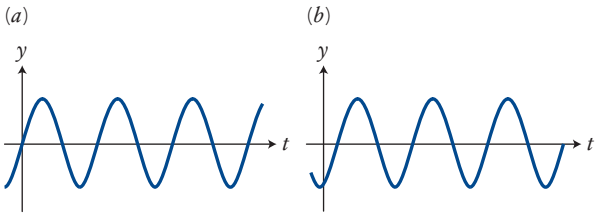


9. Is the typical up-and-down motion of a yo-yo periodic motion, assuming no energy is dissipated? Is it simple harmonic motion? ••
10. A highly elastic ball is dropped from a height of 2.0 m onto a hard surface. Assume the collision is elastic and no energy is lost to air friction. (*a*) Show that the ball's motion after it hits the surface is periodic. (*b*) Determine the period of the motion. (*c*) Is it simple harmonic motion? Why or why not? ••

15.3 Fourier's theorem

11. Fourier analysis of a particular periodic function includes the harmonic frequencies 889 Hz, 1143 Hz, and 1270 Hz. What is the fundamental frequency f_1, assuming that $f_1 > 100$ Hz? •
12. Even when a piano and a trumpet play the same note (which means the sounds have the same frequency f), the two instruments sound completely different. What is it about the sound from the instruments that accounts for this difference? ••
13. Estimate the number of harmonics (counting the fundamental frequency) that contribute significantly in the Fourier analysis of the spectrum in Figure P15.7. ••
14. Suppose you create a periodic function by adding together only sine functions whose amplitudes decrease like $1/n^2$, where n is any odd integer multiple of the fundamental frequency, and where every other term is subtracted rather than added. (*a*) What general properties would this periodic function exhibit? (*b*) Describe the shape of the function obtained by adding only the four terms of frequencies f, $3f$, $5f$, and $7f$. (Hint: Construct the graph using superposition.) •••
15. What harmonic series is required to produce a "square wave" of amplitude 1, as illustrated in Figure P15.15? •••

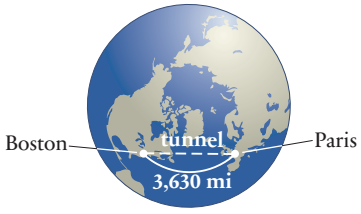
Figure P15.15



15.4 Restoring forces in simple harmonic motion

16. Which of these forces could result in simple harmonic motion: (*a*) $F(x) = 2x$, (*b*) $F(x) = -2x$, (*c*) $F(x) = -2x^2$, (*d*) $F(x) = 2x^2$, (*e*) $F(x) = -2x + 2$, (*f*) $F(x) = -2(x-2)^2$? •
17. When you dive off a diving board, the board oscillates while you are flying toward the swimming pool. (These oscillations are significantly damped for a good diving board.) Identify the restoring force (or torque) responsible for these oscillations as well as the relevant mass. ••
18. A spring-cart system and a simple pendulum both have the same period near Earth's surface. What happens to the period of each motion when both systems are placed on the surface of the Moon, which has an acceleration due to gravity of 1/6 of that of Earth's? ••
19. Figure 15.12 illustrates the x component of the vector sum of forces on an object for conditions of stable, unstable, and neutral equilibrium. (*a*) Examine this graph carefully. What visible feature differs in the three types of equilibrium? (*b*) Express your result as a set of mathematical relationships that can be used to discriminate stable from unstable or neutral equilibrium. (*c*) Are these relationships general? That is, can you construct a graph showing the x component of the vector sum of forces versus position that meets the requirements for stable equilibrium but violates your mathematical expression? ••
20. The period of a pendulum on the surface of the Earth is 1. It is then brought at a higher altitude. For it to maintain its period, should the length of the pendulum string be made longer or shorter? ••

15.5 Energy of a simple harmonic oscillator

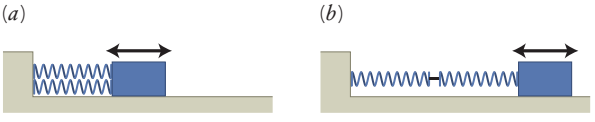


21. Write Eqs. 15.6, 15.7, and 15.8 in terms of the period T of the motion. •
22. Is the initial phase ϕ_i positive, zero, or negative for each oscillation graphed in Figure P15.22? •

Figure P15.22

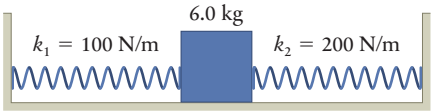
23. In Figure 15.22, the vertical component of the phasor moves in simple harmonic motion. (*a*) Does the horizontal component also move in simple harmonic motion? (*b*) What is the phase difference $\Delta\phi = \phi_v - \phi_h$ between the vertical and horizontal components? ••
24. On average, Mars takes 687 days to make a complete revolution around the sun. Considering its orbit as nearly circular as seen by a distant observer standing in the plane of the orbit, what is the effective "spring constant" of this simple harmonic motion? ••
25. Consider the reference circle shown in Figure 15.22. (*a*) In terms of the rotational speed ω of the phasor, what is the magnitude of the tangential velocity $\vec{v}$ of the phasor tip? What is the vertical component of this velocity? How does this phasor velocity compare with the velocity of an object moving in simple harmonic motion? (*b*) In terms of the rotational speed ω of the phasor, what is the magnitude of the centripetal acceleration of the phasor tip? What is the vertical component of this acceleration? How does this phasor acceleration compare with the acceleration of an object moving in simple harmonic motion? ••
26. A 0.250-kg mass on a spring has velocity as a function of time given by $v(x, t) = (4.70\ \text{cm/s})\cos[(4.16\ \text{rad/s})t]$. Find the (*a*) the period; (*b*) the amplitude; (*c*) the frequency; and (*d*) the force constant of the spring? ••
27. A toy, initially equilibrium position, attached to a spring undergoes simple harmonic motion horizontally with a period of 0.75 s and amplitude of 4.0 cm. Write an equation describing the toy's motion with all variables identified. •
28. You are standing next to a table and looking down on a record player sitting on the table. Take the spindle (axis of rotation) to be the center of your coordinate system and the y axis to be perpendicular to the side of the player you are standing next to. Long-playing records revolve $33\frac{1}{3}$ times per minute. You put a small blob of clay at the edge of a record that has a radius of 0.15 m, positioning the clay such that it is at its greatest value of y at $t = 0$. (*a*) What is the rotational speed of the clay? (*b*) Write the equation of motion for the y component of the clay's position. ••
29. A 0.200-kg small block is attached to an ideal spring with a spring constant of 316 N/m and is moving in simple harmonic motion on a horizontal frictionless surface. Find the energy of the block if its maximum displacement from the equilibrium position is 16.5 cm. ••
30. The position of a particle undergoing simple harmonic motion is given by $x(t) = a\cos(bt + \pi/3)$, where $a = 8.00$ m and $b = 2.00\ \text{s}^{-1}$. What are the (*a*) amplitude, (*b*) frequency f, and (*c*) period? (*d*) What are the speed and acceleration magnitude of the particle at $t = \pi/2$ s? (*e*) What is its maximum acceleration magnitude, and at what instant after $t = 0$ does the particle first have this acceleration? (*f*) What is its maximum speed, and at what instant after $t = 0$ does it first have this speed? ••
31. For any simple harmonic motion, the position, velocity, and acceleration can all be written as the same type of trigonometric function (sine or cosine) by correctly adding a *relative phase factor*. (*a*) Show that an x component of the position function given by $x(t) = \beta\cos(\omega t + \delta)$ is also a valid general solution for simple harmonic motion. (*b*) Write the x components of the velocity and acceleration associated with this position function. (*c*) Draw the reference circles for the x components of position, velocity, and acceleration, with the phasors correctly drawn for $t = 0$ and the amplitude clearly indicated. •••
32. You get a crazy idea to dig a tunnel through Earth from Boston to Paris, a surface distance of 5850 km, and run a passenger train between the two cities (Figure P15.32). The train would move down the first part of the tunnel under the pull of gravity and then coast upward against gravity. If you assume that the motion will be simple harmonic motion, how long will a one-way trip take? •••

Figure P15.32



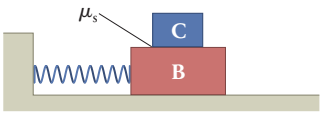
33. You have developed a method in which a paint shaker is used to measure the coefficient of static friction between various objects and a known surface. The shaker oscillates with a fixed amplitude of 50 mm, but you can adjust the frequency of the motion. You have affixed a horizontal tabletop (the known surface) to the shaker so that the tabletop oscillates with it. Then you put an object on the tabletop and increase the frequency until the object begins to slip on the surface. If a frequency $f = 1.85$ Hz is required before a penny positioned on the tabletop starts to slide, what is the coefficient of static friction between penny and tabletop? •••

15.6 Simple harmonic motion and springs



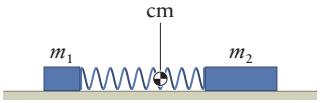
34. Even a spring without a block hanging on the end of it has an oscillation period. Why isn't the period zero? •
35. A vertical spring, on which a block of mass m_1 is hung, oscillates with period T. When replaced with mass m_2, the period is $T/3$. What is the ratio m_1/m_2? ••
36. Two vertical springs, one with spring constant k and the other with spring constant $2k$, each have a ball of mass m hanging from them. Compare the period of oscillation of the two springs undergoing simple harmonic motion. ••
37. A horizontal spring-block system made up of one block and one spring has oscillation frequency f. A second spring, identical to the first, is to be added to the system. (*a*) Does f increase, decrease, or stay the same when the two springs are connected as shown in Figure P15.37*a*? (*b*) What happens to f when the springs are arranged as in Figure P15.37*b*? ••

Figure P15.37



38. An astronaut who recently landed on an unfamiliar planet wants to measure the acceleration due to gravity. He constructs a simple pendulum of length 40.0 cm and then finds that the pendulum makes 35.0 complete swings per minute. Find the value of g on this planet. ••
39. A table outfitted with springs on its feet bounces vertically in simple harmonic motion. A cup of coffee is sitting on the table. Discuss whether any of the following changes to this system could cause the cup to lose contact with the table: (*a*) increase the amplitude, (*b*) increase the period, (*c*) decrease the period, (*d*) decrease the mass of the table, (*e*) increase the mass of the table, (*f*) change the phase of the motion. (*g*) Would your answers be different if you considered not the cup bottom losing contact with the table but rather the coffee flying out of the cup? ••
40. A 5.0-kg cart is attached to a horizontal spring for which the spring constant is 75 N/m. The system is set in motion when the cart is 0.32 m from its equilibrium position, and the initial velocity is 1.5 m/s directed towards the equilibrium position. (*a*) What is the amplitude of the oscillation? (*b*) What is the speed of the cart at the equilibrium position? (*c*) What is the speed of the cart at maximum displacement? (*d*) How would the answers to parts *a*, *b*, and *c* change if the initial direction of the motions is directed away from the cart's equilibrium position? •••
41. A vertical spring-block system with a period of 2.3 s and a mass of 0.35 kg is released 40 mm below its equilibrium position with an initial upward velocity of 0.12 m/s. For this system, determine the (*a*) amplitude, (*b*) angular frequency ω, (*c*) energy, (*d*) spring constant, (*e*) initial phase angle, and (*f*) equation of motion. ••
42. A 5.0-kg object is suspended from the ceiling by a strong spring, which stretches 0.10 m when the object is attached. The object is lifted 0.050 m from this equilibrium position and released. Determine the amplitude and period of the resulting simple harmonic motion. ••
43. A 5.0-kg block is suspended from the ceiling by a strong spring and released to perform simple harmonic motion with a period of 0.50 s. The block is brought to rest, and the length of the spring with the block attached is measured. By how much is this length reduced when the block is removed? ••
44. A 4.0-kg object is suspended from the ceiling by a spring and undergoes simple harmonic motion with an amplitude of 0.50 m. At the highest position in the motion, the spring is at the length that would be its relaxed length if no object were attached. (*a*) Calculate the energy of the system. For the object at its lowest position, its equilibrium position, and its highest position, calculate (*b*) the elastic potential energy of the spring, (*c*) the kinetic energy of the object, and (*d*) the gravitational potential energy of the Earth-object system. ••
45. A 6.0-kg block free to slide on a horizontal surface is anchored to two facing walls by springs (Figure P15.45). Both springs are initially at their relaxed length. The block is then displaced 20 mm to the right and released. (*a*) What is the effective spring constant of the system? (*b*) What is the equation for the position of the block as a function of time, assuming $+x$ to be to the right? Ignore friction. ••

Figure P15.45



46. Block B in Figure P15.46 is free to slide on the horizontal surface. With block C placed on top of B, the system undergoes simple harmonic motion with an amplitude of 0.10 m. Block B has a speed of 0.24 m/s at a displacement of 0.060 m from its equilibrium position. (*a*) Determine the period of the motion. (*b*) What minimum value for the coefficient of static friction μ_s between B and C is needed if C is never to slip? Ignore any friction between B and the horizontal surface. •••

Figure P15.46

47. After gluing two 0.50-kg blocks together, you determine that you can pull the blocks apart with a force of 20 N applied to one block. You attach the top block to a vertical spring for which the spring constant is 500 N/m. What is the maximum possible amplitude of oscillation for which the glue can keep the blocks together? •••
48. Two blocks, of masses m_1 and m_2, are placed on a horizontal surface and attached to opposite ends of a spring as in Figure P15.48. The blocks are then pushed toward each other to compress the spring. When the blocks are released, (*a*) describe the motion of the center of mass of the system and (*b*) derive an expression for the angular frequency ω of the motion. (*c*) What is ω in the limit $m_2 \gg m_1$? (*d*) What is ω when $m_1 = m_2$? Ignore friction and the mass of the spring. •••

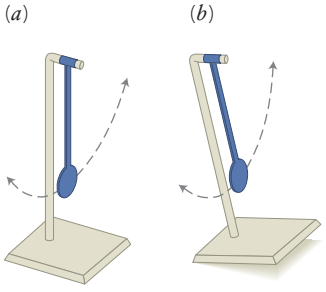


Figure P15.48

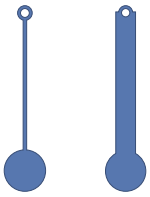
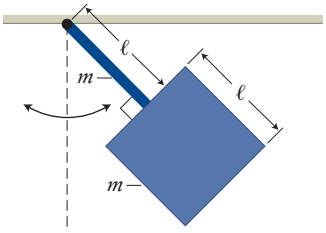
15.7 Restoring torques



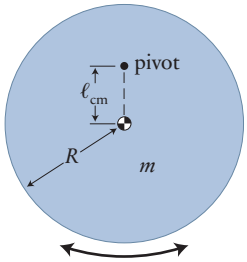
49. You want to build a pendulum clock in which the time interval between the "tick" sound (when the pendulum is swinging one way) and the "tock" sound (when the pendulum is swinging the other way) is 0.50 s. If we assume the pendulum is a simple one, what should its length be? •
50. What happens to the period of the pendulum shown in Figure P15.50*a* when the stand supporting the pendulum is tipped backward as shown in Figure P15.50*b*? •

Figure P15.50



51. Which pendulum in Figure P15.51 has the greater period? ••

Figure P15.51



52. A small-angle approximation was used to derive Eq. 15.31, $\tau = -(m\ell g)\vartheta$. (*a*) What constitutes *small* in this context? In other words, how large can ϑ be before it can no longer be called small? (*b*) As a quantitative benchmark, how large does ϑ have to be before $(m\ell g)\vartheta$ deviates by more than 1% from the true value of τ? ••
53. The maximum angle from the vertical reached by a simple pendulum of length ℓ is ϑ_{max}. What is the linear speed v of the bob for any angle ϑ from the vertical? ••
54. The 800-mg balance wheel of a certain clock is made up of a thin metal ring of radius 15 mm connected by spokes of negligible mass to a fine suspension fiber as in Figure 15.31. The back-and-forth twisting of the fiber causes the wheel to move in simple harmonic motion with period T. The clock ticks four times each second, with the interval between ticks equal to $T/2$. (*a*) Determine the rotational inertia I of the balance wheel. (*b*) What is the torsional constant of the fiber that drives the balance wheel? ••
55. A thin 0.100-kg rod that is 250 mm long has a small hole drilled through it 62.5 mm from one end. A metal wire is strung through the hole and fixed horizontally, and the rod is free to rotate about the wire and to oscillate. (*a*) Determine the rod's rotational inertia I about this axis. (*b*) Determine the period of the rod's oscillation. ••
56. A rod of mass m and length ℓ is rigidly connected at a right angle to the midpoint of one face of a uniform cube of mass m and side length ℓ (Figure P15.56). The other end of the rod is connected to a pivot so that the system can oscillate freely. What is the period of small oscillations about the pivot? ••

Figure P15.56

57. A simple pendulum of length 0.30 m has a 0.30-kg bob. At $t = 0$, the bob passes through the lowest position in its motion, and at this instant it has a horizontal speed of 0.25 m/s. (*a*) What is the maximum angular displacement ϑ_{max} away from vertical that the pendulum reaches? (*b*) What is the bob's linear speed v when it has angular displacement $\vartheta_{max}/2$? ••
58. A uniform disk of mass m and radius R lies in a vertical plane and is pivoted about a point a distance ℓ_{cm} from its center of mass (Figure P15.58). When given a small rotational displacement about the pivot, the disk undergoes simple harmonic motion. Determine the period of this motion. ••

Figure P15.58

59. A thin 0.50-kg ring of radius $R = 0.10$ m hangs vertically from a horizontal knife-edge pivot about which the ring can oscillate freely. If the amplitude of the motion is kept small, what is the period? ••
60. If a person is 20% shorter than average, what is the ratio of his walking pace (that is, the frequency f of his motion) to the walking pace of a person of average height? Assume that a person's leg swings like a pendulum and that the angular amplitude of everybody's stride is about the same. •••
61. A pendulum consists of a bob of mass m_{bob} hanging at the end of a light rod of mass m_{rod} and length ℓ. If you ignore the mass of the rod, the period is T_0, and if you use m_{rod} in your calculation, the period is T. How far from the true value T is T_0? Express the error $\Delta T = T - T_0$ in terms of some power of the ratio m_{rod}/m_{bob}. (Hint: Some sort of series expansion is useful here.) •••

15.8 Damped oscillations

62. Verify that the time constant $\tau = m/b$ has units of time for damped oscillations. •
63. As the quality factor Q for a damped oscillation increases but the period T of undamped motion is held constant, what happens to the angular frequency ω_d of the damped motion? •
64. Express, as a function of τ, the time interval needed for the amplitude of an oscillation to reduce to half of its initial value. •
65. A 0.400-kg object is oscillating on a spring for which the force constant is 300 N/m. A damping force that is linearly proportional to the object's velocity is exerted on the system, and the damping coefficient is $b = 5.00$ kg/s. (*a*) Verify that the units given for b are correct. (*b*) What is the frequency f of the oscillation? (*c*) What is the time constant τ? (*d*) What is the quality factor Q? ••
66. A simple pendulum consists of a 1.00-kg bob on a string 1.00 m long. During a time interval of 27.0 s, the maximum angle this pendulum makes with the vertical is found to decrease from 6.00° to 5.40°. Determine the numerical values of the damping coefficient b and the time constant τ. ••
67. A 0.25-kg bob is suspended from a string that is 0.60 m long. When the pendulum is set into small-amplitude oscillation, the amplitude decays to half of its initial value in 35 s. (*a*) What is the time constant τ for the pendulum? (*b*) At what instant is the energy half of its initial value? ••
68. A restoring force of unknown magnitude is exerted on a object that oscillates with a period of 0.50 s. When the object is in an evacuated container, the motion is simple harmonic motion, with an amplitude of 0.10 m. When

air is allowed into the container, the amplitude decreases by 2.0% with each cycle of the oscillation. (*a*) What is the amplitude after 25 cycles? (*b*) What fraction of the initial energy is left 6.3 s after air is admitted? ••

69. A 0.500-kg block oscillates up and down on a vertical spring for which $k = 12.5$ N/m. The initial amplitude of the motion is 0.100 m. (*a*) What is the natural angular frequency ω? (*b*) If the observed angular frequency is $\omega_d = 4.58\ s^{-1}$, what is b? (*c*) Write an equation for the position as a function of time. ••

70. A damped oscillator has a quality factor of 20. (*a*) By what fraction does the energy decrease during each cycle? (*b*) By what percentage does the damped angular frequency ω_d differ from the undamped angular frequency? ••

71. One reference book states that, after a large earthquake, Earth can be treated as an oscillator that has a period of 54 min and a quality factor of 400. (*a*) What percentage of the energy of oscillation is lost to damping forces during each cycle? (*b*) What fraction of the original energy is left after 2.0 days? ••

72. A gong makes a loud noise when struck. The noise gradually gets less and less loud until it fades below the sensitivity of the human ear. The simplest model of how the gong produces the sound we hear treats the gong as a damped harmonic oscillator. The tone we hear is related to the frequency f of the oscillation, and its loudness is proportional to the energy of the oscillation. (*a*) If the loudness drops to 85% of its original value in 4.0 s, what is the time constant of the damped oscillation? (*b*) How long does it take for the sound to be 25% as loud as it was at the start? (*c*) What fraction of the original loudness remains after 1.0 min? ••

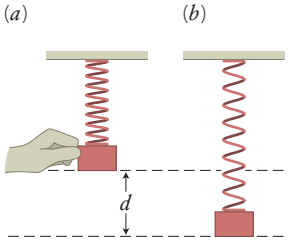
73. *Critical damping* is a term used to describe a situation where the damping coefficient b is just great enough that no oscillation occurs. (In critical damping, a moving part is displaced but returns to its equilibrium position quickly without overshooting it.) This is how you want the springs in your car to behave, so that when they flex to take you smoothly over a bump, they don't cause the car to jump up and down, reducing contact with the road.) (*a*) For an object of mass m attached to a spring of spring constant k, what is the value b_{crit} needed for critical damping? (*b*) Describe the motion if $b > b_{crit}$. ••

74. A small 3.0-kg object dropped from the roof of a tall building acquires a terminal speed of 25 m/s. Assume the drag force exerted on the object has the same form as the damping force exerted on a damped oscillator; that is, the force is opposed to the motion, and its magnitude is linearly proportional to the object's speed. An object identical to the dropped one is attached to a vertical spring ($k = 230$ N/m) and set into oscillation in the air with an initial amplitude of 0.20 m. (*a*) What is the quality factor for this oscillation? (*b*) How long does it take for the amplitude to drop to half its initial value? (*c*) How much energy is lost in this time interval? •••

75. An object resting on a table oscillates on the end of a horizontal spring. Because the table is covered with a viscous substance, the motion is damped and the amplitude gets smaller with each cycle. At $t = 1.5$ s, the object is 60 mm from its equilibrium position, and this is the farthest from equilibrium it reaches. The amplitude of the next cycle of the motion is 56 mm, and the object reaches this maximum x value at $t = 2.5$ s. Write the equation for the object's x component of position as a function of time, using numerical values for all constants. •••

Additional Problems

76. Do the turning points in simple harmonic motion have to be equidistant from the equilibrium position? •



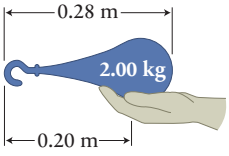
77. A mass attached to a spring oscillates in simple harmonic motion along the x-axis. The limits of its motion are $x = -5$ cm and $x = 45$ cm and it goes from one of these extremes to the other in 0.20 s. Find its (*a*) amplitude; (*b*) frequency; and (*c*) period? ••

78. A pendulum is swinging in a stationary elevator. What happens to the period when the elevator (*a*) accelerates upward, (*b*) travels downward at constant speed, and (*c*) travels downward and gradually slows to a stop? •

79. You measure the oscillation frequency f_{whole} of a vertical block-spring system. You then cut the spring in half, hang the same block from one of the halves, and measure the frequency f_{half}. What is the ratio f_{half}/f_{whole}? ••

80. The hand in Figure P15.80*a* holds a vertical block-spring system so that the spring is compressed. When the hand lets go, the block, of mass m, descends a distance d in a time interval Δt before reversing direction (Figure P15.80*b*). Once the system comes to rest, the block is removed, a block of mass $2m$ is hung in its place, and the experiment is repeated. To what maximum distance does the block descend? ••

Figure P15.80

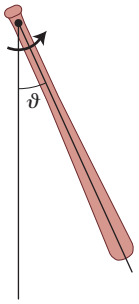


81. Two oscillatory motions are given by $x(t) = A\sin(m\omega t)$ and $y(t) = A\sin(n\omega t + \phi)$, where m and n are positive integers. Consider displaying these motions on a single graph with x and y axes oriented perpendicular to each other. What restrictions are necessary on m, n, and ϕ if the trajectory is to be a closed curve? These curves are called *Lissajous figures*. Plot these curves for (*a*) $m = n = 1$, $\phi = 0$; (*b*) $m = n = 1$, $\phi = \pi/4$; and (*c*) $m = 2$, $n = 3$, $\phi = 0$. ••

82. What would be the period of oscillation of this book if you held it at one corner between index finger and thumb and allowed it to swing slightly? To first order, ignore any effect on the oscillation by friction between your fingers and the book. ••

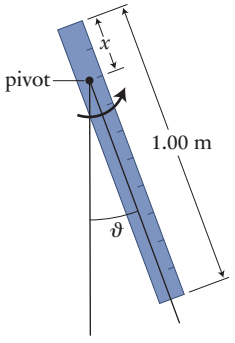
83. You have a teardrop-shaped 2.00-kg object that has a hook at one end and is 0.28 m long along its longest axis (Figure P15.83). When you try to balance the object on your fingers, it balances when

Figure P15.83



your fingers are 0.20 m from the hook end. When you hang the object by the hook and set it into simple harmonic motion, it completes 10 cycles in 11 s. What is its rotational inertia I about the hook? ••

84. A 2.00-kg object is free to slide on a horizontal surface. The object is attached to a spring of spring constant 200 N/m, and the other end of the spring is attached to a wall. The object is pulled in the direction away from the wall until the spring is stretched 50.0 mm from its relaxed position. The object is not released from rest, but is instead given an initial velocity of 2.00 m/s away from the wall. (*a*) Determine the energy of the oscillating system. (*b*) Write the equation for the object's position as a function of time. Ignore friction. ••

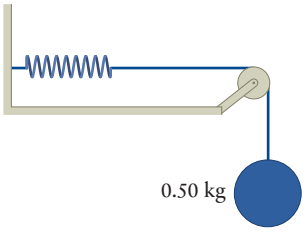


85. A hole is drilled through the narrow end of a 0.960-kg baseball bat, and the bat is hung on a nail so that it can swing freely (Figure P15.85). The bat is 0.860 m long, the hole is drilled 0.0300 m from the end, and the center of mass is located 0.670 m from the end. If the period of oscillation is 1.85 s, what is the bat's rotational inertia (*a*) about the pivot and (*b*) about the center of mass? (*c*) If the hole had been drilled 0.200 m from the end, what would the period be? ••

Figure P15.85

86. A meter stick is free to pivot around a position located a distance x below its top end, where $0 < x < 0.50$ m (Figure P15.86). (*a*) What is the frequency f of its oscillation if it moves as a pendulum? (*b*) To what position should you move the pivot if you want to minimize the period? ••

Figure P15.86



87. To determine what effect a spring's mass has on simple harmonic motion, consider a spring of mass m and relaxed length ℓ_{spring}. The spring is oriented horizontally, and one end is attached to a vertical surface. When the spring is stretched a distance x, the potential energy of the system is $\frac{1}{2}kx^2$. If the free end of the spring is moving with speed v when the free end is at x, calculate the kinetic energy of the spring in terms of m and v. (Hint: Divide the spring into many infinitesimal elements each of length $d\ell_{\text{segment}}$ and located at position ℓ_{segment}; then determine the speed of each piece in terms of ℓ_{segment}, $d\ell_{\text{segment}}$, m, v, and x and integrate from $\ell_{\text{segment}} = 0$ to $\ell_{\text{segment}} = \ell_{\text{spring}} + x$.) •••

88. (*a*) Show that for an object moving in simple harmonic motion, the speed of the object as a function of position is given by $v(x) = \omega\sqrt{A^2 - x^2}$. (*b*) Noting that $v_x = dx/dt$, isolate dt and integrate to determine how long it takes for an oscillator to move from its equilibrium position to some arbitrary position $x < A$. Compare this result with the value of $\Delta t = t_{x<A} - t_{x=A}$ calculated from Eq. 15.6, $x(t) = A\sin(\omega t + \phi_i)$. •••

89. The King's clock fails to keep time, and because you designed it, he's holding you responsible. Examining the spring-ball system you used as the central timekeeping oscillator, you realize that a simple pendulum might be more reliable, and there happens to be a bit of thin, strong wire handy. Unfortunately, you don't have any way of timing the oscillations, nor can you remember what the period is supposed to be. You don't even have a ruler to measure the wire for the pendulum, and there is not enough wire on hand to rely on trial and error. You suddenly realize that all you need to do is observe how far the ball stretches the spring when the spring is held vertically! You calm the King's wrath by putting your new design for the pendulum timekeeping mechanism in operation. ••• CR

90. In physics lab, you are measuring the period of a vertically hung spring-ball system in which the mass of the ball is 0.50 kg. As the system oscillates up and down, it also swings from side to side, a motion that interferes with your measurements of the vertical motion. After running several trials and calculating the period for the system set up this way, you decide to eliminate the side-to-side motion by rigging up the spring horizontally with a string draped over a pulley of radius 0.035 m, as in Figure P15.90. With this arrangement, your measured period is 10% greater than the value you measured for the vertically hung system. Realizing an opportunity for extra credit, you wonder if the rotational inertia of the pulley is buried in your data. ••• CR

Figure P15.90

91. You are aboard the International Space Station and are required to keep track of your mass because of your long stay in the free-fall conditions of deep space. To carry out this task, you hook a 215-kg cargo box to one end of a stiff spring and hook yourself to the spring's other end. With the spring and box initially at rest relative to you, you push off from the cargo box. Floating inside the cabin, you and the cargo box oscillate with a period of 2.21 s. You then unhook yourself from the spring and attach in your place a cargo box identical to the one at the other end of the spring. The oscillation period for this two-box system is 3.13 s. Amazingly, even with squeeze-tube food, you seem to be gaining mass. ••• CR

CONCEPTS

QUANTITATIVE TOOLS

Many phenomena around us involve waves. Throw a stone into a pond and ripples move outward along the surface of the water. Clap your hands and a sound wave travels outward. A large earthquake is detected all over the world because the earthquake causes a wave to propagate through Earth's interior. In general, a **wave** is a *disturbance* propagating (moving) either through a material or through empty space.

The most important feature of waves is that they do not carry matter from one place to another. After a wave has passed through a medium, the medium looks just as it did before it was disturbed. You prove this every time you and a stadium full of other fans work together to create a wave (**Figure 16.1**). Once you've done your small part—stand up, sit down—you are sitting in the same seat; in other words, you haven't moved from one location to another in the stadium. Or throw a rock into a still pond and watch the motion of a floating leaf: The leaf rises and falls as the wave created by the rock passes by but never moves away from its original position. Once the pond is still again, the leaf is just where it was before. A little thought will tell you that the same is true for every molecule of water in the pond. As we shall see, momentum and energy—not matter—are what move along with any wave.

Waves are collective phenomena: A stadium full of fans can create a wave that travels around the stadium; a single person, on the other hand, cannot create such a wave. The person can move up and down or run from one place to another, but neither motion is a wave. A wave can thus never exist at a single position in space: A single water molecule does not make a wave—a water wave requires an extended volume of water.

The examples with which I opened this chapter—water waves, sound waves, seismic waves—are all *mechanical waves*, which are waves that involve the (temporary) displacement of particles. Such waves require a *medium*—a substance to propagate along or through. The propagation is caused by the interaction of the particles in the medium. The medium for water ripples is the water; for the sound of clapping hands, the medium is the air; for seismic waves, it is the material that makes up Earth's interior. Some waves, such as radio waves and light, do not require any medium; they can propagate through empty space as well as through a medium. Even though such *nonmechanical waves* are very different in origin and nature from the mechanical waves we discuss in this chapter and the next, they share many of the properties of mechanical waves. For this reason, when we deal with nonmechanical waves in later chapters, we shall carry over many results derived for mechanical waves.

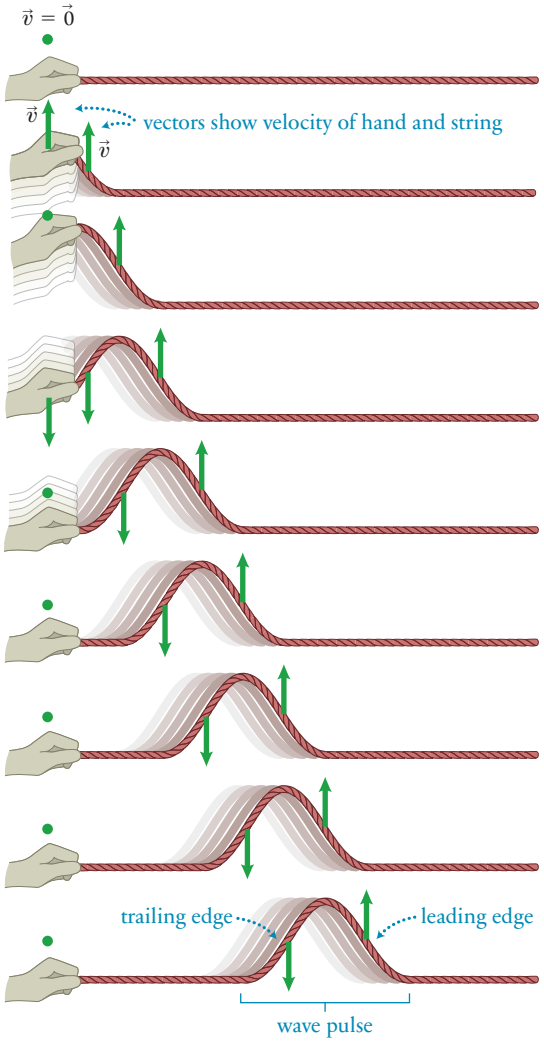

Figure 16.1 Fans at a stadium creating a wave. People get up and raise their arms as soon as the person next to them does so. Because of the small delay between one person and the next, not everyone gets up at the same instant, and the wave travels around the stadium at some finite speed.

16.1 Representing waves graphically

Suppose one end of a long, taut string is rapidly displaced up and down once, as shown in **Figure 16.2**. As the end of the string is raised, it pulls up the neighboring

Figure 16.2 Generation of a wave pulse that propagates along a string.

CONCEPTS

part of the string. As that neighboring part begins moving up, it pulls up the next part of the string, which, in turn, pulls up the next part, and so forth. The upward displacement of the end of the string is thus transmitted along the string because neighboring pieces of the string pull on each other. As the end of the string is moved back down, a similar chain of events occurs in the reverse direction. This pulling along of neighboring pieces of string, first up and then down, produces a **wave pulse**, which travels along the string at constant speed without changing shape. It is important that you do not confuse the horizontal motion of the pulse with the vertical-only motion of the string. The medium through which the pulse passes does not move in the horizontal direction. Each particle of the string moves only once up and once down as the pulse passes through it. **Figure 16.3** shows this vertical-only motion for a string of beads. (Although the string moves in two dimensions, up and down, the wave itself propagates in only one dimension.)

16.1 (*a*) Using the choice of axes shown in Figure 16.3, draw a position-versus-time graph showing how the x and y components of the position of the large bead change with time. (*b*) Are the x and y components of the velocity of the large bead positive, zero, or negative while the bead is on the leading edge of the pulse? Repeat for the trailing edge.

Figure 16.3 Video frames sequence of a wave pulse propagating along a string of beads.

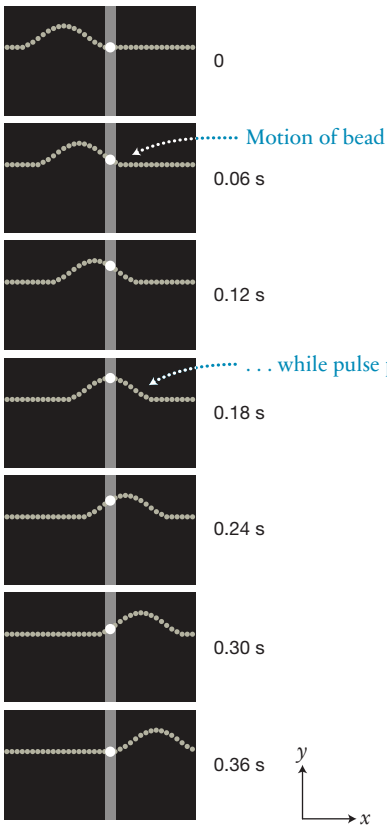

Figure 16.3 shows that the wave motion is different from the motion of the particles of the medium through which the pulse travels. The beads move in the vertical direction only, with each bead executing the same motion—first up and then down. Each bead moves at a different instant, however: first bead 1, then bead 2, then bead 3, and so on. At the leading edge of the pulse, each bead's motion is upward; at the trailing edge, it is downward. After the pulse has passed, all the beads are back in their initial positions.

An important point to keep in mind therefore is:

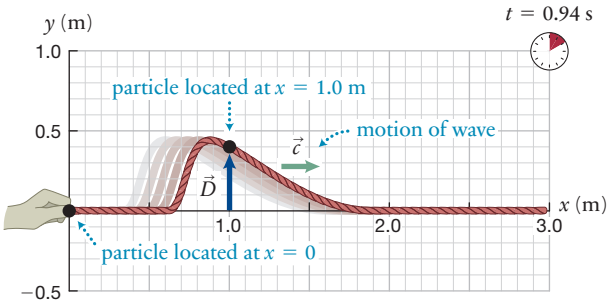
The motion of a wave (or of a single wave pulse) is distinct from the motion of the particles in the medium that transmits the wave (or pulse).

To emphasize this point, we shall use the letter c to denote the **wave speed** of a wave through a medium (along a string in this case) and v to denote the speed of the particles in the medium (the vertical motion of the beads in this case).*

16.2 (*a*) Is the wave speed c of the pulse in Figure 16.3 constant? (*b*) Determine the wave speed if the distance between the centers of adjacent beads is 5.0 mm.

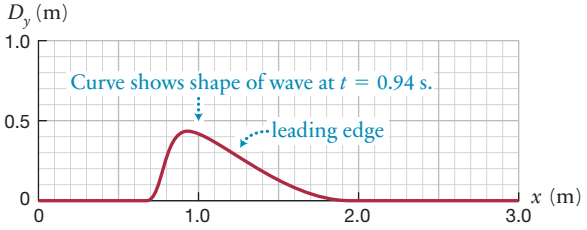
As this checkpoint shows:

The wave speed c of a wave pulse along a string is constant.



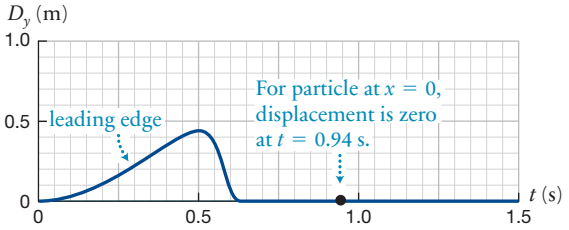
The motion of the various parts of the string, however, is not so simple. As the pulse propagates down the string, the displacements of various particles depend on time *and* on position along the string. At any given instant, different particles on the string have different displacements. Figures 16.2 and 16.3 show "snapshots" of a wave pulse along a string. Each snapshot shows the displacements of the particles on the string from their equilibrium positions as a function of position at one instant. For example, **Figure 16.4*a*** on the next page shows a snapshot of a triangular wave pulse traveling along a string. Such a triangular wave pulse is created by moving the end of the string first upward and then more rapidly downward. The snapshot is superimposed on a calibrated grid so that we can read off the displacements of various particles of the string from their equilibrium positions. The vector $\vec{D}$ in Figure 16.4*a* represents the **displacement** of the particle at $x = 1.0$ m at instant $t = 0.94$ s. In the context of waves, displacement is denoted by the symbol $\vec{D}$, and the initial position is always taken to be the equilibrium position of the particle.

*We use c for the speed of *any* wave, not just light (which is also a wave). The important point is never to confuse the speed of a wave with the speed of the particles being disturbed by the wave.

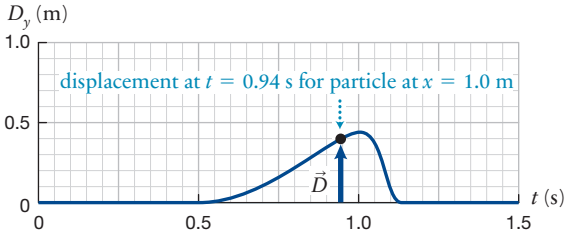


CONCEPTS

Figure 16.4 Distinction between the wave function and displacement curves for a triangular wave pulse propagating along a string parallel to the x axis.



(a) Snapshot of wave at $t = 0.94$ s



(b) Wave function at $t = 0.94$ s

(c) Displacement curve for particle located at $x = 0$

(d) Displacement curve for particle located at $x = 1.0$ m

The graphic representation of all the particle displacements at this instant is shown in Figure 16.4b, which gives the y components of the displacements of the particles of the string as a function of position x along the string (the left end of the string being at $x = 0$). The function shown in Figure 16.4b is called the **wave function**. The wave function represents the shape of the wave at a given instant and changes with time as the wave travels along the string.

16.3 From Figure 16.4a, determine the displacement of a point (a) 1.0 m, (b) 1.5 m, and (c) 2.0 m from the left end of the string. (d) On a snapshot taken a short time interval later, is the displacement at $x = 1.5$ m greater than, equal to, or smaller than that shown in Figure 16.4a?

A complementary way of representing the wave pulse of Figure 16.4a is to plot the displacement of one particle on the string as a function of time. Figure 16.4c, for example, shows the y component of the displacement of the end of the string at $x = 0$ as a function of time. The function shown in Figure 16.4c is called the **displacement curve.** The graph shows that the end of the string started moving up at $t = 0$, reached a maximum displacement of about $+0.50$ m at about $t = 0.50$ s, and then quickly moved back down to its initial position, which it reached at about 0.63 s. This is the motion that generated the triangular wave pulse propagating along the string.

The displacement curve for any string through which a wave pulse moves is different for different particles on the string, as you can see by comparing Figure 16.4c and d. Figure 16.4d shows the displacement curve for the particle at $x = 1.0$ m. The displacement remains zero until the leading edge of the pulse has traveled from $x = 0$ to $x = 1.0$ m. This happens at $t = 0.50$ s, and at that instant the leading edge of the pulse begins raising the $x = 1.0$ m particle until it reaches its maximum displacement at $t = 1.0$ s. The much steeper trailing end of the pulse shown in Figure 16.4a then quickly returns the particle to its equilibrium position between $t = 1.0$ s and $t = 1.1$ s.

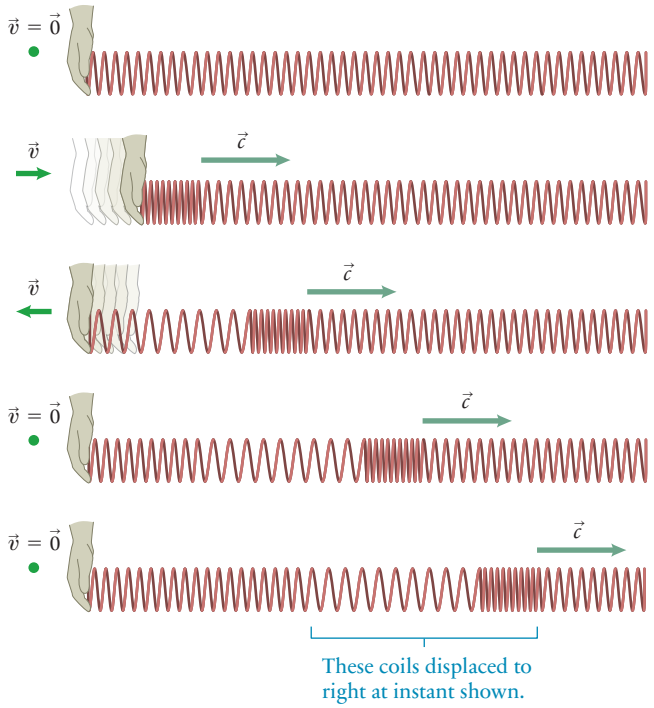
Why is the displacement curve the mirror image of the wave function? Because the wave pulse travels to the right, the leading edge of the pulse is on the right on the wave function graph. The displacement curve, on the other hand, has small values of t (earlier instants) on the left and large values of t (later instants) on the right. So in Figure 16.4c the leading edge of the pulse is on the *left*. (To convince yourself, look at the particle at $x = 1.0$ m in Figure 16.4a and visualize the motion of that particle as the pulse travels past it. Sketch the displacement of the particle as a function of time and compare your result with Figure 16.4d.)

Note that the displacement curves in Figures 16.4c and d have the same form: The one for $x = 1.0$ m is simply shifted to the right. This tells us that both particles execute the same motion at different instants.

16.4 (a) From Figures 16.4c and d, determine how long it takes the pulse to travel from $x = 0$ to $x = 1.0$ m. (b) Using your answer to part a, determine the wave speed.

CONCEPTS

Figure 16.5 Longitudinal wave pulse propagating along a spring.



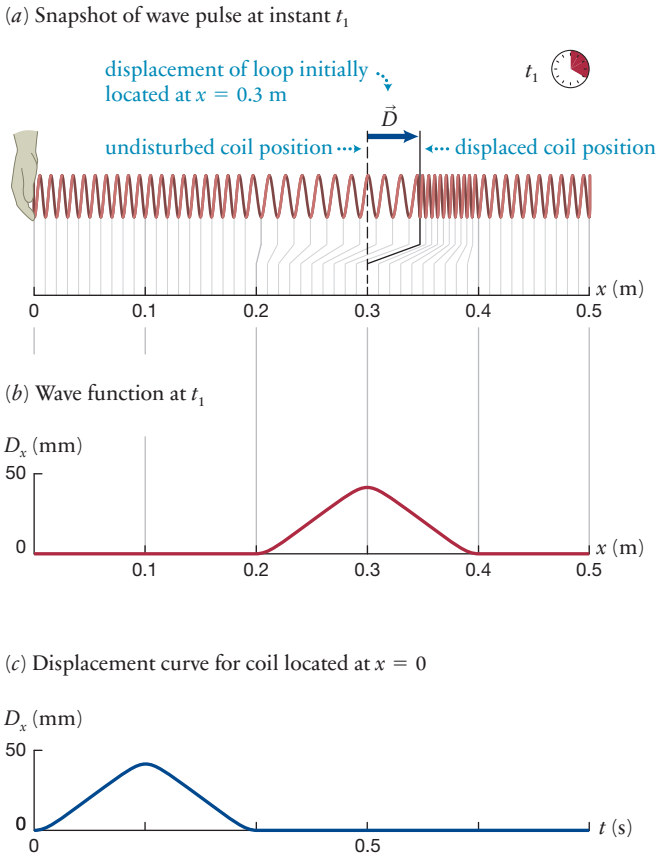


Figure 16.6 Wave function and displacement curve for a longitudinal wave pulse propagating along a spring.

Mechanical waves are divided into two categories, depending on how the medium moves relative to the wave motion. For a wave propagating along a string, the medium movement is perpendicular to the pulse movement. Such waves are called **transverse waves**. In the other type of mechanical wave, the medium movement is parallel to the pulse movement, and waves that behave this way are called **longitudinal waves**. Let's now look at this second type of wave in more detail.

Consider a long coil spring whose end is rapidly displaced back and forth as in **Figure 16.5**. As the left end of the spring is displaced to the right, each coil pushes on the next, displacing the coils one after the other to the right. When the left end is pulled back to its original position, each coil pulls the next one back. The result is again a wave pulse propagating to the right, with each coil temporarily being displaced in the direction of propagation of the wave pulse.

Even though the direction of motion of the individual coils coincides with the direction of propagation of the wave pulse, the motion of the coils and that of the pulse are still distinct. The individual coils move back and forth, but the wave pulse travels at constant speed along the spring.

Longitudinal waves can also be represented using wave functions and displacement curves, but now the wave functions no longer look like a snapshot of the propagating wave. **Figure 16.6*a*** shows a snapshot of a pulse propagating along a spring at some instant t_1, overlaid on a calibrated grid. The corresponding wave function is shown in Figure 16.6*b*—the wave function gives the x component of the displacement of each coil as a function of the coil's position. The coils between $x = 0$ and $x = +0.20$ m are undisturbed, and hence the displacement $\vec{D}$ is zero between $x = 0$ and $x = +0.20$ m. The coils between $x = +0.20$ m and $x = +0.40$ m are all displaced rightward. The x component of the displacement is positive because the displacement is in the positive x direction. To the right of $x = +0.40$ m, the displacement is again zero because the pulse has not yet reached that part of the spring.

Figure 16.6*c* shows the displacement curve for the end of the spring at $x = 0$.

16.5 (*a*) The pulse in Figure 16.6*b* is symmetrical even though Figure 16.6*a* shows that the length of the stretched portion of the spring is 0.15 m and the length of the compressed portion of the spring is only 0.05 m. Explain how the symmetrical curve of Figure 16.6*b* is a correct representation of the asymmetrical situation shown in Figure 16.6*a*. (*b*) Suppose that instead of the end of the spring moving to the right, as illustrated in Figure 16.6, the end is moved to the left. Would this disturbance still cause a wave pulse to travel to the right? If yes, sketch the wave function for this wave pulse at some instant $t > 0$. If no, what happens instead?

CONCEPTS

16.2 Wave propagation

A wave pulse is not an object—it has no mass—and so the description of wave motion is very different from the description of the motion of objects. To study the propagation of a wave pulse along a string, let us consider a collection of beads connected by short strings. The mass of the strings is negligible relative to that of the beads. **Figure 16.7*a*** shows the first ten of these beads as a pulse travels along the string. The vertical gray lines show that the motion of the beads is entirely vertical.

Let us focus on the third bead along the string. At t_1 the left end of the string has just begun moving up, and only bead 1 is displaced from its initial position. The top free-body diagram in Figure 16.7*b* shows the two contact forces exerted on bead 3. If the string is held taut, $\vec{F}^{\text{c}}_{23}$ and $\vec{F}^{\text{c}}_{43}$ point in opposite horizontal directions. (This amounts to saying that the force of gravity on the beads is negligible relative to the contact forces exerted by the strings, and because the bead does not accelerate, the vector sum of the forces exerted on it must be zero.)

16.6 Answer these five questions about the situation at t_1 in Figure 16.7, assuming the right end of the string of beads is attached to a wall that is not shown. (*a*) If $F^{\text{c}}_{43} = 5$ N, what is the magnitude of the force exerted by the wall on the rightmost bead? (*b*) What is the magnitude of the horizontal component of $\vec{F}^{\text{c}}_{12}$? (*c*) What is the direction of the force exerted by the hand on the string? (*d*) How does the magnitude of this force compare with the magnitude F^{c}_{43}? (*e*) What are the effects of the horizontal and vertical components of this force?

This checkpoint makes an important point: If the string is held taut, the magnitudes of the horizontal components of all the contact forces between adjacent beads are equal to the tension $\mathcal{T}$ in the string.

At t_2 the leading edge of the pulse has propagated to bead 3. Because of the displacement of bead 2, $\vec{F}^{\text{c}}_{23}$ is no longer horizontal. The displacement of 2 also causes the string between 2 and 3 to stretch, and so the magnitude F^{c}_{23} increases.

The magnitude of the horizontal component of $\vec{F}^{\text{c}}_{23}$ is still equal to $\mathcal{T}$, but the vector sum of the forces exerted on bead 3 is now nonzero and points vertically upward. Consequently, bead 3 now has a nonzero upward acceleration and so begins moving upward (Figure 16.7*c*). As it moves upward, it stretches and changes the direction of the string connecting it to bead 4, and so the magnitude and direction of $\vec{F}^{\text{c}}_{43}$ change. These changes in $\vec{F}^{\text{c}}_{43}$ have two effects: $\vec{F}^{\text{c}}_{43}$ begins to slow down bead 3, and the reciprocal force $\vec{F}^{\text{c}}_{34}$ begins to accelerate bead 4 upward.

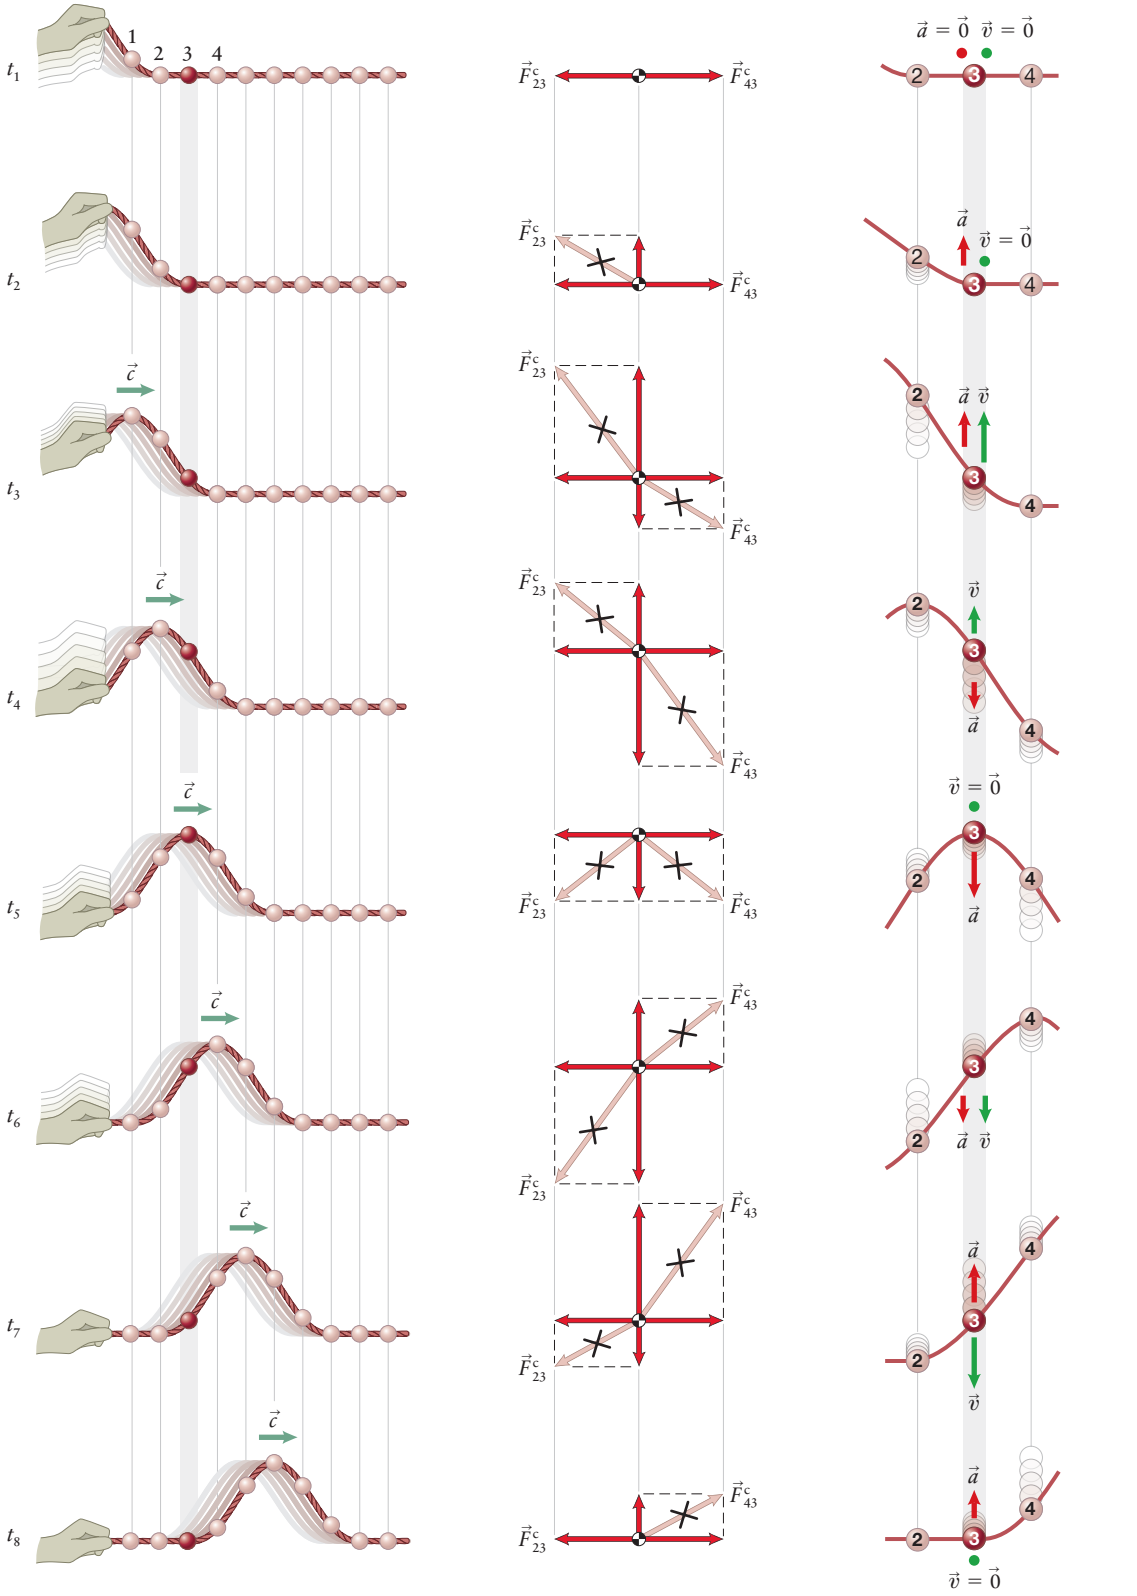
At some instant between t_3 and t_4, $\vec{F}^{\text{c}}_{23}$ and $\vec{F}^{\text{c}}_{43}$ again become equal in magnitude and opposite in direction (but this time with $\vec{F}^{\text{c}}_{23}$ directed upward and to the left and $\vec{F}^{\text{c}}_{43}$ directed downward and to the right), and so the vector sum of the forces exerted on bead 3 is zero. As the bead continues to move upward, the vector sum of the forces begins to oppose the bead's motion (free-body diagram at t_4). Consequently the bead slows down until it comes to a stop at t_5. At that instant, the bead has reached its maximum displacement, and the vector sum of the forces exerted on it points downward. As the bead moves back down, the vector sum of the forces exerted on it decreases. At t_7 the vector sum points upward again, slowing the downward motion of the bead until it reaches its initial position again at t_8. Once the pulse has moved beyond bead 3 and the string around it is straight again, the vector sum of $\vec{F}^{\text{c}}_{23}$ and $\vec{F}^{\text{c}}_{43}$ is again zero, and so the bead remains at rest.

16.7 (*a*) Note that the displacement of bead 4 at t_4 in Figure 16.7*a* is the same as that of bead 3 at t_3. How do the velocity and acceleration of bead 4 at t_4 compare with those of bead 3 at t_3? (*b*) You move one end of two different strings, A and B, up and down in the same way. Suppose the resulting pulse travels twice as fast on string A as on string B. How does the velocity of a particle of string A compare with the velocity of a particle of string B that has the same nonzero displacement? (*c*) Sketch the pulses as they propagate along the two strings and point out any differences between the two. (*d*) For each string, consider a particle located 0.20 m from the left end. Sketch a displacement-versus-time graph for each particle, and point out any differences between your two graphs.

Be sure not to skip Checkpoint 16.7 because it makes two very important—and somewhat counter-intuitive—points:

When a particle of the string is displaced from its equilibrium position, its velocity $\vec{v}$ and acceleration $\vec{a}$ are determined only by the initial disturbance and are independent of the wave speed *c*.

All particles of the string execute the same motion as that caused by the initial disturbance, *regardless of wave speed c* (which determines only how quickly they execute this motion after one another). As Checkpoint 16.7 shows, however, the *shape* of the pulse depends on *c*:



For a given disturbance, high wave speeds yield wave pulses that are stretched out and low wave speeds result in pulses that are more compressed.

Regardless of the pulse shape, however, any particle of the string that reaches a certain displacement has the same velocity and acceleration as any other particle at the instant it reaches that same displacement in the same part of the pulse.

What determines the wave speed? Our analysis of Figure 16.7 shows that the propagation of a wave

CONCEPTS

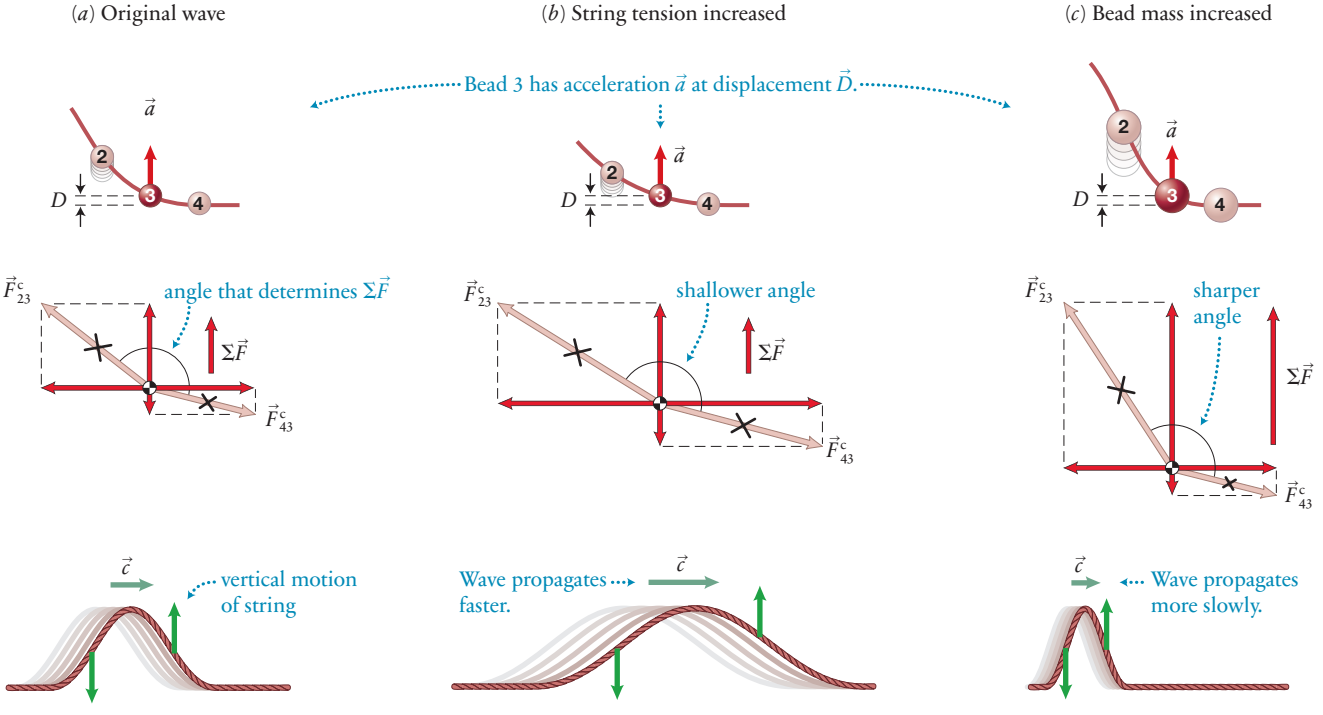
Figure 16.7 Forces and accelerations that cause a wave pulse to propagate along a string of beads.

pulse along a string is due to the forces exerted by each piece on the neighboring pieces. This suggests that wave speed is related to the strength of these forces. Let us therefore investigate what happens if we change the magnitude of the tension in the string.

Suppose that at instant t_3 in Figure 16.7, when bead 3 is on the leading edge of the pulse, this bead has an acceleration $\vec{a}$ when its vertical displacement is $\vec{D}$ (**Figure 16.8a**). This acceleration is caused by the vector sum $\Sigma\vec{F}$ of the forces exerted on the bead. If we now increase the tension in the string (Figure 16.8*b*), the magnitudes of the horizontal components of the contact forces increase by the same amount. Because the contact forces are now greater, the vector sum of the forces exerted on bead 3 reaches the same value as in Figure 16.8*a* with a smaller displacement of bead 2. In other words, it takes a shorter time interval for the pulse to propagate from one bead to the next. A greater tension in the string thus causes a higher wave speed.

Increasing the mass of each bead accomplishes the opposite effect: For a given tension, increasing the mass of each bead decreases the beads' accelerations. To give this larger bead 3 the same acceleration $\vec{a}$ that the smaller bead 3 in Figure 16.8*a* has, bead 2 must now be displaced farther. Thus now it takes a longer time interval for the pulse to propagate from one bead to the next (Figure 16.4*c*). Increasing the mass of each bead corresponds to increasing the mass per unit length of a continuous string.

The speed *c* of a wave propagating along a string increases with increasing tension in the string and decreases with increasing mass per unit length along the string.



This result makes sense: A greater tension means a greater restoring force and therefore a greater tendency to pass the displacement along, resulting in a higher wave speed. If the mass is greater, there is a greater resistance to passing the displacement along, and so the wave speed is lower.

16.8 Two strings, A and B, are identical except that the tension in A is greater than that in B. Suppose you move the left end of each string rapidly up and down once. For each string, sketch (*a*) the wave functions at the instant the pulse on A has traveled halfway down the length of the string and (*b*) the displacement curve for a particle midway down the string.

If the end of a string is made to execute a periodic motion, the resulting wave is called a **periodic wave.** **Figure 16.9** shows a special type of periodic wave, called a **harmonic wave,** obtained by moving the end of the string so that it oscillates harmonically. The result is a sinusoidally shaped wave traveling along the string.

16.9 Plot the displacement of the left end of the string in Figure 16.9 as a function of time. What similarities and differences exist between your graph and the shape of the wave in Figure 16.9?

Figure 16.8 Effects of tension and mass on wave speed. (*a*) The free-body diagrams show the angle between $\vec{F}^c_{23}$ and $\vec{F}^c_{43}$ that is required to cause an acceleration $\vec{a}$ at a displacement $\vec{D}$. (*b*) When the tension is greater, a shallower angle is required to produce the same condition so the wave propagates faster. (*c*) When the mass is greater, a sharper angle is required to produce the same condition so the wave propagates more slowly.

CONCEPTS

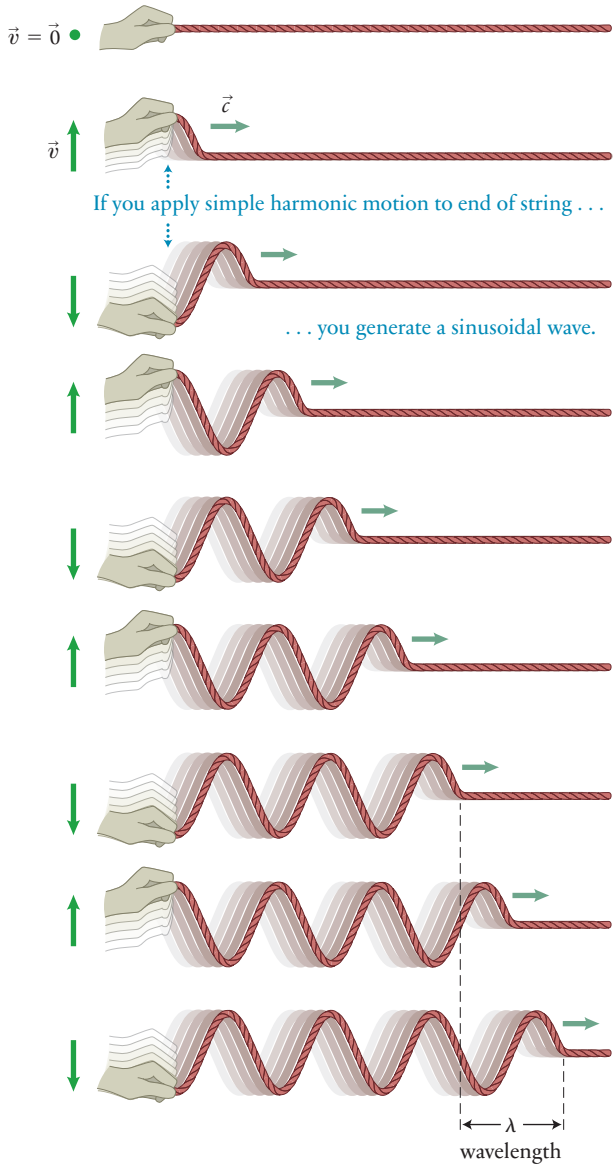
Note how the shape of the string in Figure 16.9 resembles the curves representing simple harmonic oscillations from Chapter 15. The shape in Figure 16.9, however, represents the displacement of the medium as a function of *position*, whereas the simple harmonic oscillator curves in Chapter 15 represented displacement as a function of *time*. If you focus on one particle of the string as the wave moves through it, however, you would see that its up-and-down motion is a delayed version of the hand's periodic motion. So a number of quantities we have used to describe periodic motion are also useful to describe waves (*amplitude:* maximum displacement of any given particle of the medium from its equilibrium position; *frequency:* number of cycles per second executed by each particle of the medium; *period:* time interval taken to complete one cycle). A periodic wave repeats itself over a distance called the **wavelength**, denoted by the symbol λ (Figure 16.9). Each time the left end of the string executes a complete oscillation, the wave advances by one wavelength. If the speed at which the wave propagates is c, then the wave advances a distance cT during the period T of the sinusoidal motion. Therefore:

The wavelength of a periodic wave is equal to the product of the wave speed and the period of the wave motion.

Contrary to what you may expect, moving your hand up and down more quickly does not generate a faster-traveling pulse. **Figure 16.10** shows two pulses generated on identical strings held under identical tensions. The end of the string in Figure 16.10*b* is displaced up and down more quickly than that in Figure 16.10*a*. Both pulses have the same displacement $\Delta\vec{r}$ during a time interval Δt, so the wave speed c is the same for both pulses. To a very good approximation, we determine experimentally that:

The speed c of a wave propagating along a string is independent of the velocities $\vec{v}$ of the individual pieces of string. The value of c is determined entirely by the properties of the medium.

Figure 16.9 If the end of a string is made to execute a simple harmonic motion, the resulting traveling wave is sinusoidal in shape. During one period of the motion, the wave advances by one wavelength.



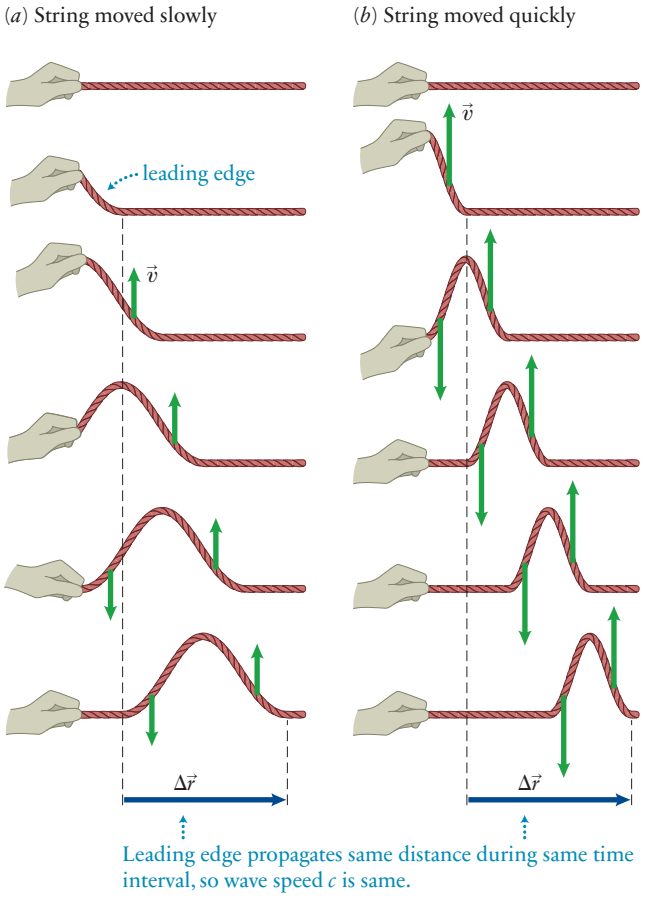


Figure 16.10 The effect on a wave pulse of the speed with which the hand moves up and down. In each case the leading edge of the pulse propagates the same distance during the same time interval, showing that the wave speed c is independent of the velocities $\vec{v}$ of the particles in the string.

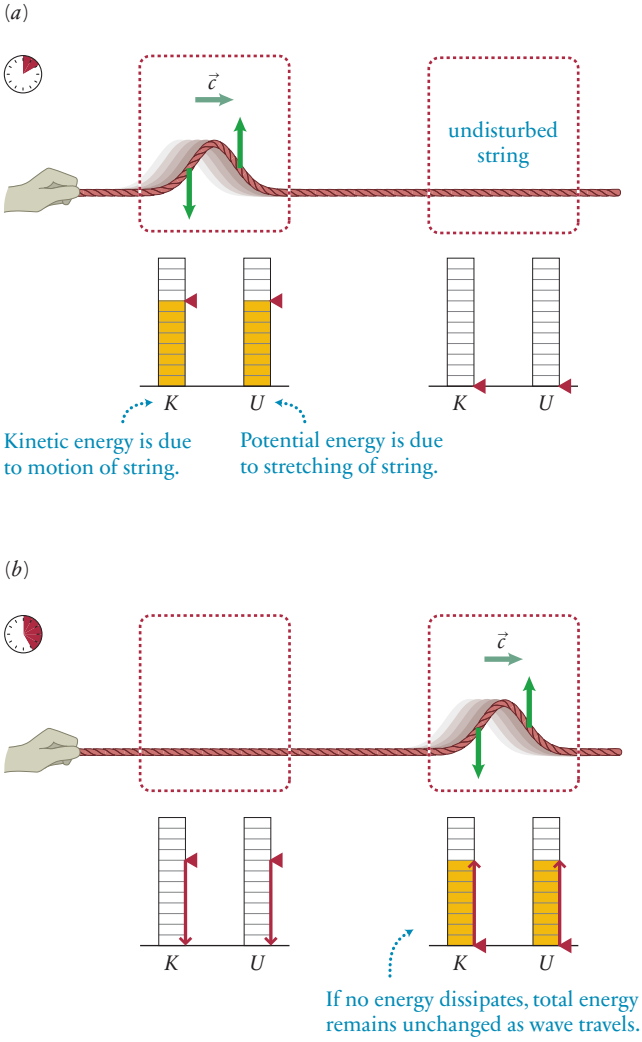


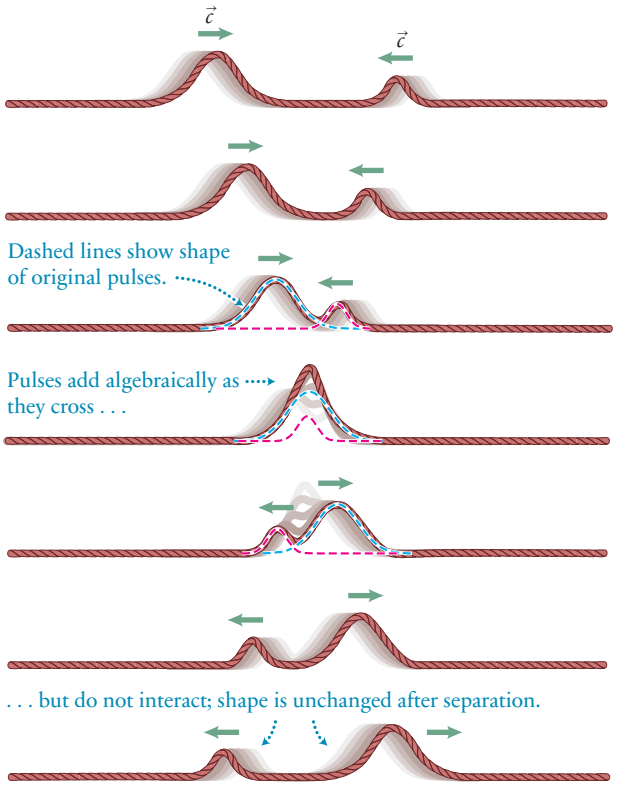
CONCEPTS

If wave speed depended on the velocity of the particles, the shape of a wave pulse would change as it propagates because some parts of it would propagate more quickly than others. As long as the displacement caused by the wave is not too large, however, the shape of the waves remains unchanged (see Figure 16.3).

16.10 Consider a harmonic wave traveling along a string. Are the following quantities determined by the source of the wave, by the properties of the string, or by both: (*a*) the period of oscillation of a particle of the string; (*b*) the speed c at which the wave travels along the string; (*c*) the wavelength; (*d*) the maximum speed v of a particle of the string?

Figure 16.11 illustrates how a propagating wave pulse carries two forms of energy along with it: kinetic energy associated with the motion of individual particles and elastic potential energy associated with the stretching of the string as the pulse is passing through. In Section 16.3 we shall see that a mechanical wave always carries equal amounts of these two forms of energy.

Figure 16.11 A wave pulse carries kinetic and potential energy. If there is no energy dissipation, the amount of energy in (*b*) is the same as that in (*a*).



16.11 Does the wave pulse in Figure 16.11 also carry along momentum? Justify your answer.

16.3 Superposition of waves

Waves have a remarkable property: Two waves can pass straight through each other without changing each other's shape. **Figure 16.12** shows a series of snapshots of two pulses propagating toward each other along a string. When the two pulses overlap, the displacements caused by the two waves add algebraically, provided the medium obeys Hooke's law (see Section 8.9) for the combined displacement. This phenomenon is called the **superposition of waves:**

> **If two or more waves overlap in a medium that obeys Hooke's law, then the resulting wave function at any instant is the algebraic sum of the individual wave functions.**

Figure 16.12 Constructive interference. Two pulses propagating in opposite directions interfere constructively if they displace the string particles in the same direction (here, upward). When the pulses cross, their displacements add algebraically, giving rise to a displacement greater than that caused by either pulse individually. The pulses do not interact with each other: After they separate, their shapes are unaltered.

CONCEPTS

The resulting wave may have a very complicated shape when the waves overlap, but when they separate again, each wave still has its original shape.

The superposition of waves further distinguishes waves from objects: Two objects cannot occupy the same location in space at the same instant, but two waves *can* occupy the same location at the same instant.

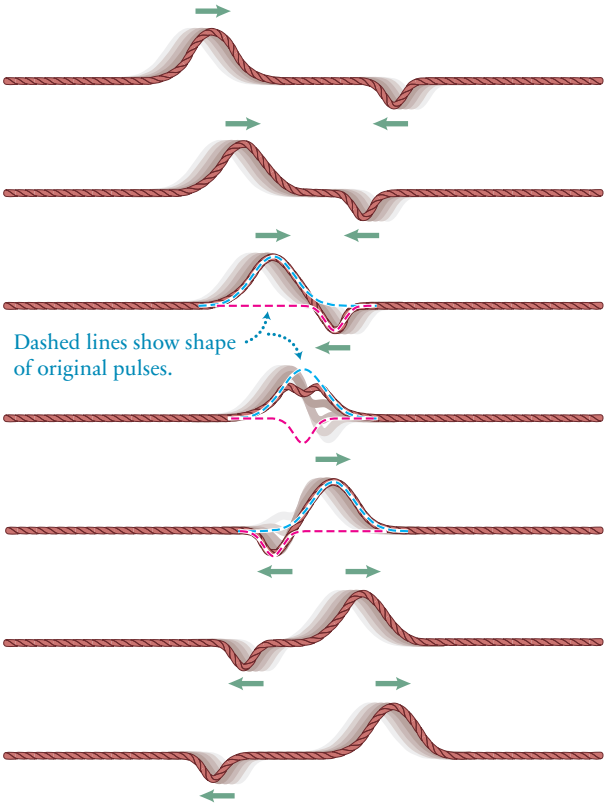
Because the wave functions of two overlapping waves add algebraically, the resultant displacement is greater than that of either wave when the individual displacements have the same sign (Figure 16.12). When they have opposite signs (**Figure 16.13**), the wave with the smaller displacement decreases the displacement caused by the other wave.

When two waves overlap, we say that the waves *interfere* with each other, and the phenomenon is called **interference**. The adding of wave displacements of the same sign, as in Figure 16.12, is called *constructive interference*, and the adding of wave displacements of opposite signs, as in Figure 16.13, is called *destructive interference*. This terminology is somewhat misleading because the waves do not *interact* in any way. As you can see from Figures 16.12 and 16.13, when the two waves separate, their shapes are unchanged. Although there is no destruction or construction, interference of waves does affect the displacement that occurs at specific locations, as the next checkpoint shows.

16.12 (*a*) Is the maximum displacement the same for all particles of the string in Figure 16.12? For all particles of the string in Figure 16.13? (*b*) For each string, sketch a displacement curve for a point near the left end of the string. (*c*) Repeat part *b* for the point of each string at which the pulses meet. (*d*) Reconcile your answer to part *a* with your sketches for parts *b* and *c*.

An extreme form of destructive interference occurs when the two pulses crossing each other are the same size and shape but of opposite algebraic signs, as in **Figure 16.14**. At the instant the two pulses overlap, the displacements cancel and the string is flat. Even though it appears as though both pulses have disappeared, they continue unchanged after the superposition.

Figure 16.13 Destructive interference. Two pulses propagating in opposite directions interfere destructively if they displace the string particles in opposite directions. When the pulses cross, their displacements add algebraically, giving rise to a decreased displacement. After the pulses separate, their shapes are unaltered.



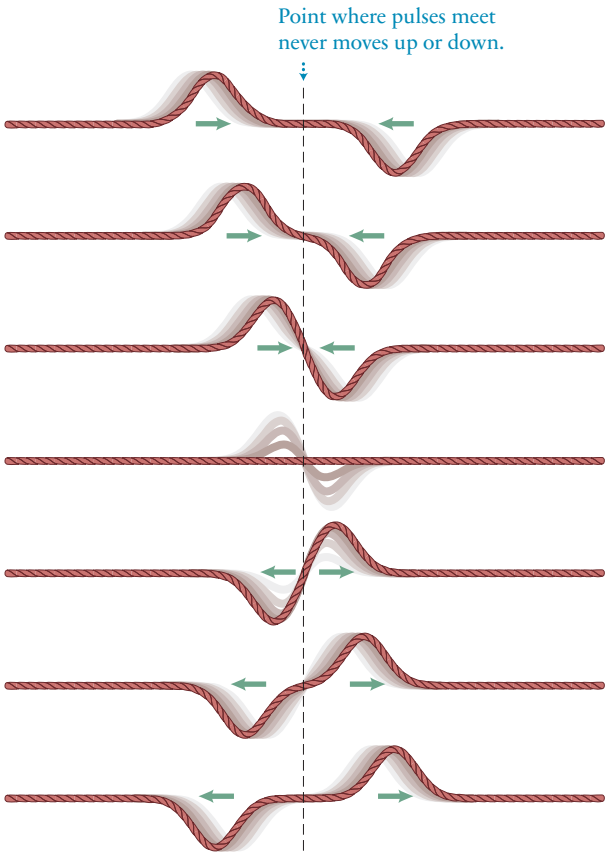


Figure 16.14 Complete destructive interference of two pulses of identical shape propagating in opposite directions while displacing string particles in opposite directions. At the instant the pulses overlap, their displacements add to zero.

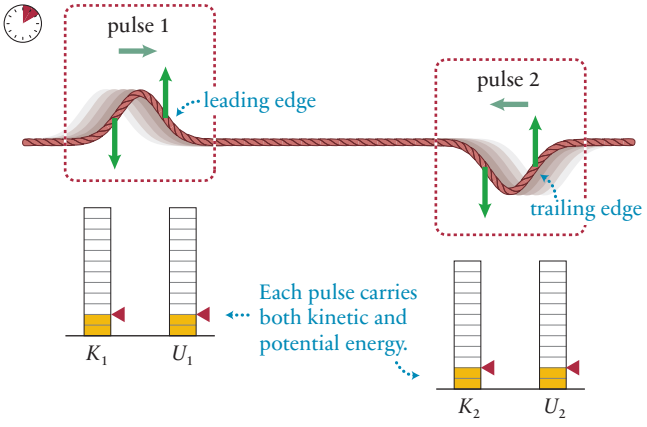
CONCEPTS

16.13 (*a*) Sketch a displacement curve for the point on the string in Figure 16.14 at which the two pulses meet. (*b*) When two wave pulses overlap, how is the velocity of a point in the overlap region related to the velocities of the corresponding points of the individual pulses?

As Checkpoint 16.13 shows, the point at which the two pulses in Figure 16.14 meet never moves. When the two pulses overlap, they cause equal displacements in opposite directions, and so the vector sum of the displacements is zero. A point that remains stationary in a medium through which waves move is called a **node**.

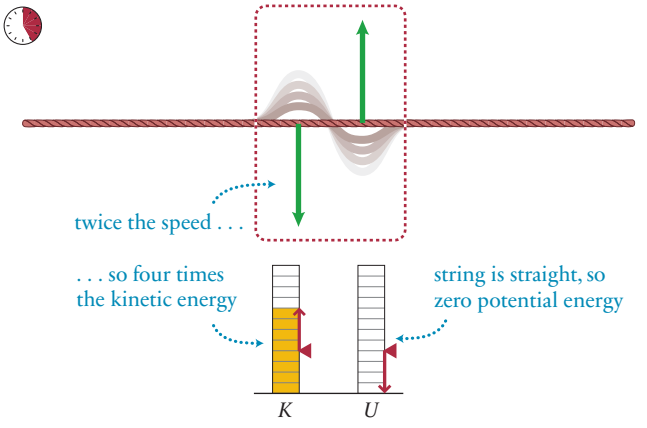
We can deduce a useful fact by examining what happens to the energy in the pulses when they overlap exactly. Because the two pulses are identical, each carries the same amount of energy $E_1 = K_1 + U_1$, and the total energy in the two pulses is thus $2K_1 + 2U_1$ (**Figure 16.15a**). When the string displacements caused by the two pulses cancel each other exactly (the pulses interfere destructively), the string is straight, and so the elastic potential energy is zero. The kinetic energy, however, is not zero. The upward-moving leading edge of pulse 1 adds to the upward-moving trailing edge of pulse 2, and likewise for the downward-moving edges. The result is that the points within the overlapping pulses move twice as fast as those within the individual pulses before and after the overlap. Because kinetic energy depends on the square of the velocities, the kinetic energy of points in the overlap region is four times as great as that of an individual pulse. The energy during the instant shown in Figure 16.15*b* is thus $4K_1$, which must be equal to the initial energy $2K_1 + 2U_1$ of the two separate pulses. So we determine that $2K_1 + 2U_1 = 4K_1$, which can be true only if $K_1 = U_1$—in other words, if each pulse has an equal amount of kinetic and potential energy. Because these arguments do not depend on the shape of the pulse, it follows that:

A wave contains equal amounts of kinetic and potential energy.



CONCEPTS

16.4 Boundary effects



When a wave pulse reaches a boundary where the transmitting medium ends, the pulse is *reflected*, which means that its direction of propagation is reversed. After reaching the boundary, a pulse originally traveling to the right starts moving to the left through the medium, and a pulse originally traveling to the left starts moving to the right. Before the pulse reaches the boundary, we refer to it as the *incident pulse;* after reflection, it is the *reflected pulse*. Whether or not a reflected pulse has the same orientation as the incident pulse depends on the properties of the boundary.

Figure 16.15 Interference of two pulses traveling in opposite directions. At the instant the pulses overlap, the string displacement is zero everywhere, and so the potential energy is zero; all the energy is kinetic.

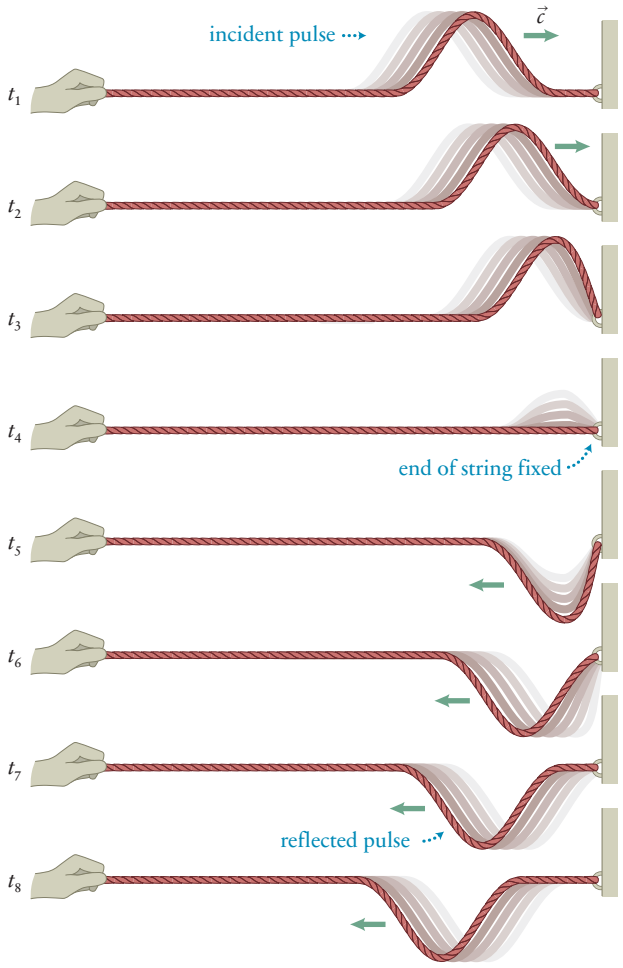
(*a*) Two pulses of identical shape traveling in opposite directions and having displacements in opposite directions

(*b*) At the instant the pulses overlap, the string displacement is zero everywhere, and so the potential energy is zero; all the energy is kinetic

Consider first a pulse propagating along a string toward the end of the string that has been anchored so that it cannot move (**Figure 16.16**). As the leading edge of the pulse reaches the fixed end, the pulse pulls the end upward. The effect of this upward pull is that the fixed end exerts a downward force on the string.* This downward force exerted on the string produces an *inverted* reflected pulse. If no energy is lost in the reflection, the reflected pulse is identical in shape to the incident pulse.

*If you think it is hard to imagine that the fixed end pulls the string downward, imagine pulling yourself up from a chinning bar. When you do so, you exert a downward force on the bar, and the bar exerts an upward force on you. Because the bar is fixed, you end up moving up even though you pull down on the bar.

Figure 16.16 Reflection of a pulse at a boundary where the string end is fixed and so cannot move.



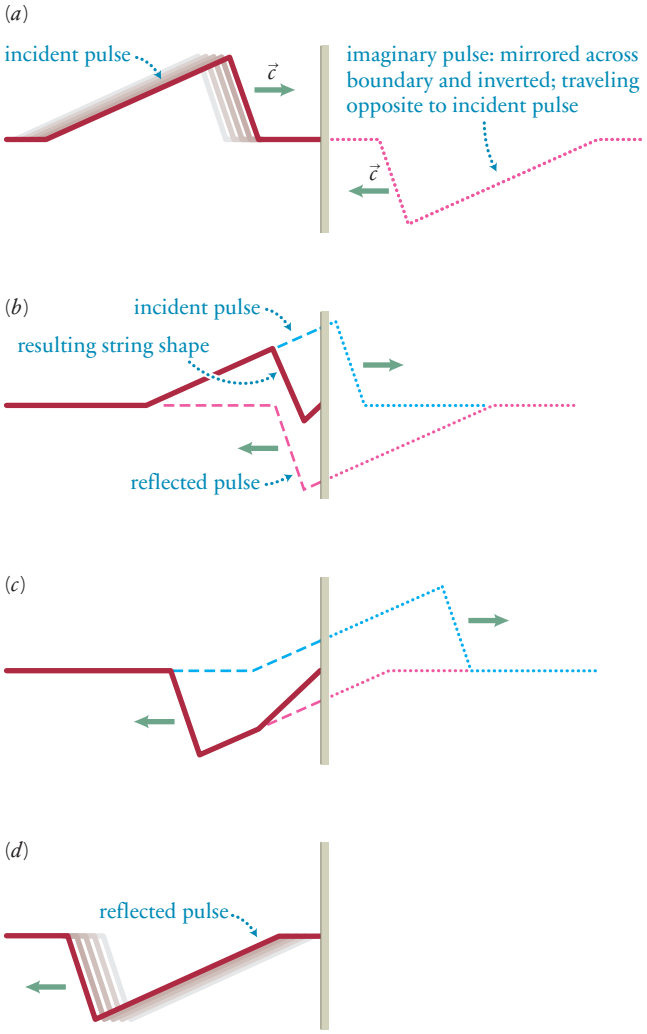


Figure 16.17 Reflection of a triangular pulse at a boundary where the string end cannot move.

16.14 The string in Figure 16.16 is perfectly straight at t_4. What has happened to the energy in the incident pulse at that instant?

Notice the similarity between Figures 16.16 and 16.14. If you cover the right half of Figure 16.14 with a piece of paper so that the left edge of the paper goes through the point at which the pulses meet, the two figures are identical. Indeed, as we saw in Checkpoint 16.13, the point at which the pulses meet in Figure 16.14 is a node, precisely like the fixed end of the string in Figure 16.16.

The correspondence between Figure 16.16 and the left side of Figure 16.14 suggests a procedure for determining the shape of a reflected wave pulse: On the incident pulse superpose an identical, but inverted, pulse that approaches from the opposite side of the fixed end and reaches the fixed end at the same instant as the incident pulse. This procedure is best illustrated using an example involving a pulse with an asymmetrical shape (**Figure 16.17**).

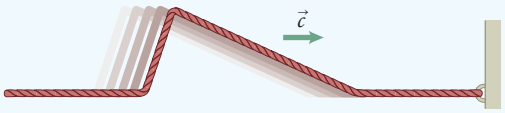

Figure 16.17*a* shows a triangular wave pulse approaching the fixed end of a string. To construct the reflected pulse we first draw an inverted triangular pulse on the opposite side of the fixed point and moving in the opposite direction. This inverted "reflected pulse" reaches the fixed point at the same instant as the incident pulse, and the two interfere (Figures 16.17*b* and *c*). While the two pulses overlap in space, the resulting shape of the pulse is obtained by adding the incident and reflected waves. Once the reflected pulse separates from the fixed end, its shape is the inverse of the incident wave pulse (Figure 16.17*d*).

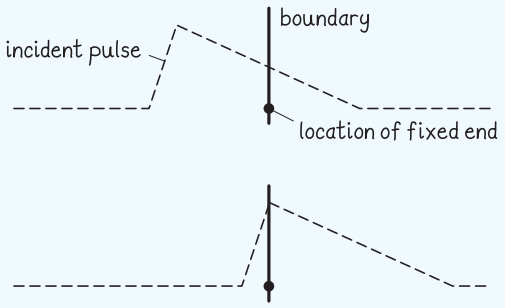
CONCEPTS

EXAMPLE 16.1 Reflection from a fixed end

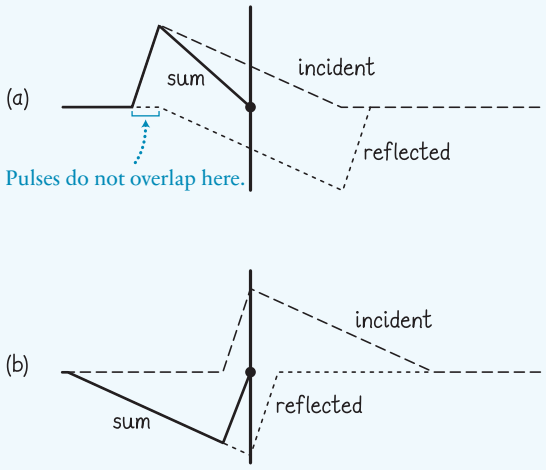


Consider a triangular wave pulse approaching the fixed end of a string (**Figure 16.18**). Sketch the shape of the string (*a*) when a point halfway up the leading edge of the pulse has reached the fixed end and (*b*) when the peak of the pulse has reached the fixed end.

Figure 16.18 Examples 16.1 and 16.2.

❶ **GETTING STARTED** I begin by sketching the pulse at the two instants given in the problem, pretending that the fixed end is not there and no reflection has occurred (**Figure 16.19**). I use a dashed line for the pulse to indicate that this is not the actual shape of the string at these instants (because reflection *has* occurred), and I draw a vertical line to indicate the (horizontal) position of the fixed end.

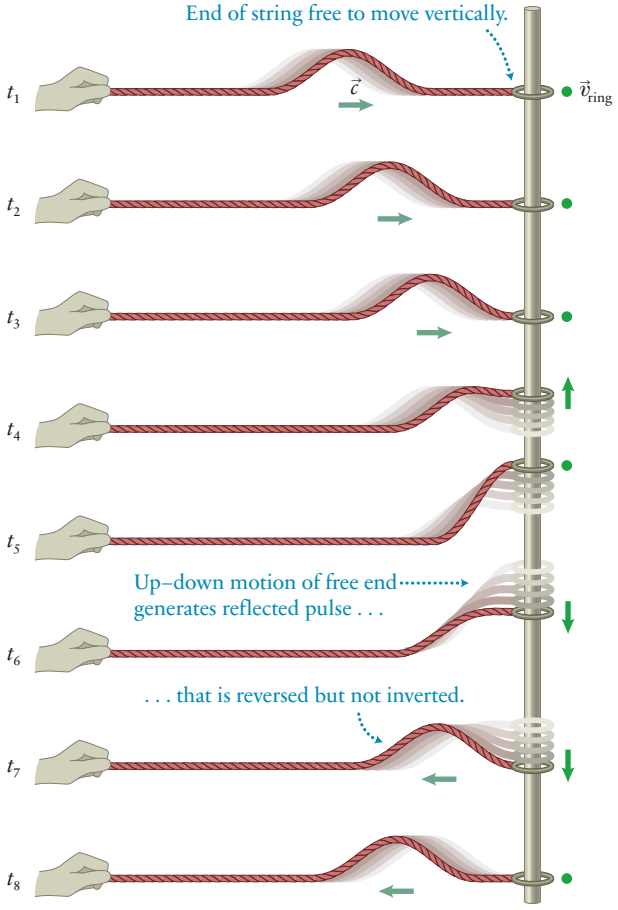
Figure 16.19



❷ **DEVISE PLAN** Once any part of the pulse reaches the fixed end, reflection begins. To determine the pulse shape during reflection, I must draw a reflected pulse that is both inverted and reversed relative to the incident pulse and then add that reflected pulse to my incident pulses in Figure 16.19.

❸ **EXECUTE PLAN** (*a*) At the fixed end, the sum of the displacement of the incident pulse and the displacement of the reflected pulse is zero. In the region where the two pulses do not overlap, the sum of the displacements of the two pulses is equal to the displacement of the trailing edge of the incident pulse. Between this no-overlap region and the fixed end, I add the dashed and dotted lines algebraically to determine the shape of the string. The resulting shape is shown in **Figure 16.20***a*. ✔

(*b*) Following the same procedure yields Figure 16.20*b*. ✔



❹ **EVALUATE RESULT** The pulses I drew terminate at the node at the fixed end, as expected. In Figure 16.20*b* the string shape resembles the reflected pulse more than the incident pulse because most of the incident pulse has traveled past the fixed end.

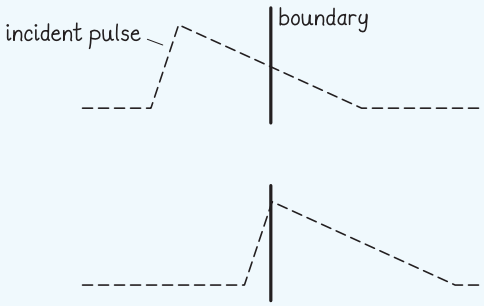
Figure 16.20

Next consider reflection from a free end. To maintain the tension in the string at the free end, we connect the end to a light ring that can slide freely along a vertical rod (**Figure 16.21**). When it reaches a height equal

Figure 16.21 Reflection of a wave pulse at a boundary where the string end is free to move vertically.

CONCEPTS

to the maximum height of the pulse, however, the free end keeps moving upward, as you can see in Figure 16.21. The reason for this overshooting is that there are no string particles to the right of the free end exerting a downward force. As it overshoots, the free end exerts an upward force on the string to its left, pulling the string above the maximum height of the pulse. After reaching its maximum height, the ring moves back down to the equilibrium level. This up and down motion of the ring creates a left-moving pulse in the string, just as the up and down motion of the hand at the left created the original pulse. This leftward-moving pulse is the reflection of the original pulse. Although the reflected pulse is left–right reversed, it is not inverted.



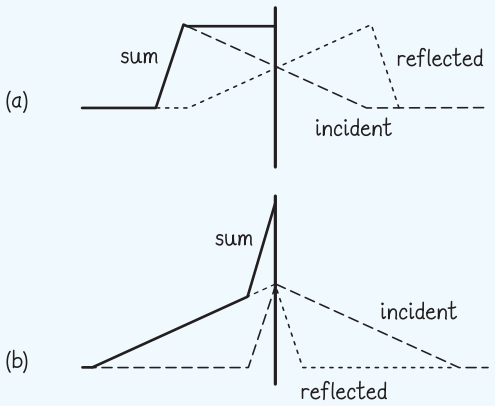
To construct the reflected pulse, we follow the same procedure we used to construct a pulse reflected from a fixed end, but we do not invert the reflected pulse.

EXAMPLE 16.2 Reflection from a free end

Let the triangular wave pulse of Figure 16.18 approach the free end of a string. Sketch the shape of the string (*a*) when a point halfway up the leading edge of the incident pulse has reached the fixed end and (*b*) when the peak of the pulse has reached the fixed end.

❶ **GETTING STARTED** I begin by sketching the pulse at the two instants given in the problem, ignoring the free end (**Figure 16.22**). I use a dashed line for the pulse to indicate that this is not the actual shape of the string at these instants, and I draw a vertical line to indicate the (horizontal) position of the free end of the string.

Figure 16.22



❷ **DEVISE PLAN** Once any part of the pulse reaches the free end, reflection begins. To determine the pulse shape during reflection, I must draw a reflected pulse that is reversed but not inverted and then add that reflected pulse to my incident pulses in Figure 16.22.

❸ **EXECUTE PLAN** (*a*) At the free end, the displacement of the reflected pulse is the same as that of the incident pulse, and so the string displacement is double what it was before the incident pulse arrived. In the region where the two pulses do not overlap, the sum of the displacements of the two pulses is equal to the displacement of the trailing edge of the incident pulse. Between this no-overlap region and the free end, I add the dashed and dotted lines algebraically to determine the shape of the string shown in **Figure 16.23*a***. ✔

(*b*) Following the same procedure yields Figure 16.23*b*. ✔

Figure 16.23

❹ **EVALUATE RESULT** Once the incident pulse arrives at the free end, the displacement of the free end at any given instant is twice that of the incident pulse, and therefore the free end swings far up in Figure 16.23*b*, in agreement with what I expect from Figure 16.21.

16.15 (*a*) When the free end of the string in Figure 16.21 reaches its maximum displacement at t_5, what is the kinetic energy in the pulse? (*b*) What is the potential energy in the pulse? (*c*) Is the energy in the pulse at this instant the same as the energy at t_1?

A case intermediate between a boundary where the end of the string is fixed and a boundary where it is free to move vertically is when a pulse reaches the boundary between two different mediums. The pulse is partially transmitted to the second medium and partially reflected. **Figure 16.24*a*** on the next page shows a heavy string connected to a lighter string. String 1 has a greater mass per unit length—a quantity called the **linear mass density** and represented by the symbol μ—than string 2. The wave speed along string 1 is c_1, and that along string 2 is c_2. The tensions in the two strings are equal, but because of the difference in mass density, $c_2 > c_1$. Because string 2 is much less massive than string 1, the end of string 1 behaves somewhat like a free end, and so the reflected pulse is not inverted.

CONCEPTS

Figure 16.24 Reflection and transmission of a wave pulse at the boundary between two strings that have different linear mass densities.

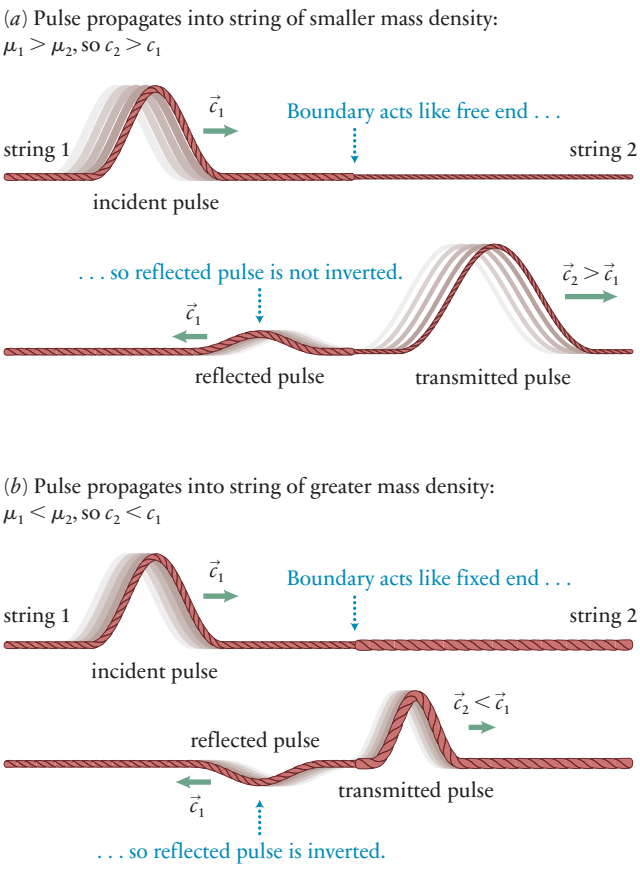


Figure 16.24*b* illustrates a pulse propagating along the same string 1 toward a string 2 that has a greater linear mass density. String 2 restricts the movement of the end of string 1, so now the boundary behaves like a fixed end, reflecting an inverted pulse back along string 1. The tensions in the two strings are again equal, but because of the difference in linear mass density, $c_2 < c_1$ and so the transmitted pulse travels more slowly than the incident pulse.

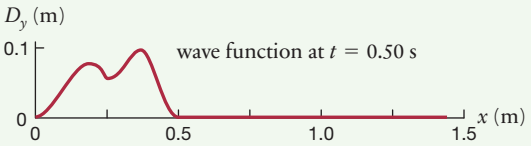
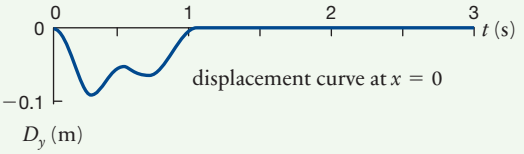


16.16 For the strings and pulse in Figure 16.24, what happens in the limit where (*a*) $\mu_2 \to 0$, (*b*) $\mu_2 \to \infty$, and (*c*) $\mu_2 = \mu_1$? (*d*) Why is the transmitted pulse in Figure 16.24*a* wider than the incident pulse?

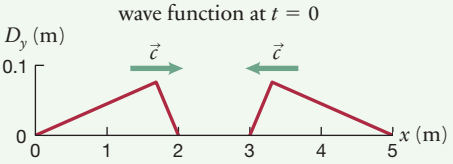
CONCEPTS

Self-quiz



1. Given the wave function for $t = 0.50$ s shown in **Figure 16.25**, draw the displacement curves of particles at $x = 0$ and $x = 1.0$ m as the wave passes them. If the leading edge of the wave was at $x = 0$ at time $t = 0$, what is the speed of the wave?

Figure 16.25



2. Given the displacement curve shown in **Figure 16.26** for a bead at $x = 0$ on a string as a wave moving toward the right with a speed of 2.0 m/s passes, draw the wave function at $t = 2.0$ s.

Figure 16.26

3. The two pulses shown in **Figure 16.27** are traveling in opposite directions; both have a speed of 1.0 m/s. Draw the sum of the two pulses at $t = 1.0$ s, $t = 2.0$ s, and $t = 3.0$ s.

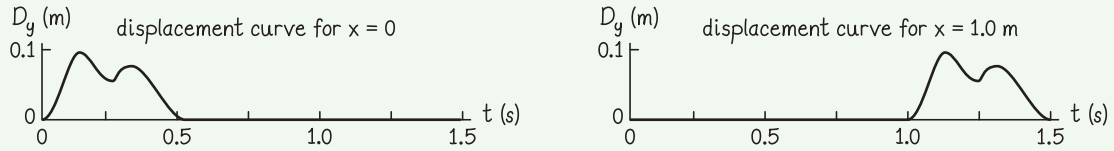


Figure 16.27

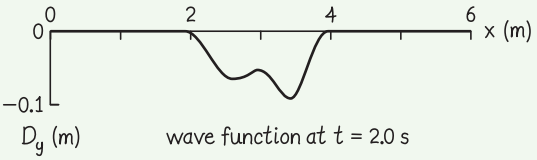
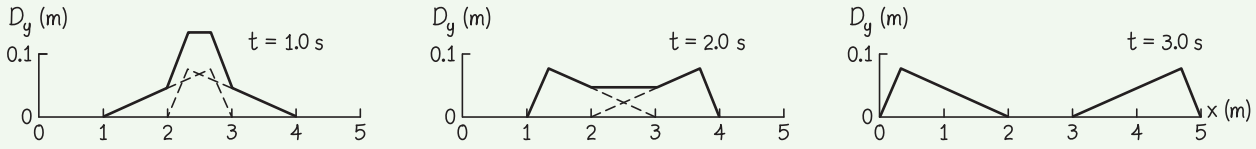
Answers



1. See **Figure 16.28**. The leading edge of the wave travels 0.50 m in 0.50 s, giving a wave speed of 1.0 m/s. In the displacement for the particle at $x = 0$, the leading edge passes $x = 0$ at $t = 0$ and the trailing edge passes $x = 0$ at 0.50 s. In the displacement curve for the particle at $x = 1.0$ m, the leading edge passes $x = 1.0$ m at $t = 1.0$ s and the trailing edge passes $x = 1.0$ m at 1.5 s.

Figure 16.28



2. See **Figure 16.29**. With a wave speed of 2.0 m/s and 1.0 s needed for the whole wave to pass $x = 0$, the length of the wave must be 2.0 m. At $t = 1.0$ s, the leading edge of the wave passes $x = 2.0$ m. At $t = 2.0$ s, the leading edge passes $x = 4.0$ m and the trailing edge passes 2.0 m.

Figure 16.29

3. See **Figure 16.30**. The two pulses start out 1.0 m apart, and each has a width of 2.0 m. With a relative speed of 2.0 m/s, they begin to interfere at $t = 0.5$ s. At $t = 1.0$ s, the pulses overlap by half their width, with the trailing edges sticking out. At $t = 2.0$ s, the pulses also overlap by half their width, but now the leading edges are sticking out. At $t = 3.0$ s, the waves are separated again.

Figure 16.30

16.5 Wave functions

The displacement of the medium caused by a traveling wave is a function of both space and time, and so the mathematical description of a one-dimensional traveling wave requires a function in two variables. Let us begin by examining a traveling wave of constant shape, looking at the pulses first from a reference frame moving along with the wave and then from the Earth reference frame, which is stationary relative to the medium. In the moving reference frame, the wave is stationary and so its description is simple.

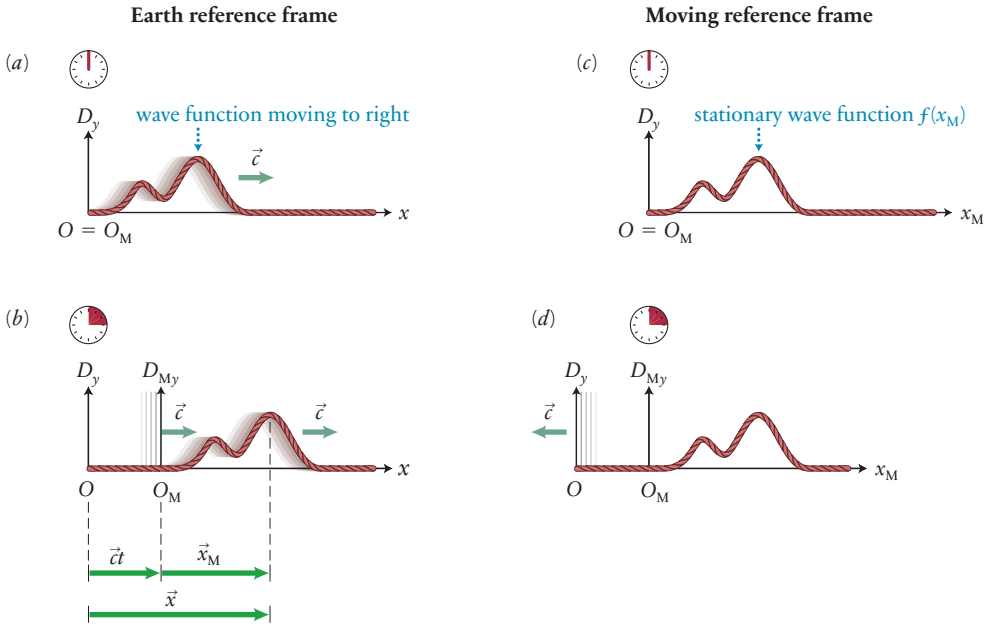
Figure 16.31*a* shows a transverse wave on a string at instant $t = 0$ when the origins of the two reference frames coincide. The wave travels in the positive x direction at speed c without changing its shape. Figure 16.31*b* shows the situation at some instant t, when the wave and the moving reference frame have traveled a distance ct to the right. As seen from the reference frame moving along with the wave, the wave remains stationary (Figures 16.31*c* and *d*). If the curve in the moving reference frame is described by some function $f(x_M)$, then the y component of the displacement $\vec{D}_M$ of any particle of the string as seen from the moving reference frame is given by

$$D_{My} = f(x_M). \tag{16.1}$$

What this tells us is that when we view the situation from the moving reference frame, x_M is the only variable we need to specify to determine the displacement D_{My}. The function $f(x_M)$, which specifies the (constant) shape of the wave as seen from the moving reference frame, is called the *time-independent wave function*.

When we view from the Earth reference frame, the wave has the same shape as in the moving reference frame but it is moving in the positive direction along the x axis. We must therefore specify both x and t in order to determine the displacement $\vec{D}$, and so we write $D_y = f(x, t)$. The function $f(x, t)$, called the *time-dependent wave function*, completely specifies

Figure 16.31 Traveling wave pulses seen from the Earth reference frame and from a reference frame moving along with the pulse at instant $t = 0$ (when the origins of the two reference frames overlap) and at some instant t later.



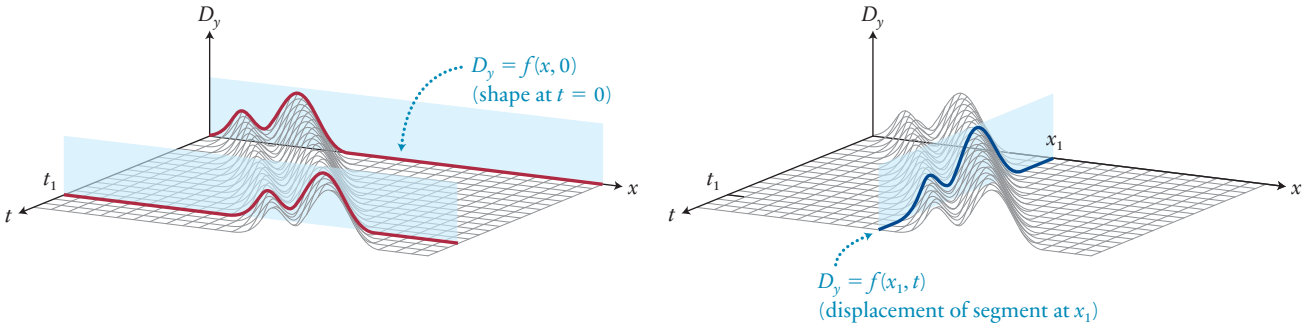


Figure 16.32 Time-dependent wave function.

(*a*) Shape of the medium at instants $t = 0$ and $t = t_1$

(*b*) Displacement of the medium at a fixed position as a function of time

the changing shape of the wave disturbance in the medium as seen from the Earth reference frame. To visualize this function, we need to make a three-dimensional graph of $f(x, t)$ versus the variables x and t (**Figure 16.32*a***). The surface shown in the graph gives the value of $D_y = f(x, t)$ for each pair of values of x and t. A vertical cut through the surface along the x axis yields the curve labeled $D_y = f(x, 0)$. This curve gives the shape of the wave disturbance at $t = 0$. A vertical cut through the surface parallel to the x axis intercepting the t axis at t_1 gives $D_y = f(x, t_1)$, the shape of the wave disturbance at t_1. As you can see, the wave has advanced in the positive x direction. Vertical cuts parallel to the t axis give the displacement at a fixed position in the medium as a function of time (Figure 16.32*b*). The curve $f(x_1, t)$, for example, shows how the displacement at x_1 changes with time.

The surface in Figure 16.32 is completely determined by the constant shape shown in Figure 16.31*c* and the wave speed c. To see how this is true, imagine sliding the curve in Figure 16.31*c* diagonally across the xt plane in Figure 16.32*a*. Because three-dimensional graphs are difficult to draw and to read, we shall use two-dimensional graphs to represent traveling waves that are constant in shape.

Let us now relate the displacement viewed from a moving reference frame to the displacement viewed from the Earth reference frame. At instant t, the y component of the displacement of any point P on the three-dimensional surface of an $f(x, t)$ graph is given by $D_y = f(x, t)$ in the Earth reference frame and by $D_{My} = f(x_M)$ in the moving reference frame (Figure 16.31*b*). Because the displacement of the string particles does not depend on which reference frame we use, we must have $D_y = D_{My}$. From Figure 16.31*b* we see that $x_M = x - ct$, so

$$f(x_M) = f(x - ct). \tag{16.2}$$

Substituting these relationships into Eq. 16.1, we discover that the y component of the displacement viewed from the Earth reference frame is given by

$$D_y = f(x - ct). \tag{16.3}$$

This equation describes a wave of constant form $f(x)$ traveling in the positive x direction at speed c. For a wave traveling in the negative x direction at speed c, we have

$$D_y = f(x + ct). \tag{16.4}$$

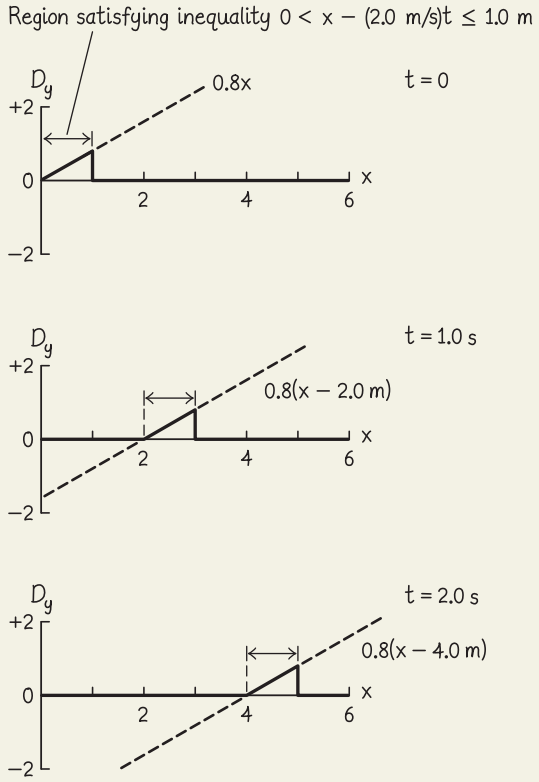
Any wave traveling along the x axis has either the form $f(x - ct)$ or the form $f(x + ct)$. Provided the quantities x, c, and t appear in the combination $(x - ct)$ or $(x + ct)$ in a function, that function can represent a traveling wave. Thus, the function $\sin[k(x - ct)]$, where k is a constant, represents a harmonic wave that travels in the positive direction along the x axis. The function $\sin[k^2(x^2 - c^2t^2)]$, however, does not represent a traveling harmonic wave.

EXERCISE 16.3 Traveling waves

(a) Consider the time-dependent wave function

$$D_y = f(x, t) = \begin{cases} b(x - ct) & \text{for } 0 < x - ct \leq 1.0 \text{ m} \\ 0 \text{ for} & x - ct \leq 0 \quad \text{or} \quad x - ct > 1.0 \text{ m}, \end{cases}$$

where $b = 0.80$ and $c = 2.0$ m/s. Plot the time-independent wave function for a few values of t to verify that the function corresponds to a wave traveling in the positive x direction at a speed of 2.0 m/s.



(b) Let the shape of a wave at $t = 0$ be described by the function

$$f(x, 0) = \frac{a}{x^2 + b}.$$

If the wave travels in the negative x direction at a speed c, what is the mathematical form of the time-dependent wave function $f(x, t)$?

SOLUTION (a) Because I need to plot the function versus x, I first add ct to each term in the inequality $0 < x - ct \leq 1.0$ m and get $ct < x \leq (1.0 \text{ m}) + ct$. For $t = 0$, the function is nonzero when $0 < x \leq 1.0$ m; for $t = 1.0$ s when $2.0 \text{ m} < x \leq 3.0$ m; for $t = 2.0$ s when $4.0 \text{ m} < x \leq 5.0$ m; and so on. So, for $t = 0$ I plot the function $(0.80)x$ between $x = 0$ and $x = 1.0$ m; for $t = 1.0$ s I plot the function $0.80(x - 2.0 \text{ m})$ between $x = 2.0$ m and $x = 3.0$ m; and so on (**Figure 16.33**). My graphs show a triangular wave that is constant in shape and displaced in the positive x direction by +2.0 m each second. ✔

Figure 16.33

QUANTITATIVE TOOLS

(*b*) When viewed from a reference frame traveling along with the wave, the wave function does not depend on time and has the form

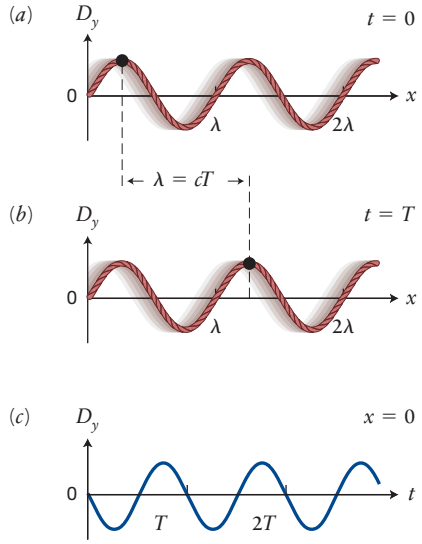
$$f(x_M) = \frac{a}{x_M^2 + b}.$$

Equation 16.2 gives me the relationship between the displacement viewed from the Earth reference frame and one moving along with the pulse in the positive x direction. Because the pulse in part *b* of this exercise moves in the negative direction, I have to invert the sign in front of the speed c, so $f(x + ct) = f(x_M)$ and $x_M = x + ct$. Substituting these relationships into $f(x_M)$, I obtain the time-dependent wave function

$$f(x, t) = \frac{a}{(x + ct)^2 + b}. \checkmark$$

Let us consider a transverse harmonic wave traveling along a string aligned with an x axis. Such a wave can be generated by making the end of the string execute a simple harmonic motion. **Figure 16.34*a*** shows the shape of the string at an instant at which the left end, at $x = 0$, is in the equilibrium position. For convenience, we choose this instant to be $t = 0$. The time-independent wave function is

$$f(x) = A \sin(kx), \tag{16.5}$$



where A is the amplitude of the wave and k is a constant.The wave repeats itself over a distance λ (the wavelength), so the displacement $f(x)$ is the same at both ends of a wavelength—that is, at x and $x + \lambda$:

$$A \sin(kx) = A \sin(kx + k\lambda). \tag{16.6}$$

Because a sine function repeats itself when its argument is increased by 2π, it follows from Eq. 16.6 that $k\lambda = 2\pi$, so

$$k = \frac{2\pi}{\lambda}. \tag{16.7}$$

Figure 16.34 Wave function of a harmonic wave (*a*) at $t = 0$ and (*b*) after one period. (*c*) The corresponding displacement curve for $x = 0$.

The constant k, called the **wave number** of the motion, thus gives the number of wavelengths in a length of 2π m. Because wavelength has units of meters, the wave number k has SI units of m^{-1}.

If the wave travels at speed c in the positive x direction, the time-dependent wave function is obtained by replacing x in Eq. 16.5 by $(x - ct)$:

$$D_y = f(x, t) = A \sin[k(x - ct)]. \tag{16.8}$$

Figure 16.34*b* shows the wave function after the string end at $x = 0$ has executed one complete cycle (that is, at $t = T$, where T is the period of the motion). During this cycle, the wave has advanced by a distance corresponding to one wavelength. To see what this means, compare the positions of the black dots in Figures 16.34*a* and *b*. Think of these two dots as representing the same point on the traveling wave. In the time interval from $t = 0$ to $t = T$, this point of the wave has moved a distance λ. (Do *not* think of the dots as representing the same particle *of the string* because, remember, the medium does not move horizontally in this wave motion; only the momentum and energy associated with the wave move horizontally.) Because the wave moves at wave speed c, this distance corresponds to

$$\lambda = cT \tag{16.9}$$

or, substituting the frequency $f \equiv 1/T$,

$$\lambda f = c. \tag{16.10}$$

Because the period of the motion is T, we have for $x = 0$ $\sin(kct) = \sin[kc(t + T)]$. This can be true only if $kcT = 2\pi$, or

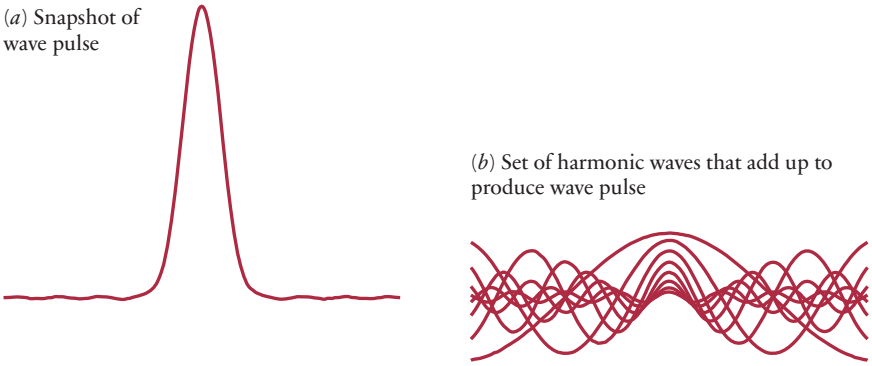
$$kc = \frac{2\pi}{T} \equiv \omega, \tag{16.11}$$

where ω is the angular frequency as defined in Section 15.5: $\omega = 2\pi f = 2\pi/T$. Using the angular frequency, we can rewrite the time-dependent wave function in Eq. 16.8 in the form:

$$D_y = f(x, t) = A \sin(kx - \omega t). \tag{16.12}$$

Let us now analyze the vertical displacement of the string as the wave passes through. We can use Eq. 16.12 to examine the vertical displacement of any particle of the string as a function of time. For instance, substituting $x = 0$ into Eq. 16.12 and using the trigonometric identity $\sin(-\alpha) = -\sin\alpha$, we obtain

$$D_y = f(0, t) = A \sin(-\omega t) = -A \sin(\omega t). \tag{16.13}$$



The displacement curve for this function $D_y(0, t)$ is shown in Figure 16.34*c*. (If you are having trouble understanding why the displacement curve dips downward initially, think about what is going to happen in Figure 16.34*a* to the string particle located at $x = 0$ just after $t = 0$: It is going to be pulled down below the x axis.)

Next we consider a point a distance d from the end of the string. Substituting $x = d$ into Eq. 16.12 yields

$$\begin{aligned} D_y = f(d, t) &= A \sin(kd - \omega t) \\ &= A \sin(-\omega t + kd) \end{aligned} \tag{16.14}$$

QUANTITATIVE TOOLS

Figure 16.35 Any wave can be expressed in terms of sinusoidally varying (harmonic) waves.

or, using the trigonometric identity $\sin(-\alpha) = \sin(\alpha - \pi)$,

$$D_y = f(d, t) = A \sin(\omega t - kd - \pi) = A \sin(\omega t + \text{constant}). \quad (16.15)$$

This expression, which gives the y component of the displacement of the string at any arbitrary position $x = d$, shows that all points along the string execute a simple harmonic motion with a period $2\pi/\omega = T$.

In deriving Eq. 16.8, we assumed that $f = 0$ at $x = 0$ and $t = 0$. To obtain a more general expression that allows for a nonzero initial displacement, we add to the argument of the sine in Eq. 16.12 (the *phase* of the wave, see Section 15.5) an initial phase ϕ_i:

$$D_y = f(x, t) = A \sin(kx - \omega t + \phi_i). \quad (16.16)$$

The initial phase specifies the initial condition: At $x = 0$ and $t = 0$, Eq. 16.16 becomes $D_y = f(0, 0) = A \sin \phi_i$, and so, for a given amplitude, ϕ_i determines the initial value of the vertical displacement at $x = 0$.

In Section 15.3 we discussed Fourier's theorem, which states that the time dependence of any function can be expressed in terms of sinusoidally varying functions of time. Because of the superposition principle, the same theorem can be applied to waves: Any wave can be expressed in terms of sinusoidally varying waves (harmonic waves). **Figure 16.35a**, for example, shows a wave pulse obtained by adding together the harmonic waves shown in Figure 16.35*b*. At the center, all of the harmonic waves add up to form the pulse; everywhere else, they add up to nearly zero (surprising, but true!). So, if we understand harmonic waves, we can deal with more complicated waves by determining the harmonic waves that add up to give these waves.

16.17 (*a*) Which of the following functions could represent a traveling wave?

(*i*) $A \cos(kx + \omega t)$

(*ii*) $e^{-k|x-ct|^2}$

(*iii*) $b(x - ct)^2 e^{-x}$

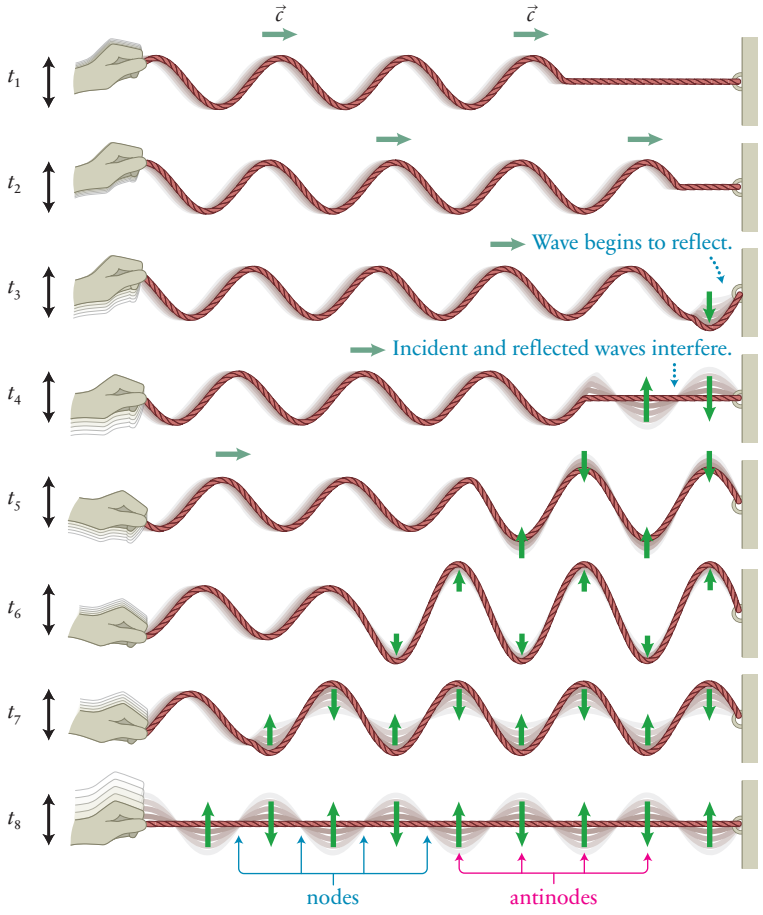
(*iv*) $-(b^2 t - x)^2$

(*b*) Which of the following functions can be made to represent a traveling wave?

(*i*) $x/(1 + bx^2)$

(*ii*) xe^{-kx}

(*iii*) x^2



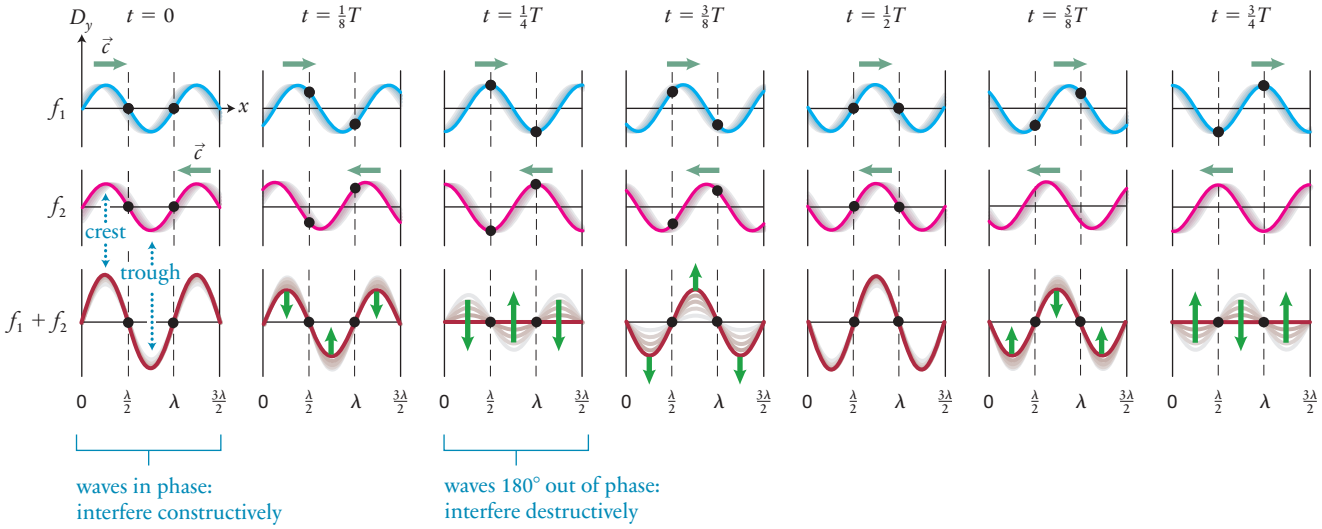


Figure 16.36 When a harmonic wave is reflected from the fixed end of a string, the reflected wave interferes with the incident wave, forming a standing wave.

16.6 Standing waves

When a harmonic wave travels along a string that has a fixed end, the reflected wave interferes with the incident wave. **Figure 16.36** shows the striking pattern that results from this interference. Initially the wave travels to the right, but as the reflected wave begins traveling back at t_3, the two waves traveling in opposite directions create a pulsating *stationary* pattern. Some particles of the string—the nodes (see Section 16.3)—do not move at all, while the sinusoidal loops between the nodes move up and down rather than along the string. The motion has its greatest amplitude at points halfway between the nodes; these points are called **antinodes**. The pulsating stationary pattern caused by harmonic waves of the same amplitude traveling in opposite directions is called a **standing wave.**

Figure 16.37 illustrates how standing waves come about. Each diagram shows a blue wave propagating to the right and a red wave propagating to the left. The two waves have the same amplitude and wavelength. The speed at which they propagate is determined by the medium and is therefore the same for both waves. The bottom part of each diagram shows the sum of the two waves, obtained by adding, for each value of x, the vertical displacements of the two waves at that value of x. In the diagram labeled $t = 0$, the crests of the red wave have the same x coordinate as the crests of the blue wave, and the same is true for the troughs: Each trough in the red wave aligns with a trough in the blue wave. Waves like this, where comparable points align, are said to be *in phase* (their phases are the same). The two waves reinforce each other—they interfere constructively—and adding them yields a wave that has twice the amplitude. A quarter period later, at $t = \frac{1}{4}T$, one has a crest when the other has a trough and the waves

Figure 16.37 Standing wave created by two counterpropagating waves f_1 and f_2.

are 180° *out of phase*. The two waves now interfere destructively, and the string is flat at this instant.

16.18 (*a*) In the standing wave pattern of Figure 16.37, how is the energy distributed between kinetic and potential at $t = 0$, $t = \frac{1}{8}T$, and $t = \frac{1}{4}T$? (*b*) Is the energy in a length of the string corresponding to one wavelength constant? (*c*) Does the standing wave transport energy? If so, in which direction? If not, why not?

To see why certain points are nodes, let us denote the y components of the displacements of the red and blue waves by $D_{1y} = f_1(x, t)$ and $D_{2y} = f_2(x, t)$, respectively, and look at what happens at the points $x = \lambda/2$ and $x = \lambda$. At $t = 0$, we have $D_{1y} = D_{2y} = 0$, and so $D_{1y} + D_{2y} = 0$. Now consider the situation at $t = \frac{1}{8}T$. Wave f_1 has advanced to the right, while wave f_2 has moved an equal distance to the left. At $\lambda/2$, the vertical displacement of the string caused by wave f_1 is now positive, but that caused by wave f_2 is negative and equal in magnitude, so the two add to zero and the string does not move from its equilibrium position. At $x = \lambda$ in the $t = \frac{1}{8}T$ diagram, we see the same thing but with the displacement directions reversed: f_1 displaces the string in the negative y direction, and f_2 displaces it by the same amount in the positive y direction. Because both waves always travel equal distances in opposite directions, the displacements caused by them at the points $x = \lambda/2$ and $x = \lambda$ are *always* equal in magnitude and opposite in sign. Consequently $D_{1y} + D_{2y}$ remains zero at these points for all t.

We can analyze the situation quantitatively by writing the wave traveling to the right as

$$D_{1y} = f_1(x, t) = A \sin(kx - \omega t) \tag{16.17}$$

and the wave traveling to the left as

$$D_{2y} = f_2(x, t) = A \sin(kx + \omega t). \tag{16.18}$$

The combined wave then is

$$D_y = f_1(x, t) + f_2(x, t) = A[\sin(kx - \omega t) + \sin(kx + \omega t)]. \tag{16.19}$$

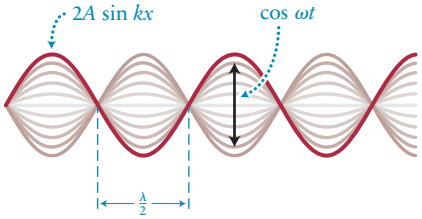

Figure 16.38 A standing wave is a stationary harmonic wave with an amplitude that varies like a sine. The spacing between adjacent nodes is equal to $\lambda/2$.

Using the trigonometric identities $\sin\alpha+\sin\beta = 2\sin\frac{1}{2}(\alpha+\beta)\cos\frac{1}{2}(\alpha-\beta)$ and $\cos\alpha = \cos(-\alpha)$ (see Appendix B), we can write Eq. 16.19 as

$$D_y = f_1(x,t) + f_2(x,t) = 2A\sin kx\cos\omega t = [2A\sin kx]\cos\omega t. \quad (16.20)$$

This is *not* a traveling wave because it is not a function of $x-ct$ or of $x+ct$ (see the text immediately following Eq. 16.4). Instead this function describes a standing wave on a string, one in which the string displacement oscillates harmonically as $\cos\omega t$ with an amplitude that varies along x as $2A\sin kx$ (**Figure 16.38**).

For a standing wave of the form given in Eq. 16.20 the displacement is *always* zero at the locations where $\sin kx$ is zero. These points are the nodes; they occur when kx is a whole-number multiple of π. Using the fact that $k = 2\pi/\lambda$ (Eq. 16.7), we obtain

$$\frac{2\pi}{\lambda}x = n\pi \qquad n = 0, \pm1, \pm2, \ldots, \quad (16.21)$$

and so nodes occur at

$$x = 0, \pm\frac{\lambda}{2}, \pm\lambda, \pm\frac{3\lambda}{2}, \ldots. \quad (16.22)$$

The displacement has its maximum value at the points where $\sin kx = \pm1$. These antinodes occur when kx is an odd whole-number multiple of $\pi/2$:

$$\frac{2\pi}{\lambda}x = \frac{n\pi}{2} \qquad n = \pm1, \pm3, \pm5, \ldots, \quad (16.23)$$

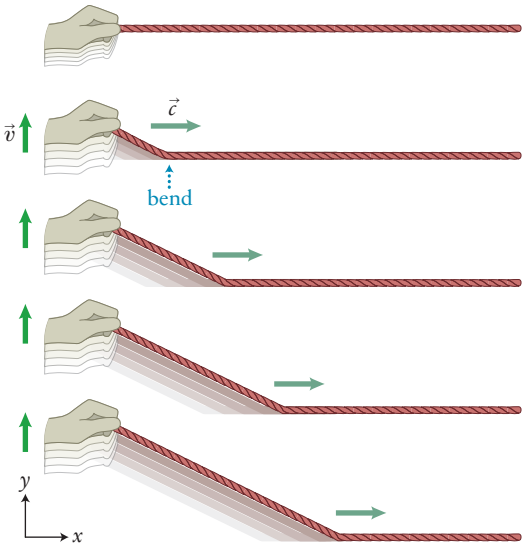
and so antinodes occur at

$$x = \pm\frac{\lambda}{4}, \pm\frac{3\lambda}{4}, \pm\frac{5\lambda}{4}, \ldots. \quad (16.24)$$

Note that, as shown in Figure 16.38, adjacent nodes are separated by a distance $\lambda/2$. Adjacent antinodes are also spaced by a distance $\lambda/2$ and lie midway between the nodes.

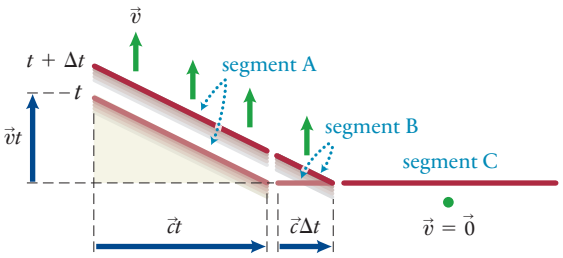
16.19 (*a*) Do two counterpropagating waves that have the same wavelength but different amplitudes cause standing waves? (*b*) Do two counterpropagating waves that have the same amplitude but different wavelengths cause standing waves?

16.7 Wave speed



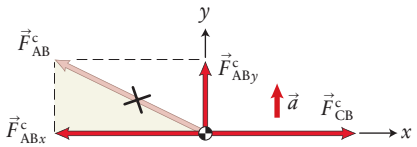
To determine a quantitative expression for the wave speed c, consider the situation shown in **Figure 16.39**. The end of a taut horizontal string is moved vertically upward at a constant velocity $\vec{v}$. The displacement of the end causes a triangular wave pulse to propagate along the string. The bend on the leading edge travels in the horizontal direction with wave speed c. Just as with the string of beads in Section 16.2, all segments of the string execute the same motion as the end of the string: Each segment begins at rest and then, as the pulse reaches it, moves vertically upward at speed v.

Let us consider the motion of the string during a small time interval Δt beginning at some instant t. At the beginning of the interval, the end of the string has been raised a distance vt and the bend has traveled a distance ct (Figure 16.39*b*). The slanted segment of the string moves vertically up at constant speed v; at the instant represented in Figure 16.39*b*, segment A moves up while the rest of the string remains horizontal. A short time



QUANTITATIVE TOOLS

Figure 16.39 Procedure for obtaining a quantitative expression for the wave speed c.



(a) Triangular wave pulse generated by lifting end of string at constant velocity

(b) In time interval Δt, bend advances distance $c\Delta t$

(c) Free-body diagram for segment B

interval Δt later, segment A has moved farther up and is still moving at v, so the momentum of segment A has not changed.

Let us choose the x axis in the direction of the wave and the y axis in the upward direction. During the time interval Δt, the bend has advanced by a distance $\Delta x = c\Delta t$, and so an additional length $c\Delta t$ of string (segment B) now also moves vertically upward with speed v. The mass of this segment is $\mu(c\Delta t)$, where μ is the mass per unit length, or **linear mass density,** of the string. For a uniform string of length ℓ and mass m, the linear mass density is

$$\mu \equiv \frac{m}{\ell} \quad \text{(uniform linear object)}. \tag{16.25}$$

The SI units of linear mass density are kg/m. The change in the momentum of segment B is equal to the mass of B times its change in velocity $\Delta\vec{v}_B = \vec{v} - 0 = \vec{v}$. The mass of B is equal to the linear mass density of the string times the equilibrium length of B, $m_B = \mu(c\Delta t)$, and so $\Delta\vec{p}_B = m_B\Delta\vec{v}_B = \mu(c\Delta t)\vec{v}$. This change in momentum occurs during the time interval Δt, and so the rate of change is

$$\frac{\Delta\vec{p}_B}{\Delta t} = \frac{\mu(c\Delta t)\vec{v}}{\Delta t} = \mu c\vec{v}. \tag{16.26}$$

The rate of change in momentum of segment B of the string is by definition equal to the vector sum of the forces exerted on it:

$$\Sigma\vec{F}_B = \frac{\Delta\vec{p}_B}{\Delta t} = \mu c\vec{v}. \tag{16.27}$$

Figure 16.39c shows the free-body diagram for segment B. Segment A exerts on B a force slanting upward along the direction of segment A; segment C exerts on B a force in the horizontal direction. The x components of these two forces must balance because segment B is not accelerating in the horizontal direction. We also know that the x components of these two forces are equal in magnitude to the tension $\mathcal{T}$ in the string. The

vector sum of the forces exerted on B is thus equal to the vertical component of the force exerted by A on B. Finally, we note that the shaded triangles in Figures 16.39*b* and *c* are similar, so

$$\frac{F^c_{ABy}}{F^c_{ABx}} = \frac{F^c_{ABy}}{\mathcal{T}} = \frac{vt}{ct} = \frac{v}{c}, \tag{16.28}$$

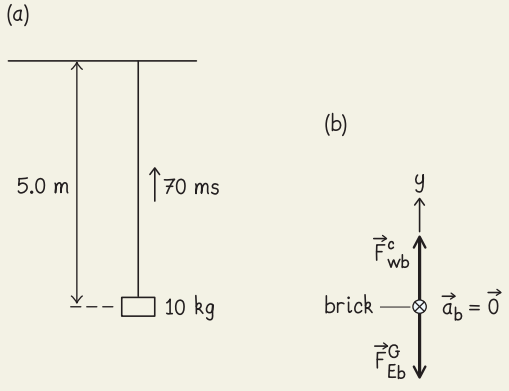
and thus the vector sum of the forces acting on segment B of the string is

$$\Sigma F_y = F^c_{ABy} = \frac{\mathcal{T}v}{c}. \tag{16.29}$$

Combining this result with Eq. 16.27, we get $\mu cv = \mathcal{T}v/c$, or

$$c = \sqrt{\frac{\mathcal{T}}{\mu}}. \tag{16.30}$$

Note that the wave speed is independent of the velocity v of the string segments. The result in Eq. 16.30 agrees with the qualitative arguments in Section 16.2: The speed of a pulse along a string increases with increasing tension $\mathcal{T}$ and with decreasing linear mass density.



16.20 (*a*) Draw a free-body diagram for segment A of the string at instant *t* in Figure 16.39. What is the vector sum of the forces exerted on A? (*b*) What does your answer to part *a* tell you about the change in momentum of A? Does your conclusion about A's momentum make sense? (*c*) Does the hand do work on the string? (*d*) What happens to the energy of the string as the end moves upward?

EXAMPLE 16.4 Measuring mass

You use a hammer to give a sharp horizontal blow to a 10-kg lead brick suspended from the ceiling by a wire that is 5.0 m long. It takes 70 ms for the pulse generated by the sudden displacement of the brick to reach the ceiling. What is the mass of the wire?

1 GETTING STARTED I begin by making a sketch of the situation (**Figure 16.40*a***). Because I know the pulse travels 5.0 m in 70 ms, I can determine the wave speed along the wire: $c = (5.0\text{ m})/(0.070\text{ s}) = 71\text{ m/s}$. This wave speed depends on the linear mass density of the wire and the tension in the wire. The latter is determined by the force exerted by the brick on the wire. Because the force exerted by the brick on the wire and the force exerted by the wire on the brick are equal in magnitude, I draw a free-body diagram for the brick (Figure 16.40*b*) to help me determine that magnitude.

Figure 16.40

2 DEVISE PLAN To determine the mass of the wire, I can use Eq. 16.25. To use this equation, I must know the length of the wire, which is given, and the linear mass density μ, which I can calculate from Eq. 16.30. To obtain μ from Eq. 16.30, I need to know c (which I already calculated) and the tension $\mathcal{T}$ in the wire. This tension is equal to F^c_{bw}, which in turn is equal to F^c_{wb}. From my free-body diagram, I see that $F^c_{wb} = F^G_{Eb}$, and so I know F^c_{bw} and therefore $\mathcal{T}$.

3 EXECUTE PLAN The tension is equal to the downward force of gravity exerted on the brick: $\mathcal{T} = F^G_{Eb} = (10\text{ kg})(9.8\text{ m/s}^2) = 98\text{ N}$. Substituting the values for $\mathcal{T}$ and c into Eq. 16.30, I calculate the linear mass density of the wire $\mu = \mathcal{T}/c^2 = (98\text{ N})/(71\text{ m/s})^2 = 0.019\text{ kg/m}$. The mass of the wire is thus $m = (0.019\text{ kg/m})(5.0\text{ m}) = 9.5 \times 10^{-2}\text{ kg}$. ✔

4 EVALUATE RESULT The value I obtain—about 0.1 kg—is not unreasonable for a 5.0-m-long wire that can support a lead brick.

QUANTITATIVE TOOLS

16.8 Energy transport in waves

Imagine moving the end of a very long, taut string up and down so that a harmonic wave begins traveling along the string at the wave speed c given in Eq. 16.30. Energy moves along with the wave, and so, as you shake the string end, you must supply energy to the string. At what rate must you supply this energy? To answer this question, let us first consider the energy involved in generating a simple triangular wave as shown in **Figure 16.41**.

As it raises the end of the string, the hand does work on the string. The work done by the hand on the string during a time interval Δt is equal to the scalar product of the force $\vec{F}^{\text{c}}_{\text{hA}}$ exerted by the hand on segment A of the string and the force displacement. From Figures 16.41*a* and *b*, we see that

$$W = F^{\text{c}}_{\text{hA}y}(v\Delta t), \tag{16.31}$$

where $F^{\text{c}}_{\text{hA}y}$ is the y component of $\vec{F}^{\text{c}}_{\text{hA}}$ and $v\Delta t$ is the y component of the force displacement. If we ignore the force of gravity on segment A of the string, the force exerted by the hand on A is transmitted undiminished to B, and so $\vec{F}^{\text{c}}_{\text{hA}}$ is equal in magnitude to the force $\vec{F}^{\text{c}}_{\text{AB}}$ exerted by A on B. Using Eq. 16.29, we then have

$$F^{\text{c}}_{\text{hA}y} = \mathcal{T}\frac{v}{c}. \tag{16.32}$$

Substituting this result and $\mathcal{T} = \mu c^2$ from Eq. 16.30 into Eq. 16.31, we discover that the work done by the hand on the string during the time interval Δt is

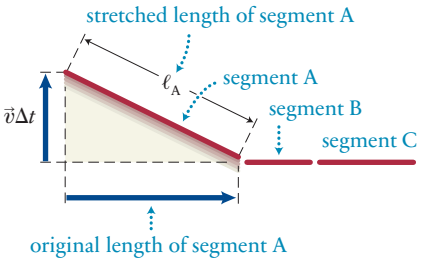
$$W = \left(\mathcal{T}\frac{v}{c}\right)v\Delta t = \mu c\, v^2\Delta t. \tag{16.33}$$

The energy law, $\Delta E = W$ (Eq. 9.1), tells us that the work done by the hand on the string changes the energy of the string. The average rate at which the hand supplies energy to the string (the *average power*) is equal to the change in the energy of the string divided by the time interval over which the energy changes (Eq. 9.29), and so $P_{\text{av}} \equiv \Delta E/\Delta t = \mu c v^2$.

As the hand does work on the string, the kinetic energy and the potential energy of the string change: The kinetic energy changes because more of the string is set in motion, and the potential energy changes because the raising stretches the string, storing elastic potential energy. Let us first calculate the change in kinetic energy. After a time interval Δt, segment A has a velocity v, and so its kinetic energy is $\frac{1}{2}m_{\text{A}}v^2$, where m_{A} is the mass of A. The original length of segment A is $c\Delta t$ (Figure 16.41*a*), and so $m_{\text{A}} = \mu c\Delta t$. The change in kinetic energy is thus

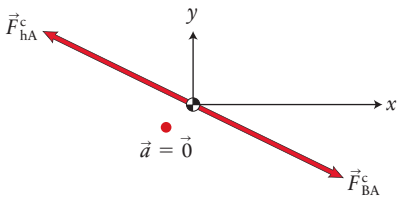
$$\Delta K = \tfrac{1}{2}(\mu c\Delta t)v^2 - 0 = \tfrac{1}{2}\mu c v^2\Delta t, \tag{16.34}$$

which, Eq. 16.33 tells us, is exactly half the energy supplied to the string!



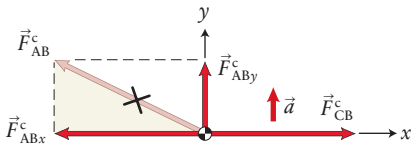
The other half must be potential energy associated with the stretching of segment A (the rest of the string is undisturbed). Let the length of A at the instant shown in Figure 16.41*a* be ℓ_{A}. The change in the length of the string is then $\Delta\ell = \ell_{\text{A}} - c\Delta t$. If $\Delta\ell$ is small, we can treat the string as a spring of spring constant k_{s}, and so Eq. 9.23 tells us the change in potential energy stored in the stretched string is

$$\Delta U = \tfrac{1}{2}k_{\text{s}}\Delta\ell^2 = \tfrac{1}{2}(k_{\text{s}}\Delta\ell)\Delta\ell = \tfrac{1}{2}F^{\text{c}}_{\text{hA}}\Delta\ell, \tag{16.35}$$



where we have used Hooke's law, Eq. 8.18, to substitute $F^{\text{c}}_{\text{hA}} = k_{\text{s}}\Delta\ell$. Because segment A is not accelerating, we see from the free-body diagram

Figure 16.41 Procedure for determining the energy involved in generating a simple triangular wave.



(*a*) Triangular wave pulse generated by lifting end of string at constant velocity

(*b*) Free-body diagram for segment A

(*c*) Free-body diagram for segment B

QUANTITATIVE TOOLS

for segment A (Figure 16.41*b*) that $\vec{F}^{\,c}_{hA} = -\vec{F}^{\,c}_{BA}$. Because the force exerted by segment B on segment A and the force exerted by segment A on segment B form an interaction pair, we have $\vec{F}^{\,c}_{hA} = \vec{F}^{\,c}_{AB}$. Comparing the similar shaded triangles in Figure 16.41*a* and the free-body diagram for segment B (Figure 16.41*c*), we see that

$$\frac{F^c_{AB}}{F^c_{ABx}} = \frac{F^c_{hA}}{\mathcal{T}} = \frac{\ell_A}{c\Delta t} \tag{16.36}$$

or $F^c_{hA} = \mathcal{T}\ell_A/(c\Delta t)$, and so Eq. 16.35 becomes

$$\Delta U_A = \tfrac{1}{2}\frac{\mathcal{T}\ell_A}{c\Delta t}\Delta\ell = \tfrac{1}{2}(\mu c^2)\frac{\ell_A}{c\Delta t}\Delta\ell = \tfrac{1}{2}\frac{\mu c}{\Delta t}\ell_A\Delta\ell, \tag{16.37}$$

where we have used Eq. 16.30 to eliminate $\mathcal{T}$. As long as the vertical displacement of the end of the string is small, $\ell_A \approx c\Delta t$, and so

$$\ell_A\Delta\ell = \ell_A(\ell_A - c\Delta t) = \ell_A^2 - \ell_A(c\Delta t) \approx \ell_A^2 - (c\Delta t)^2 \tag{16.38}$$

or, when we apply the Pythagorean theorem to the shaded triangle in Figure 16.41*a*, $\ell_A\Delta\ell = (v\Delta t)^2$, and therefore

$$\Delta U = \tfrac{1}{2}\frac{\mu c}{\Delta t}(v\Delta t)^2 = \tfrac{1}{2}\mu c v^2\Delta t. \tag{16.39}$$

So, in the limit of small displacement, the change in elastic potential energy is indeed equal to the change in kinetic energy, and the triangular pulse contains equal amounts of kinetic and potential energy.

Let us next consider the energy carried in a harmonic wave described by $y(x, t) = A\sin(kx - \omega t)$. We begin by calculating the amount of energy E_λ stored in a length of string corresponding to one wavelength of the harmonic wave. Because during each period T the wave advances by one wavelength, E_λ is the amount of energy that must be supplied in one period. The average power is then

$$P_{av} \equiv \frac{\Delta E}{\Delta t} = \frac{E_\lambda}{T}. \tag{16.40}$$

To calculate E_λ, we first divide the string into very small segments, each of length dx. If the linear mass density of the string is μ, the mass of each segment is $dm = \mu\, dx$. Each segment carries out a simple harmonic motion, and the energy associated with this simple harmonic motion is $\frac{1}{2}(dm)\omega^2A^2$ (Eq. 15.17). At any given instant, part of this energy is in the form of kinetic energy associated with the motion of the segment and part is in the form of potential energy associated with its deformation. The sum of the two, however, always equals $\frac{1}{2}(dm)\omega^2A^2$. All the segments in a length of string one wavelength long add up to a mass of $\sum dm = m$, and from the definition of linear mass density, we have $m = \mu\lambda$. In a length of string one wavelength long, therefore, the combined energy contributed by all the segments of length dx is

$$E_\lambda = \tfrac{1}{2}(\mu\lambda)\omega^2A^2. \tag{16.41}$$

The average power that must be supplied is thus

$$P_{av} = \tfrac{1}{2}\mu\lambda A^2\omega^2/T = \tfrac{1}{2}\mu A^2\omega^2 c, \tag{16.42}$$

where we have used the fact that $\lambda/T = c$ (Eq. 16.9). This result makes sense: It takes more effort to generate a wave of greater (angular) frequency or amplitude (in each case you must shake the end with a greater speed). Furthermore, as we would expect, a string of greater linear mass density requires

QUANTITATIVE TOOLS

more energy. Finally, if the wave speed increases, the energy is carried away more quickly, and so the rate at which it needs to be supplied increases.

EXAMPLE 16.5 Delivering energy

A wire with linear mass density $\mu = 0.0500$ kg/m is held taut with a tension of 100 N. At what rate must energy be supplied to the wire to generate a traveling harmonic wave that has a frequency of 500 Hz and an amplitude of 5.00 mm?

❶ **GETTING STARTED** The rate at which energy must be supplied to the wire is the power. Because none of the quantities given varies with time, the (instantaneous) power is equal to the average power, which is given by Eq. 16.42.

❷ **DEVISE PLAN** To calculate the average power, I need to know μ and A, both of which are given, as well as ω and c. The angular frequency ω is related to the frequency f by Eq. 15.4, $\omega = 2\pi f$, and I can obtain the wave speed c from Eq. 16.30.

❸ **EXECUTE PLAN** From Eq. 16.30 I obtain $c = \sqrt{\mathcal{T}/\mu} = \sqrt{(100\text{ N})/(0.0500\text{ kg/m})} = 44.7$ m/s. Equation 15.4 yields $\omega = 2\pi f = 2\pi(500\text{ Hz}) = 3.14\times10^3\text{ s}^{-1}$. Substituting these values into Eq. 16.42 gives

$$P_{av} = \tfrac{1}{2}(0.0500\text{ kg/m})(0.00500\text{ m})^2 \times (3.14\times10^3\text{ s}^{-1})^2(44.7\text{ m/s}) = 275\text{ W}. \checkmark$$

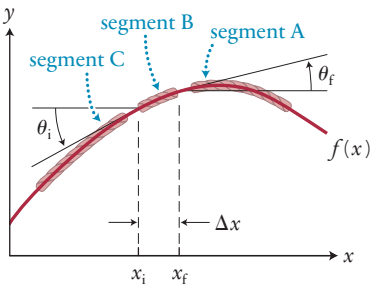
❹ **EVALUATE RESULT** The answer I obtain is a fairly large power—comparable to the power delivered by a 250-W light bulb or by a person exercising. The wave travels very fast, though, and the frequency is high, so the answer is not unreasonable.

16.21 Suppose that instead of shaking the end of a very long, taut string, you shake a point in the center of the string, keeping the amplitude and the frequency the same. Is the rate at which you must supply energy smaller than, equal to, or greater than if you shake the end?

16.9 The wave equation

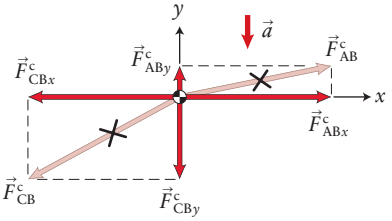
In Chapter 15 I argued that simple harmonic oscillations are common because linear restoring forces are common. Linear restoring forces give rise to the equation of motion for a simple harmonic oscillator, which in turn gives rise to sinusoidally oscillating solutions. Waves are equally common because whenever a medium is disturbed it tends to oscillate sinusoidally and the oscillation couples to neighboring regions of the medium. As we shall show in this section, systems of coupled simple harmonic oscillators give rise to an equation called the wave equation, whose solutions are traveling waves. Here we derive this equation for the special case of a transverse wave traveling along a string; we shall encounter the same equation again when discussing electromagnetic waves.

Figure 16.42*a* shows a piece of a string that has been displaced from equilibrium by a passing wave. Let us focus on segment B between the positions x_i and $x_f = x_i + \Delta x$ and write the equation of motion for that segment. The segment is subject to two forces, one from each of the two adjacent pieces of string (we again ignore the force of gravity because it is much smaller than the tension). Figure 16.42*b* shows the free-body diagram for segment B. As we saw in Section 16.2, the x components of the forces are equal in magnitude to the tension $\mathcal{T}$ in the string and add to zero. The vector sum of the forces exerted on B is thus equal to the sum of the y components:



$$\Sigma F_{By} = F^c_{ABy} + F^c_{CBy} = \mathcal{T}\tan\theta_f - \mathcal{T}\tan\theta_i, \qquad (16.43)$$

where θ_i and θ_f are the directions of the tangents to the string at x_i and x_f. For small displacements, these angles are small, and so we can use the small-angle approximation $\tan\theta \approx \theta$ and rewrite Eq. 16.43 as



$$\Sigma F_{By} \approx \mathcal{T}(\theta_f - \theta_i) = \mathcal{T}\Delta\theta. \qquad (16.44)$$

Figure 16.42 Segment of a string transmitting a wave pulse.

(*a*) String transmitting wave pulse

(*b*) Free-body diagram for segment B

QUANTITATIVE TOOLS

The equation of motion for segment B is

$$\Sigma F_{By} = m_B a_{By} = (\mu \Delta x) a_{By}, \tag{16.45}$$

where m_B is the mass of segment B, a_{By} is the y component of its acceleration, and μ is its linear mass density. Substituting $\mathcal{T}\Delta\theta$ from Eq. 16.44 into the left side of Eq. 16.45 and rearranging terms yields

$$\frac{\Delta\theta}{\Delta x} = \frac{\mu}{\mathcal{T}} a_{By}. \tag{16.46}$$

In the limit $\Delta x \to 0$, the left side of this expression yields the derivative of the angle θ with respect to x. The angle θ is determined by the function f that describes the shape of the string in Figure 16.42*a*—the derivative of f with respect to x is equal to the slope, $\tan\theta$. A complication is that the shape of the string changes with time and so is a function of both x and t. We therefore have to use the *partial derivative* of $f(x, t)$ with respect to x, which means that we hold t constant while taking the derivative with respect to x (see Appendix B). The partial derivative of $f(x, t)$ with respect to x is written $\partial f/\partial x$, so we have

$$\tan\theta = \frac{\partial f}{\partial x}. \tag{16.47}$$

For small θ we can write $\tan\theta \approx \theta$, and so, in the limit $\Delta x \to 0$, the left side of Eq. 16.46 becomes the second partial derivative of $f(x, t)$ with respect to x:

$$\lim_{\Delta x \to 0} \frac{\Delta\theta}{\Delta x} \equiv \frac{\partial\theta}{\partial x} \approx \frac{\partial}{\partial x}\left(\frac{\partial f}{\partial x}\right) \equiv \frac{\partial^2 f}{\partial x^2}. \tag{16.48}$$

Next we consider the right side of Eq. 16.46. The acceleration a_{By} is given by the second derivative with respect to time of the vertical position $y = f(x, t)$ of segment B. So the first partial derivative with respect to time $\partial f/\partial t$ gives the y component of the velocity of segment B, and the second partial derivative gives the y component of the acceleration:

$$a_{By} = \frac{\partial^2 f}{\partial t^2}. \tag{16.49}$$

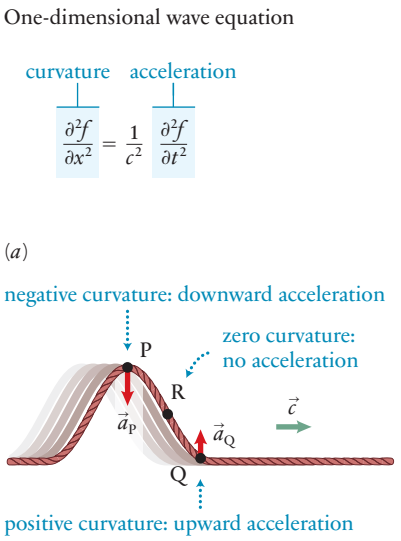
Substituting Eqs. 16.48 and 16.49 into Eq. 16.46, we get

$$\frac{\partial^2 f}{\partial x^2} = \frac{\mu}{\mathcal{T}} \frac{\partial^2 f}{\partial t^2}, \tag{16.50}$$

and substituting Eq. 16.30, $c = \sqrt{\mathcal{T}/\mu}$, yields

$$\frac{\partial^2 f}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 f}{\partial t^2}. \tag{16.51}$$

This is the one-dimensional **wave equation**. Any function of the form $f(x - ct)$ or $f(x + ct)$ is a solution to this equation (the proof of this is left as a homework exercise). All waves, mechanical and nonmechanical, result from equations of this form (but only for a taut string do we get Eq. 16.50 with $c = \sqrt{\mathcal{T}/\mu}$).



It is helpful to keep in mind what the terms in the wave equation tell us about the wave. The second partial derivative of f with respect to x on the left is related to the curvature of the string carrying the wave—the greater $\partial^2 f/\partial x^2$, the sharper the curvature of the string. The right side is the acceleration of particles of the string divided by the square of the wave speed. Thus the wave equation tells us that the curvature of the wave increases as the medium acceleration increases and decreases as the wave speed increases.

QUANTITATIVE TOOLS

For a fixed wave speed, the greater the acceleration of the particles in the medium, the greater the curvature. A downward curvature (concave down or $\partial^2 f/\partial x^2 < 0$) corresponds to a downward acceleration ($\partial^2 f/\partial t^2 < 0$). An upward curvature (concave up or $\partial^2 f/\partial x^2 > 0$) corresponds to an upward acceleration ($\partial^2 f/\partial t^2 > 0$). This is shown graphically in **Figure 16.43**. In Figure 16.43*a*, the curvature of the string is greatest (and downward) at the top. As we have seen, the acceleration is also greatest (and downward) at that point (compare with Figure 16.7*c*). At point Q, the curvature is upward; indeed, as the pulse travels to the right, point Q has to accelerate in the upward direction. At point R, the curvature and acceleration are both zero. Another illustration of the acceleration-curvature relationship at fixed wave speed is seen by comparing Figures 16.43*a* and *b*: If we move the end of the string up and down more quickly, the acceleration at point P increases and the pulse becomes narrower, giving a greater curvature at P.

The inverse relationship between curvature and wave speed is seen by comparing Figures 16.43*a* and *c*. With P (as well as all other points) having the same acceleration in the two drawings, the greater wave speed in part *c* stretches the string horizontally, decreasing the curvature.

Figure 16.43 Relationships among curvature, acceleration, and wave speed.

EXERCISE 16.6 Sinusoidal solution to the wave equation

Show that a sinusoidal traveling wave of the form $f(x, t) = A \sin(kx - \omega t)$ satisfies the wave equation for any value of k and ω.

SOLUTION The first partial derivative of $f(x, t)$ with respect to x is

$$\frac{\partial f}{\partial x} = kA \cos(kx - \omega t),$$

and so the second partial derivative with respect to x is

$$\frac{\partial^2 f}{\partial x^2} = -k^2 A \sin(kx - \omega t). \qquad (1)$$

The first partial derivative of $f(x, t)$ with respect to t is

$$\frac{\partial f}{\partial t} = -\omega A \cos(kx - \omega t).$$

Differentiating again gives

$$\frac{\partial^2 f}{\partial t^2} = -\omega^2 A \sin(kx - \omega t).$$

Multiplying both sides of this equation by $1/c^2$ and using $k = \omega/c$ (Eq. 16.11), I obtain

$$\frac{1}{c^2}\frac{\partial^2 f}{\partial t^2} = -\frac{\omega^2}{c^2} A \sin(kx - \omega t) = -k^2 A \sin(kx - \omega t). \qquad (2)$$

Because the right sides of Eqs. 1 and 2 are equal, the left sides must also be equal, so

$$\frac{\partial^2 f}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 f}{\partial t^2},$$

which is Eq. 16.51, and so the wave equation is satisfied. ✔

16.22 If any time-dependent sinusoidal harmonic function, $f(x, t) = A \sin(kx - \omega t)$, satisfies the wave equation, what determines the values of the wave number k and the angular frequency ω for, say, a wave on a string?

Chapter Summary

Representing waves (Sections 16.1, 16.2, 16.5)

Concepts A **wave** is a *disturbance* that propagates through material (the medium) or through empty space.

A **wave pulse** is a single isolated propagating disturbance.

The **wave function** represents the shape of a wave at any given instant and changes with time as the wave travels.

The **wave speed** c is the speed at which a wave propagates. For a mechanical wave, c is different from the speed v of the particles of the medium and is determined by the properties of the medium.

The **displacement** $\vec{D}$ of any particle of a medium through which a mechanical wave travels is a vector that points from the equilibrium position of the particle to its actual position.

In a **transverse** mechanical wave, the particles of the medium move perpendicular to the direction of the pulse movement. In a **longitudinal** mechanical wave, these particles move parallel to the direction of the pulse movement.

In a **periodic wave,** the displacement at any location in the medium is a periodic function of time. A periodic wave is **harmonic** when the particle displacement can be represented by a sinusoidally varying function of space and time.

Quantitative Tools If a wave travels in the x direction with speed c and $f(x)$ describes the form (shape) of the wave, then the y component D_y of the displacement of a particle of the medium is

$$D_y = f(x - ct) \tag{16.3}$$

if the wave travels in the positive x direction and

$$D_y = f(x + ct) \tag{16.4}$$

if the wave travels in the negative x direction.

The **wavelength** λ of a periodic wave is the minimum distance over which the wave repeats itself.

For a periodic wave of period T, frequency f, and speed c, the **wave number** k is

$$k = \frac{2\pi}{\lambda}. \tag{16.7}$$

The wavelength λ is

$$\lambda = cT, \tag{16.9}$$

the angular frequency ω is

$$\omega = \frac{2\pi}{T}, \tag{16.11}$$

and the wave speed is

$$c = \lambda f. \tag{16.10}$$

For a transverse harmonic wave of amplitude A and initial phase ϕ_i traveling in the positive x direction, the y component D_y of the displacement of a particle of the medium is

$$D_y = f(x, t) = A \sin(kx - \omega t + \phi_i). \tag{16.16}$$

Combining waves (Sections 16.3, 16.4, 16.6)

Concepts **Superposition of waves:** The resultant displacement of two or more overlapping waves is the algebraic sum of the displacements of the individual waves.

Interference occurs when two waves overlap. The interference is *constructive* when the displacements due to the two waves are in the same direction and *destructive* when the displacements are in opposite directions.

If the displacement at a point in space remains zero as a wave travels through, that point is a **node**. The displacement at other points typically varies with time. If the displacement at a point in space varies over the greatest range as a wave travels through, that point is an **antinode**.

Quantitative Tools If two harmonic waves of equal wavelength λ and equal amplitude A travel in opposite directions on a string, they produce a standing wave. The y component D_y of the string displacement at any position x along the string is given by

$$D_y = 2A \sin kx \cos \omega t. \tag{16.20}$$

The nodes occur at

$$x = 0, \pm \frac{\lambda}{2}, \pm \lambda, \pm \frac{3\lambda}{2}, \ldots \tag{16.22}$$

and the antinodes occur at

$$x = \pm \frac{\lambda}{4}, \pm \frac{3\lambda}{4}, \pm \frac{5\lambda}{4}, \ldots. \tag{16.24}$$

When a wave pulse (the *incident* wave) reaches a boundary where the transmitting medium ends, the pulse is *reflected*, which means it reverses its direction.

When a wave pulse is reflected from a fixed boundary, the reflected pulse is *inverted* relative to the incident pulse. When the reflection is from a boundary that is free to move, the reflected pulse is not inverted.

A **standing wave** is a pulsating stationary pattern caused by the interference of harmonic waves of equal amplitude and wavelength traveling in opposite directions.

Waves on a string (Sections 16.7–16.9)

Quantitative Tools For a uniform string of mass m and length ℓ, the **linear mass density** μ (mass per unit length) is

$$\mu = \frac{m}{\ell}. \tag{16.25}$$

The speed of a wave on a string under tension $\mathcal{T}$ is

$$c = \sqrt{\frac{\mathcal{T}}{\mu}}. \tag{16.30}$$

The average power P_{av} that must be supplied to generate a wave of period T is

$$P_{\text{av}} = \tfrac{1}{2}\mu\lambda A^2\omega^2/T = \tfrac{1}{2}\mu A^2\omega^2 c. \tag{16.42}$$

Any function f of the form $f(x - ct)$ or $f(x + ct)$ that represents a wave traveling with speed c is a solution of the **wave equation:**

$$\frac{\partial^2 f}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 f}{\partial t^2}. \tag{16.51}$$

Questions and Problems

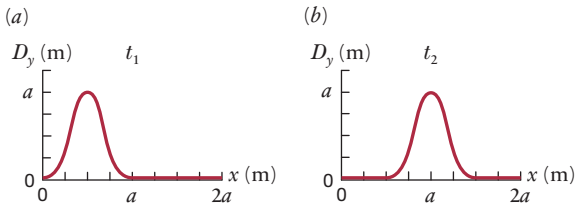
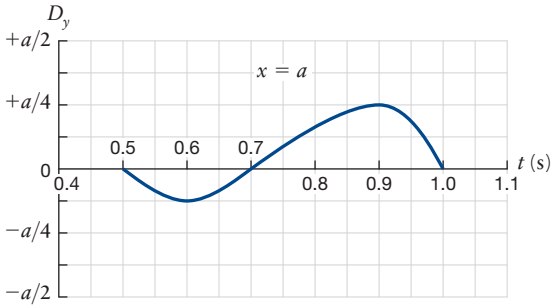
Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

16.1 Representing waves graphically



1. Is it possible for the same medium to carry both a longitudinal and a transverse wave? If so, give an example. If not, explain why not. •
2. Suppose you have a light spring stretched out and one end is attached to a wall. With this setup, you can move the free end in any of three directions (x, y, z). If the spring lies along, say, the z axis, which type of wave—transverse or longitudinal—do you create when you move the free end along the z axis? Along the x axis? Along the y axis? •
3. Figure P16.3 is a snapshot at $t = 0.80$ s of a wave pulse traveling on a string. Construct (*a*) the wave function at $t = 1.1$ s and (*b*) the displacement curve for the position $x = 3.0$ m. Assume that the wave pulse was created at the origin at $t = 0$. ••

Figure P16.3



4. The graphs in Figure P16.4 show the displacement caused by a wave moving along a string at two instants, (*a*) t_1 and (*b*) t_2. Let v_{av} denote the average speed of a piece of string during the time interval between t_1 and t_2. Compare the wave speed c to v_{av} of a piece of the string at the position $x = a$. ●●

Figure P16.4

5. Figure P16.5 shows the displacement curve for the particle located at $x = a$ as a wave moves to the right along a string. If the wave advances a distance a each second, draw the wave function at the instant $t = 0$. ●●●

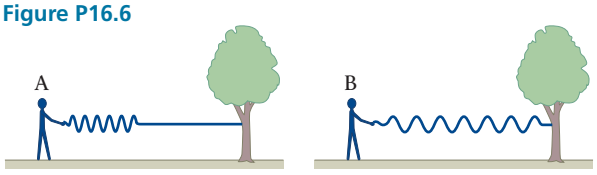


Figure P16.5

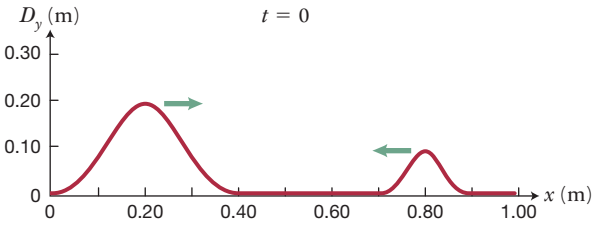
16.2 Wave propagation

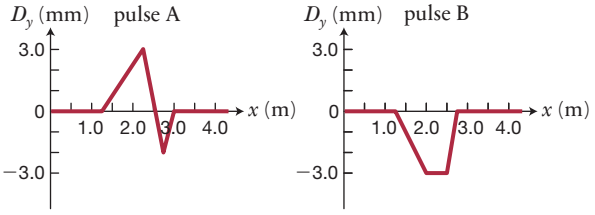
6. Identical ropes were tied to two trees, and two men, A and B, started shaking the free ends at the same instant a short while ago (Figure P16.6). Which rope has the greater tension? Which man is shaking with the greater frequency? ●

Figure P16.6



7. Waves propagating in a rope are observed to travel at 35 cm/s and their adjacent crests are 7.0 cm apart. Find the frequency and the period of the waves? ●
8. You and a friend each have one rope. You tie the two ropes together and stand as far apart as possible, each holding one end of the new longer rope and pulling to put it under tension. You then begin moving your arm in such a way as to produce a harmonic wave with a wavelength of 1.0 m. Your friend looks at the waves as they reach her arm. Is it possible that she measures a wavelength of (*a*) 0.8 m, (*b*) 1.0 m, or (*c*) 1.2 m? ●●
9. A ball of mass m_1 is attached on a rope and hangs vertically. The mass is slightly disturbed, and it generated a wave traveling through the rope. Suppose the ball is replaced with a heavier mass m_2 ($m_2 = 2m_1$) and the same disturbance is struck to the ball, compare the speed of the generated waves in both scenarios. ●●
10. A harmonic wave is made to travel along a string when you move your hand up and down. The wave has a specific period T_1, wavelength λ_1, amplitude A_1, and speed c_1, and also causes a certain transverse speed $v(x, t)$ of the particles that make up the rope. If you repeat this up-and-down motion, this time completing the same motion twice as fast as before, what happens to the (*a*) period, (*b*) wavelength, (*c*) amplitude, (*d*) speed, and (*e*) transverse speed? ●●●

16.3 Superposition of waves



11. Water parks often have a pool with a wave-making machine at one end, consisting of a piston that pushes water back and forth. There are some places in the pool where the waves make inner-tube riders bounce up and down wildly, but other places where the water hardly moves. Explain what is happening. ●
12. Sinusoidal water waves are generated by a 18-W mechanical motor in an aquarium tank. How much the kinetic energy is in each 1.25-Hz wave generated? ●●
13. Figure P16.13 shows two waves in a rope approaching each other at instant $t = 0$. For any instant after $t = 0$, determine the maximum displacement that occurs (*a*) at $x = 0$, (*b*) at $x = 0.90$ m, and (*c*) anywhere along the rope. ●●

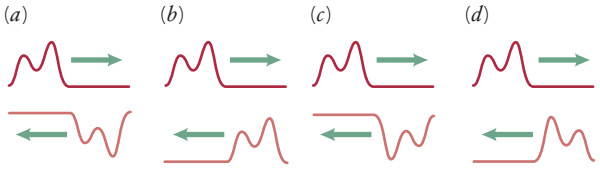
Figure P16.13

14. The two wave pulses in Figure P16.14 are traveling on the same string at $t = 1.0$ s. Sketch the shape of the string at this instant. ●●

Figure P16.14

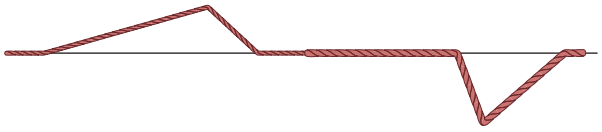
15. Suppose two waves, identical except for the direction of travel, approach each other in a medium that obeys Hooke's law. At certain instants, the waves interfere constructively at all positions. At one such instant, when their peaks align, determine the kinetic energy of the wave function that results from the superposition of both waves. •••

16.4 Boundary effects



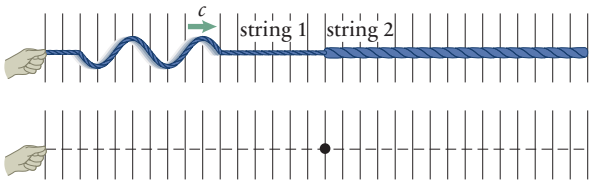
16. A harmonic wave traveling along a light string approaches a splice to a heavier string, as shown in Figure P16.16. Which changes as the wave crosses the boundary: wavelength, frequency, both, or neither? •

Figure P16.16



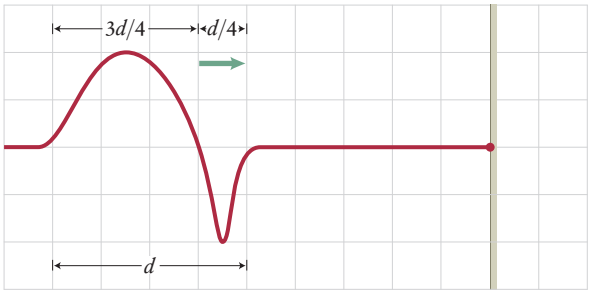
17. A transverse wave in a swimming pool reaches the concrete side and is reflected. Determine whether the reflected wave is inverted. •
18. A rope is attached to a tree trunk and made taut, and then a pulse traveling rightward is sent along the rope. For each case depicted in Figure P16.18, determine whether or not the reflected pulse is depicted correctly. ••

Figure P16.18



19. Figure P16.19 shows two strings of different linear mass densities, connected and held taut, at some instant. At some earlier instant, only one pulse existed on one of the strings. (*a*) Determine which string carried the initial pulse, and (*b*) sketch the approximate shape of the strings at the instant the initial pulse was created. ••

Figure P16.19



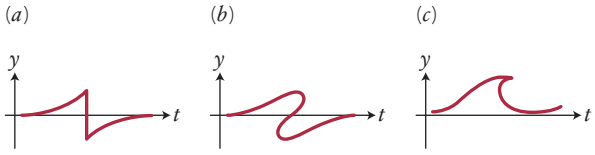
20. You shake the end of a taut string, creating two periods of a traveling sinusoidal wave, as shown in Figure P16.20. The string you are shaking (string 1) is connected to a second, much more massive, string (string 2). The wave speeds on the two strings differ by a factor of 2. (*a*) On the template, sketch the shape of the two strings a time interval $4T$ after the instant represented in Figure P16.20, with T the period of the original wave on string 1. Briefly explain how you determined the shape of the strings. (*b*) How do the periods of the waves on string 1 and string 2 compare? ••

Figure P16.20

21. Figure P16.21 shows a pulse as it approaches a fixed end of a rope. Draw the shape of the rope halfway through the reflection (that is, when half of the pulse length is still moving to the right and the other half of the pulse has already been reflected). •••

Figure P16.21

16.5 Wave functions



22. A kayaker on the near the shore observes 3 waves reaches the shore every 10 s. At what speed are the waves are moving if he estimates that adjacent crests are 5.0 m apart? •
23. While on a sailboat, you notice that the boat is moving up and down fifteen times periodically every minute. Find the period of oscillation and the distance between two adjacent wave crests if the waves are travelling at a rate of 4.5 m/s. ••
24. Participating in a human rally wave at a football game, you have to stand up every 15 s. (*a*) What is the wave frequency? (*b*) If the stadium is oval and the inner circumference of the oval is 0.56 km, what is the wave speed? Assume that the main wave pulse spans 30 people and that the distance between the heads of any two adjacent people is 1.0 m. ••
25. (*a*) Plot the time-independent wave function for the traveling pulse described by the time-dependent wave function

$$D_y(x, t) = \frac{a}{b^2 + (x - ct)^2},$$

with $a = 5.0\ \text{m}^3$, $b = 1.0$ m, and $c = 2.0$ m/s for $t = 0$, 1.0 s, 2.0 s, and 3.0 s. (*b*) What is the wave speed c of this pulse? ••

26. What is wrong with each displacement curve in Figure P16.26 ●●?

Figure P16.26

27. At $t = 0$, a wave pulse has a shape given by the time-independent wave function

$$f(x) = \frac{a}{b^2 + x^2},$$

where $a = 0.030\ \text{m}^3$ and $b = 2.0$ m. (*a*) If the pulse travels in the positive x direction at a wave speed of 1.75 m/s, write the time-dependent wave function $f(x, t)$ for this transverse wave. (*b*) Plot the time-dependent wave function $f(x, t)$ at $t = -0.50$ s and at $t = +0.50$ s over the range of x in which $f(x, t)$ is substantially changing. (*c*) Plot the displacement curve at $x = 2.0$ m. ●●

28. A wave traveling along a rope is described by

$$y(x, t) = (2.0\ \text{mm})\ \sin[(4.0\ \text{m}^{-1})x - (3.0\ \text{s}^{-1})t].$$

(*a*) Calculate the amplitude, wavelength, frequency, period, and speed of the wave. (*b*) Compute the y-component of the string from the equilibrium at $x = 0.30$ m and $t = 1.20$ s. ●●●

29. A certain wave is described by the function

$$f(x) = a\cos(b\pi x),$$

Where $a = 0.0750$ m and $b = 1.80\ \text{m}^{-1}$. (*a*) Calculate its wavelength. (*b*) If the wave is traveling at a speed of 12.5 m/s, what is its frequency f? (*c*) Find the angular frequency of the oscillation. ●●

30. As an earthquake starts, you are standing 150 km (as the wave travels) from the epicenter. A geophysicist near the epicenter immediately telephones you to let you know that the transverse wave from the earthquake is on its way to you and that it is described by the equation

$$f(x, t) = a\sin(bx - \omega t),$$

where $a = 0.560$ m, $b = 0.0157\ \text{m}^{-1}$, and a full wavelength passes any given location every 0.500 s. How long will it be before the ground you are standing on starts to shake? ●●

31. You are watching a large ripple tank and observed that the waves generated by a mechanical motor have a period of 3.5 s and the distance between two adjacent crests is 15 m. Write a possible general equation of the observed wave if the waves reach a vertical height of 0.30 m. ●●

32. A plucked violin string carries a traveling wave given by the equation

$$f(x, t) = a\sin[b(x - ct) + \phi_i],$$

with $a = 0.00580$ m, $b = 33.05\ \text{m}^{-1}$, and $c = 245$ m/s. (*a*) If $f(0, 0) = 0$, what is ϕ_i? (*b*) Determine the simple harmonic period of a point on the string. ●●

33. A wave on a rope is given by

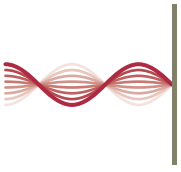
$$f(x, t) = (0.750\ \text{cm})\cos\pi[(4.00\ \text{m}^{-1})x - (4.50\ \text{s}^{-1})t]$$

Calculate the (*a*) wavelength, (*b*) angular frequency, (*c*) frequency, (*d*) period, and (*e*) wave number. ●●●

34. The amplitude of a wave traveling on a string is 0.250 m. The 80.0-Hz wave is traveling in the positive x direction at a wave speed of 17.5 m/s. (*a*) Determine its wavelength, and write the equation for its time-independent wave function. (*b*) For $t = 3.00$ s, compute the displacement and transverse velocity of the point on the string at $x = 1.25$ m, assuming an initial phase ϕ_i of zero. (*c*) Write the time-dependent wave function for the wave. (*d*) If the string displacement at $x = 1.25$ m is 0.210 m at $t = 3.00$ s, write the time-dependent wave function that uses the smallest possible value of ϕ_i. ●●●

16.6 Standing waves

35. Watching your fish swim in their tank, you notice that when one fish repeatedly jumps, it causes a standing wave given by the time-independent function



$$f(x) = a\sin(bx),$$

with $a = 0.015$ m and $b = 19.6\ \text{m}^{-1}$. If the tank is 0.96 m long, determine the positions of the first three nodes, beginning with the node at one end of the tank. ●

36. After tying one end of a rope to a stationary object, you flick the free end so as to cause a sinusoidal standing wave that has a maximum displacement of 0.50 m and a wavelength of 1.33 m. Write the time-dependent wave function in terms of the wave speed. ●

37. When one end of a string is tied to a pole and the other end is moved with frequency f, the standing wave pattern shown in Figure P16.37 is created. What is the smallest frequency at which the string can be moved to produce any standing wave? ●●

Figure P16.37

38. You have two string segments of equal length, segment 1 of linear mass density μ_1 and segment 2 of linear mass density $\mu_2 > \mu_1$. You splice the two together and then tie the combination tautly between two posts. You splice in such a way that, once attached to the posts, the length of

segment 1 to the left of the splice is the same as the length of segment 2 to the right of the splice. When you pluck at a particular frequency, you set up a standing wave that has this pattern: nodes at the splice and where each segment is attached to its pole plus two more nodes in one of the segments and three more nodes in the other segment (eight nodes in all). What is the numerical value of the ratio μ_1/μ_2? ●●

39. A guitar string has a length of 0.650 m and a mass of 4.00×10^{-3} kg. (*a*) If it is kept under a tension of 126 N, what is the fundamental (smallest harmonic) frequency at which it vibrates? (*b*) At what other frequencies (higher harmonics) could it vibrate at this fixed length? ●●

40. The equations for two waves traveling along the same string are

$$f_1(x, t) = a \sin(bx - qt)$$

and

$$f_2(x, t) = a \sin(bx + qt + \tfrac{1}{3}\pi),$$

with $a = 3.00 \times 10^{-2}$ m, $b = 4\pi$ m^{-1}, and $q = 500$ s^{-1}. (*a*) Calculate the amplitude and wavelength of the resultant displacement of the string at $t = 3.00$ s. (*b*) At $t = 1.70$ s, what is the displacement of the point on the string located at $x = 2.00$ m? ●●

41. A string vibrates in a standing wave according to the function

$$f(x, t) = a \sin(bx)\cos(qt),$$

with $a = 6.00 \times 10^{-2}$ m, $b = \frac{1}{3}\pi$ cm^{-1}, and $q = 40\pi$ s^{-1}. What are the amplitude and wave speed of each of the component waves that form this standing wave? ●●

42. A traveling wave on a long string is described by the time-dependent wave function

$$f(x, t) = a \sin(bx - qt),$$

with $a = 6.00 \times 10^{-2}$ m, $b = 5\pi$ m^{-1}, and $q = 314$ s^{-1}. You want a traveling wave of this frequency and wavelength but with amplitude 0.0400 m. Write the time-dependent wave function for a second traveling wave that could be added to the same string in order to achieve this. ●●

43. You have a trough 3.60 m long. It is filled with water, and you want to create a standing wave such that a node occurs every 0.30 m. (*a*) What is the wavelength of this wave? (*b*) A leaf floating on the water 0.60 m from one end of the trough is displaced a vertical distance $D_y = 10$ mm at $t = 3.2$ s, and the leaf's displacement has a period of 0.60 s. What is the resultant displacement of the standing wave? (*c*) Write the time-dependent wave function for the standing wave. ●●

44. Two sinusoidal waves travel along the same string. Their time-dependent wave functions are

$$f_1(x, t) = a \sin(bx - qt - \tfrac{1}{4}\pi)$$

$$f_2(x, t) = a \sin(bx - qt - \tfrac{1}{3}\pi),$$

with $a = 5.00 \times 10^{-2}$ m, $b = 0.120$ m^{-1}, and $q = 180$ s^{-1}. (*a*) What is the phase difference between these two waves? (*b*) Write the time-dependent wave function for the wave created by the superposition of these two waves. (*c*) What is the displacement of the string at $x = 2.00$ m at $t = 1.70$ s? ●●●

45. Two sinusoidal waves travel in opposite directions along the same string. The wavelength and frequency are the same in both waves, and each has amplitude 0.0289 m. If there is a phase difference $\Delta\phi$ between the two waves, what is the maximum displacement of the wave created by the superposition? ●●●

16.7 Wave speed

46. A piano wire has a linear mass density of 5.00×10^{-3} kg/m and is under 1.35 kN of tension. What is the frequency of the wave if it has a wavelength of 20 cm? ●●

47. What must be the tension applied to a 12-m plastic string weighing 43.5 N to produce a wave that propagates at a speed of 25 m/s? ●●●

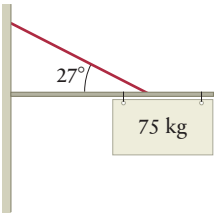
48. A large crane is being used to lower a 10,000-kg storage unit into place on a barge. If the cable that supports the unit from the end of the crane is 12 m long, and the linear mass density of the cable is 1.78 kg/m, how long does it take a wave to travel the length of the cable? ●

49. A violinist is bowing one string to produce a certain note. List three ways in which she can produce a note of higher frequency, either while playing or by preparing the violin differently before she begins to play. ●●

50. How long after the propellers at the back of an oil tanker start turning does the front of the ship start to move? ●●

51. A wave traveling along a string has a speed of 24 m/s when the tension in the string is 120 N. What is the speed of the same wave if the tension is reduced to 100 N? ●●

52. Two wires that have different linear mass densities, 0.45 kg/m and 0.29 kg/m, are spliced together. They are then used as a guy line to secure a telephone pole. If the tension is 300 N, what is the difference in the speed of a wave traveling from one wire to the other? ●●



53. A string of linear mass density μ_1 fixed at both ends is replaced by a string of linear mass density $16\mu_1$. By what factor does the frequency of the fundamental standing wave change if the tension and wavelength remain what they were in the original string? ●●

54. A 25.0-m steel wire and a 50.0-m copper wire are attached end to end and stretched to a tension of 145 N. Both wires have a radius of 0.450 mm, and the densities are 7.86×10^3 kg/m^3 for the steel and 8.92×10^3 kg/m^3 for the copper. (Note that these are mass densities, mass per unit volume, not linear mass densities, mass per unit length.) How long does a wave take to travel from one end to the other end of the combination wire? ●●

55. A 100-m steel cable that helps support the Golden Gate Bridge is 72.0 mm in diameter and composed of 100 steel wires twisted together. Approximate this as a single uniform steel cable that has a mass density of 7.86×10^3 kg/m^3. The wind generates in the cable a vibration that creates a wave that travels down the cable at 380 m/s. What is the tension in the cable? ●●

56. One end of the wire in Figure P16.56 is anchored to the side of a building, and the other end is attached at an angle of 27° to a light horizontal bar from which a 75-kg sign hangs. The linear mass density of the wire is 0.067 kg/m. If the wind causes the sign to vibrate so that a wave travels along the wire, at what speed does the wave travel? •••

Figure P16.56

16.8 Energy transport in waves

57. A taut rope has a mass of 0.128 kg and a length of 3.60 m. What average power must be supplied to the rope to generate sinusoidal waves that have amplitude 0.200 m and wavelength 0.600 m if the waves are to travel at 25.0 m/s? •
58. Consider two waves X and Y traveling in the same medium. The two carry the same amount of energy per unit time, but X has half the amplitude of Y. What is the ratio of their wavelengths? Which wave has the longer wavelength? •
59. Transverse waves are being generated on a rope being held under constant tension. By what factor is the power required to generate the wave increased or decreased (*a*) if the length of the rope is halved, (*b*) if the amplitude and angular frequency are doubled, and (*c*) if the wavelength and rope length are doubled? ••
60. You hold one end of a string that is attached to a wall by its other end. The string has a linear mass density of 0.067 kg/m. You raise your end briskly at 12 m/s for 0.016 s, creating a transverse wave that moves at 31 m/s. (*a*) How much work did you do on the string? What are the wave's (*b*) energy, (*c*) potential energy, and (*d*) kinetic energy? ••
61. One end of a horizontal string that has a linear mass density of 3.5 kg/m is displaced vertically at a speed of 45 m/s for 6.7 ms. The pulse created by this motion travels down the string at 78 m/s. How much kinetic energy travels along the string? ••
62. A wave traveling along a string is described by the time-dependent wave function $f(x, t) = a \sin(bx + qt)$, with $a = 0.0268$ m, $b = 5.85\ \text{m}^{-1}$, and $q = 76.3\ \text{s}^{-1}$. The linear mass density of the string is 0.0456 kg/m. Calculate (*a*) the wave speed c, (*b*) the wave frequency f, and (*c*) the power P supplied by the wave. ••
63. An oscillator attached to a string transmits 350 mW of power down the string. The wave created by this motion has amplitude 0.0165 m and wavelength 1.80 m. If the string is under 14.8 N of tension, what is the wave speed? ••
64. A cord of linear mass density 0.360 kg/m is attached to a harmonic oscillator that has a maximum output of 200 W. (*a*) With the oscillator operating at this maximum power and the tension in the cord set at 30.0 N, a wave of amplitude 8.00×10^{-3} m is created. What is the minimum wavelength possible for a wave of this amplitude? (*b*) What is the power output of the oscillator if the wave generated has the same amplitude but double the wavelength you calculated in part *a*, and the tension is 15.0 N? •••
65. One end of a 9.00-m wire vibrates sinusoidally, creating a wave that travels in the positive x direction. The wave has a frequency of 60.0 Hz, a wavelength of 3.00 m, and an amplitude of 0.0725 m. (*a*) Write the time-dependent wave function that describes this wave. (*b*) If the mass of the wire is 1.20×10^{-2} kg, what is the power supplied to the wire to create this wave? •••

16.9 The wave equation

66. Show that $f(x, t) = e^{b(x-vt)}$, where b and v are constants, is a solution to Eq. 16.51, the wave equation. •
67. What keeps a surfer riding the crest of a wave from dropping down to the wave's base? ••
68. A string initially hanging vertically is displaced to the right with a speed of 25 m/s for 0.040 s, then returned to its original position in 0.010 s. This motion is repeated, with no delays, numerous times. The wave created by this motion travels down the string at 67 m/s and has a period of 0.050 s. (*a*) Write the time-dependent wave function for this pulse, and (*b*) show that this function is a solution to the wave equation (Eq. 16.51). ••
69. Show that if $f_1(x, t) = A_1 \sin(k_1 x - \omega_1 t)$ and $f_2(x, t) = A_2 \sin(k_2 x - \omega_2 t)$ are both solutions to the wave equation (Eq. 16.51), then $f(x, t) = f_1(x, t) + f_2(x, t)$ is also a solution. ••
70. (*a*) Show that the equations (*i*) $A \cos(kx + \omega t)$, (*ii*) $e^{-b|x-qt|^2}$, and (*iii*) $-(b^2 t - x)^2$ all satisfy the wave equation (Eq. 16.51) provided that A, k, ω, b, and q are constants. (*b*) Calculate the speed of each wave of part *a*. •••

Additional Problems

71. Two children are holding a rope taut between them when one suddenly yanks the rope. (*a*) Does the child at the other end instantly get pulled? (*b*) Answer the same question for two children holding a rigid steel bar between them. •
72. A heavy rope is hanging by one end from the ceiling with a block hanging from the other end. Is the speed of a pulse in the rope greater at the top or the bottom of the rope? •
73. First you stretch a spring to twice its unstretched length and send pulse A from one end to the other. Then you stretch the spring to three times its unstretched length and send pulse B from one end to the other. How does the time interval needed for A to travel through the spring compare with the time interval needed for B to do so? ••
74. You pluck a guitar string so as to produce a standing wave for which $\lambda = 1.3$ m. What is the maximum value of the string's displacement at a position 0.500 m from the lower end of the string if the maximum resultant displacement of the wave is 0.75 mm? ••

75. Tossing rocks into the center of a pond, you notice that the ripples are evenly spaced 170 mm apart. If it takes 5.0 s for 15 ripples to pass a log sticking up out of the water, (*a*) what is the wave speed? (*b*) How long does it take a ripple to reach shore if the pond is 12 m in diameter? ●●

76. When a person sings in the shower, certain notes seem louder than others. What's going on? ●●

77. A standing wave is created on a string that is 1.75 m long. The wave has eight nodes counting the nodes at the two ends. (*a*) What is the wavelength? (*b*) What is the frequency if the wave speed is 130 m/s? (*c*) If the resultant displacement is 20.0 mm, write the time-dependent wave function that describes the standing wave, including units where appropriate. ●●

78. Would water waves traveling along a trough on the surface of Mars travel faster than, slower than, or at the same speed as water waves traveling along a similar trough on the surface of Earth? (Hint: You'll need data from Table 13.1 on page 430.) ●●

79. You hold one end of a horizontal string and raise your hand during a time interval of 0.18 s, doing 1.2 J of work on the string in the process. You then allow your hand to return to its original position. If the wave pulse you create travels along the string at 67 m/s and the linear mass density of the string is 0.0282 kg/m, what was the vertical speed of your hand? ●●

80. Your friend wants to test your understanding of waves. She weaves together one end of two different ropes (one with greater mass density than the other, but each with the same radius and length) to make a single rope. Then she attaches one end of the combination to a pole. You are blindfolded and asked to hold the other end of the stretched rope. Your friend expects you to determine not only which end you are holding (the heavier or lighter rope), but also whether your friend used a fixed or free method of attachment to the pole. You think for a minute, then laugh and declare that you can even estimate the ratio of the linear mass densities! While she is speechless, you create a single wave pulse with your hand. ●●● CR

81. Your job as assistant coach is to attach one end of several heavy, 10-m ropes to the trusses that support the gym ceiling, leaving the other end of each hanging free. The team is going to spend the afternoon climbing these ropes, but you begin to wonder about wave pulses traveling on such a rope. You could shake the free end of a rope back and forth once and measure how long it takes the pulse created by this motion to arrive at the top of the rope, but you are more of a calculation person. ●●● CR

Waves in Two and Three Dimensions

CONCEPTS

17.1 Wavefronts
17.2 Sound
17.3 Interference
17.4 Diffraction

QUANTITATIVE TOOLS

17.5 Intensity
17.6 Beats
17.7 Doppler effect
17.8 Shock waves

Now that we have treated waves that propagate in one dimension, we can extend our description to waves that propagate in more than one dimension—for example, waves on a water surface, which propagate in two dimensions, and sound waves, which propagate in three dimensions. The basic mechanism for these waves is the same as that for one-dimensional waves: When particles in a medium are coupled together, a disturbance caused at one point in a medium propagates to the surrounding points. Therefore, most of what we know about waves in one dimension carries over to the waves treated in this chapter. However, there are important differences between waves in one dimension and waves in more than one dimension. For example, the amplitude of waves propagating in more than one dimension decreases even in the absence of energy dissipation, and wave interference in more than one dimension gives rise to a number of phenomena not observed in one dimension.

17.1 Wavefronts

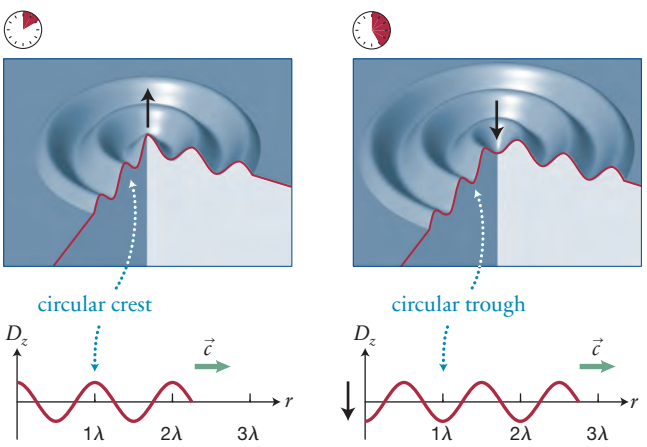
When you drop a stone in water, the stone disturbs the water surface and causes a number of circular ripples to travel outward along the water surface, emanating from the point at which the stone entered the water. The radius of each ripple starts out small and increases as the ripple moves outward at constant speed. The ripples constitute a two-dimensional **surface wave,** which is a wave that propagates in two dimensions. Surface waves are analogous to the one-dimensional waves we studied in Chapter 16, where propagation is always along a line.

If, instead of dropping a stone, you move a stick sinusoidally up and down in the water, you generate a periodic surface wave. **Figure 17.1** shows two cutaway views of a periodic surface wave at two instants that are half a period apart. The graph below each view shows the vertical component of the displacement of the water surface as a function of the radial distance r to the source—in other words, the *wave function* of the wave. Because the wave is circular, the wave function is the same in all radial directions. Note the similarity between the shape of the curves in these graphs and the shape of the wave in Figure 16.9 for a periodic wave on a string. Because the surface wave has circular symmetry, all points that are equidistant from the source have the same phase of oscillation. For example, at instant t_i all points that are a distance λ from the source have reached their maximum displacement above the equilibrium surface, forming a circular crest. Half a period later, the same points have reached their maximum displacement below the surface, forming a circular trough.

When the source of the wave can be localized to a single point in space—a small stone dropped in a pond, the stick in Figure 17.1—the source is said to be a **point source.** Point sources are treated as if they have no physical extent. The actual source need not be physically small, however. Stars, for example, are much larger than Earth, yet because they are so far away they can be treated as a point source of light (a wave). Likewise, in Figure 17.1, if the diameter of the stick is small compared to the diameter of the ripples, we can consider the stick to be a point source.

The blue region of **Figure 17.2** shows a top view of the circular crests and troughs of a periodic surface wave spreading out from a point source. We can schematically represent the wave by a series of circles

Figure 17.1 Cutaway views of a wave on the surface of a liquid and the corresponding vertical displacement of the surface as a function of distance r from the oscillating wave source, which is located at $r = 0$.



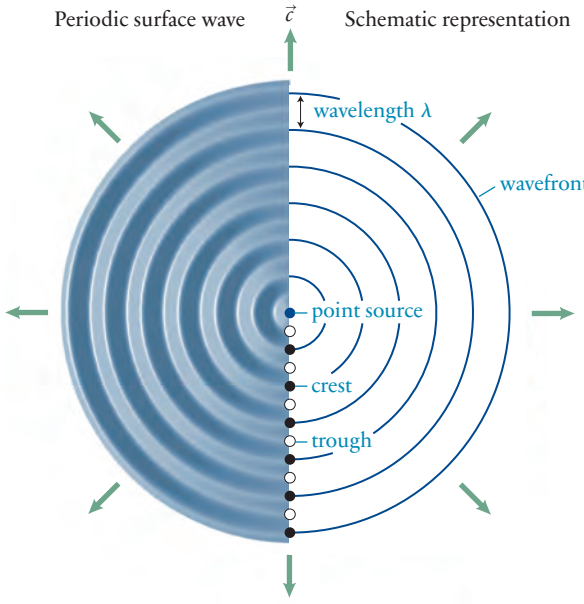


Figure 17.2 Top view of the circular crests and troughs formed in a periodic surface wave. We represent the wave schematically as a series of wavefronts.

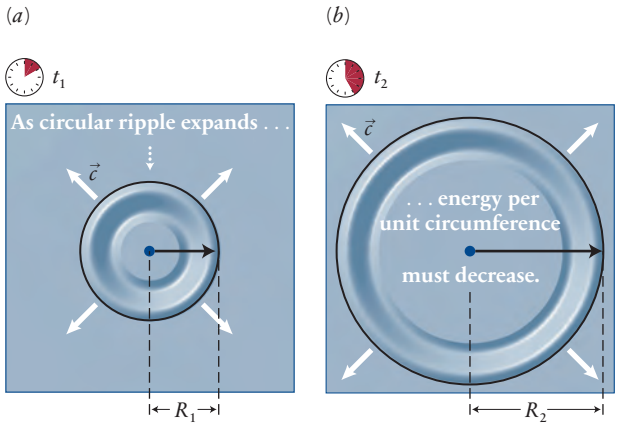
CONCEPTS

Figure 17.3 A surface wave moving at speed c. Because surface waves expand in two dimensions from the point source (at $t = 0$), the wave energy is distributed over a larger and larger circumference.



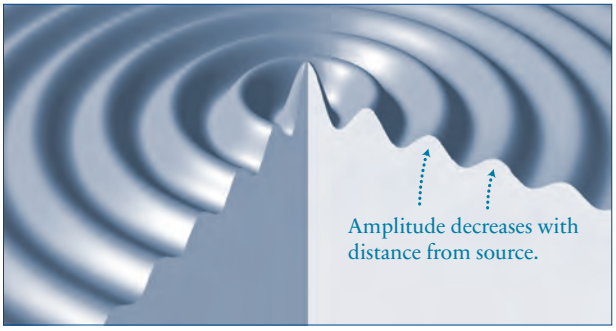


Figure 17.4 Cutaway view of a periodic surface wave. Because the energy in a given wavefront is spread out over an increasingly large circumference as the wavefront moves away from the source, the amplitude decreases as the wavefront moves away from the source.

separated by the wavelength λ (white region). Each circle corresponds to points on the surface that have the same phase of oscillation. Curves or surfaces on which all points have the same phase constitute a **wavefront.** As the wave travels away from the source at the wave speed c, the radius of each wavefront increases.

This expansion of circular surface waves causes the wave energy to be spread out over a larger and larger region. Consider, for example, the spreading ripples in **Figure 17.3**. At instant t_1 the ripples cross a circle of radius R_1 centered on the wave source; at instant t_2 they are about to cross a circle of radius R_2. If there is no loss of wave energy as the wave moves from R_1 to R_2—that is, if there is no dissipation of energy—the amount of energy that crosses the circle of radius R_2 must be the same as the amount that crosses the circle of radius R_1. Because the circumference increases, there is less energy per unit length along the circumference at t_2 than there is at t_1.

CONCEPTS

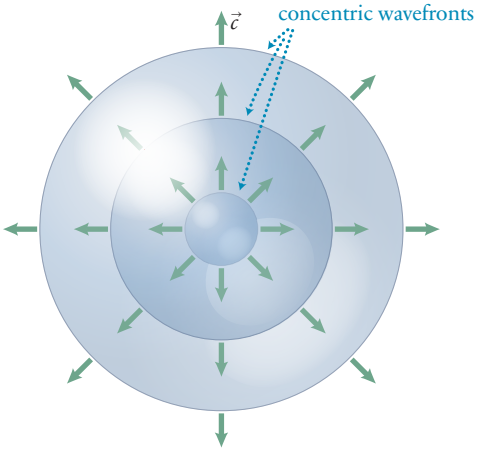
17.1 Let $t_2 = 2t_1$ in Figure 17.3. (*a*) How does R_1 compare with R_2? (*b*) If the energy in the wave is E and there is no dissipation of energy, what is the energy per unit length along the circumference at R_1? At R_2? (*c*) How does the energy per unit length along a wavefront vary with radial distance r?

As Checkpoint 17.1 shows, the expansion of circular wavefronts causes the energy per unit length along a wavefront to decrease as $1/r$. Therefore, it follows that the wave amplitude is proportional to $1/\sqrt{r}$. (You can see this amplitude decrease in the cutaway view in **Figure 17.4**.) Keep in mind that this amplitude decrease has nothing to do with energy dissipation: It is due entirely to the spreading out of the wave, which causes the energy to be distributed over a larger circumference.

Some waves—sound waves and light waves are two examples—spread out in three dimensions. If the source is a point source and the spreading is uniform in all three dimensions, the wavefronts are spherical (**Figure 17.5**). The resulting waves are called **spherical waves.** As a three-dimensional wave propagates, each wavefront expands outward at the wave speed c, and the energy carried by the wavefront is spread out over a larger and larger spherical area. When a wavefront reaches a distance r from the source, the energy in the wavefront is spread out over a surface area of $A = 4\pi r^2$, and so the energy per unit area carried by the wavefront is proportional to $1/r^2$ (**Figure 17.6**). The amplitude of a spherical wave is therefore proportional to $1/r$ (Eq. 16.41 again).

Because it is difficult to represent wavefronts in three dimensions, we usually represent spherical wavefronts by a series of circles, just as we do for two-dimensional waves. Keep in mind, however, that there

Figure 17.5 The wavefronts from a point source emitting waves in three dimensions are uniformly expanding, concentric spheres.



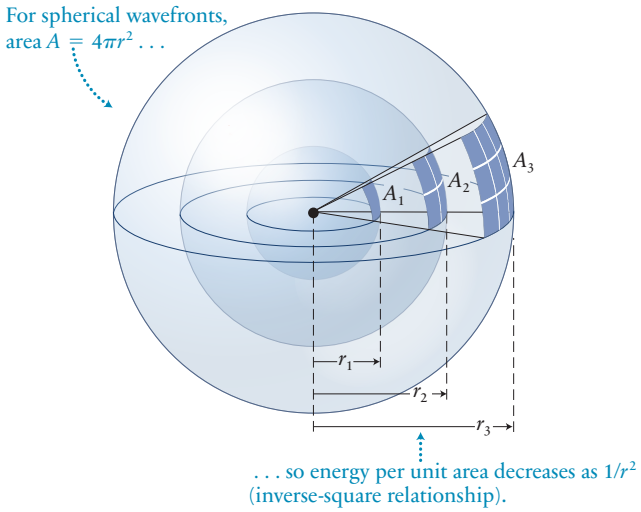


Figure 17.6 The inverse-square relationship between energy and radius for a wave expanding uniformly in three dimensions without dissipation. All the energy that crosses area A_1 also crosses A_2 and A_3. Because the area of a sphere is proportional to r^2 ($A_{\text{sphere}} = 4\pi r^2$), the energy per unit of surface area decreases as $1/r^2$.

is an important difference between waves in two and in three dimensions:

> **The amplitude of waves in two dimensions decreases with distance r from the source as $1/\sqrt{r}$; in three dimensions it decreases as $1/r$. This decrease is due purely to the spreading out of the wavefronts and involves no loss of energy.**

EXAMPLE 17.1 Ripple amplitude

The amplitude of a surface wave for which $\lambda = 0.050$ m is 5.0 mm at a distance of 1.0 m from a point source. What is the amplitude of the wave (*a*) 10 m from the source and (*b*) 100 m from the source? During a time interval equal to 100 periods, by what percentage does the amplitude of a wavefront decrease (*c*) after the wavefront passes a position 1.0 m from the source and (*d*) after it passes a position 100 m from the source?

1 GETTING STARTED I am given that the amplitude $A = 5.0$ mm at $r = 1.0$ m. As the wave spreads out, its amplitude diminishes, and I need to calculate the amplitude at $r = 10$ m and $r = 100$ m. In addition I need to determine by how much the wave is reduced as it propagates over a 100-period time interval past these two positions.

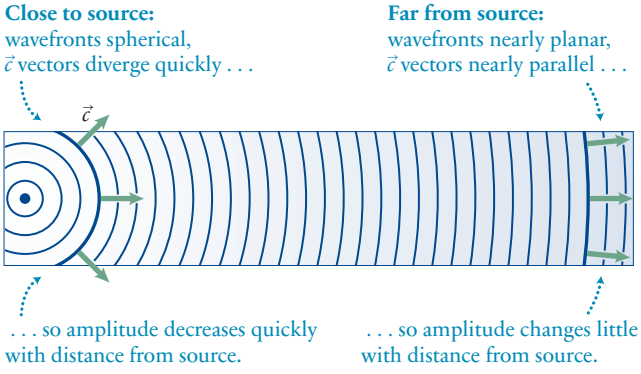
2 DEVISE PLAN Because the wave is a two-dimensional surface wave, the amplitude is proportional to $1/\sqrt{r}$. I know the amplitude $A_{1.0\text{ m}}$ at $r = 1.0$ m, so I can use this dependence to determine the amplitude at other distances from the source. For parts *a* and *b*, I need to determine $A_{10\text{ m}}$ and $A_{100\text{ m}}$ at $r = 10$ m and $r = 100$ m. In 100 periods, the wavefront travels a distance equal to 100 wavelengths, which is $100 \times (0.050\text{ m}) = 5.0$ m, so for parts *c* and *d*, I also need to determine the amplitudes 5 m beyond those positions.

3 EXECUTE PLAN (*a*) The ratio of the amplitudes at 1.0 m and 10 m is $\sqrt{(1.0\text{ m})}/\sqrt{(10\text{ m})} = \sqrt{(1.0/10)} = 0.32$, and so the amplitude at 10 m is $0.32 \times (5.0\text{ mm}) = 1.6$ mm. ✔

(*b*) At 100 m, $\sqrt{(1.0\text{ m})}/\sqrt{(100\text{ m})} = 0.10$, and so the amplitude is $0.10 \times (5.0\text{ mm}) = 0.50$ mm. ✔

(*c*) 100 periods after passing the 1.0-m position, the wavefront is 6.0 m from the source and the amplitude decreases by a factor of $\sqrt{(1.0\text{ m})}/\sqrt{(6.0\text{ m})} = 0.41$. This means $A_{6.0\text{ m}}$ is 41% of $A_{1.0\text{ m}}$: $A_{6.0\text{ m}} = 0.41(5.0\text{ mm}) = 2.0$ mm, a decrease of about 60%. ✔

(*d*) Then 100 periods after passing the 100-m position, the wavefront is 105 m from the source and the amplitude decreases by a factor of $\sqrt{(100\text{ m})}/\sqrt{(105\text{ m})} = \sqrt{(1/1.05)} = 0.98$. This means that $A_{105\text{ m}}$ is 98% of $A_{100\text{ m}}$: $A_{105\text{ m}} = 0.98(0.50\text{ mm}) = 0.49$ mm, a decrease of 2%—a mere 0.02% each period. ✔



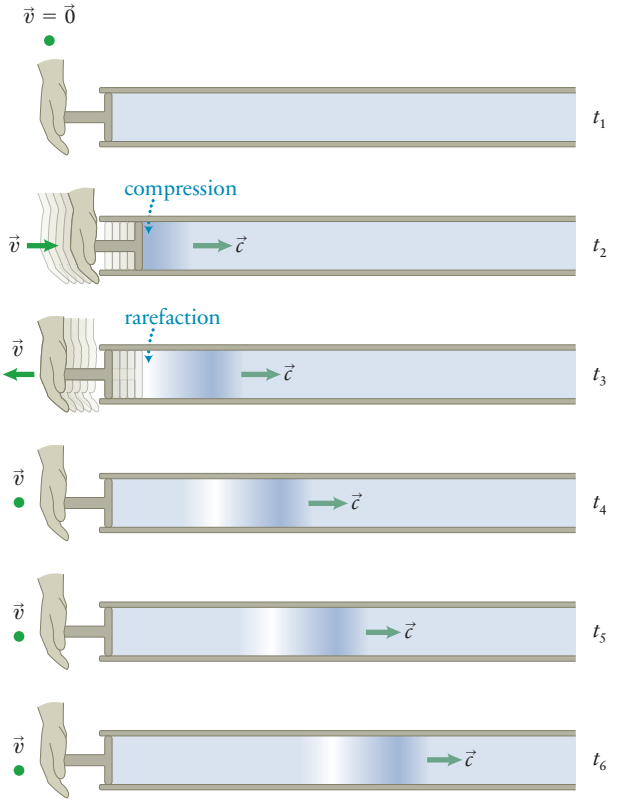
4 EVALUATE RESULT The amplitudes at 10 m and 100 m are both smaller than the amplitude at 1.0 m, which is what I expect. That the amplitude decrease over 100 wavelengths is less farther away from the source agrees with what I expect from the $1/\sqrt{r}$ dependence.

As this example demonstrates, the decrease in amplitude is most pronounced close to the source; far from the source, the decrease is hardly noticeable. **Figure 17.7** illustrates the same point in a different way: Far from the source, the wavefronts are nearly flat rather than curved, and as a wavefront straightens, a fixed length of it diverges less. Far from a point source, a spherical wavefront essentially becomes a two-dimensional flat wavefront called a **planar wavefront.** Likewise, far from a point source, a circular surface wavefront essentially becomes a one-dimensional straight wavefront.

17.2 Notice that in the views of the surface wave in Figure 17.1 the amplitude does not decrease with increasing radial distance r. How could such waves be generated?

CONCEPTS

Figure 17.7 Far from the source, wavefronts are nearly flat, so amplitude changes little with additional distance from the source.



17.2 Sound

The human ear can detect some longitudinal waves at frequencies in the range from about 20 Hz to 20 kHz. Such waves, which propagate through any kind of material—solid, liquid, or gas—constitute what we call **sound.** Sound propagates through any medium that can exert elastic restoring forces. If you find it hard to think of a gas as being able to exert an elastic force, squeeze an empty plastic bottle first with a tightly sealed cap and then without it. Without the cap, squeezing the bottle simply pushes some air out of the bottle. With the cap, the bottle exerts an elastic force because of the air in it. It is this elastic force that is responsible for transmitting sound waves.

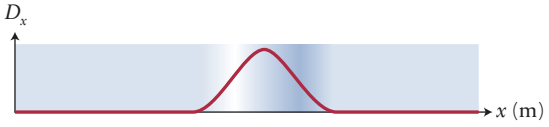


Figure 17.8 shows a simple wave pulse propagating through a long, air-filled tube. One end of the tube is fitted with a piston. Starting at t_2, the piston is rapidly moved back and forth, first pushing the molecules in the layer of air adjoining the piston closer together and then letting them expand again. These molecules, in turn, push on the molecules in a neighboring layer, and so on, creating a disturbance that propagates through the air in the tube. The disturbance consists of a *compression* (region where the molecules are crowded together) and a *rarefaction* (region where they are spaced far apart). The resulting wave is called a *compressional wave*. The wave speed c at which the disturbance travels through the tube depends on the density and the elastic properties of the medium. For dry air at a temperature of 20 °C, the speed of sound waves is 343 m/s.

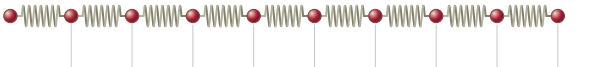
Figure 17.8 A piston generates a longitudinal sound pulse that propagates along an air-filled tube. The disturbance consists of a compression and a rarefaction. The wave function is similar to the one for a longitudinal wave in a spring (see Figure 16.6).

(*a*) Longitudinal wave pulse created by in-and-out movement of piston

(*b*) Wave function of pulse at instant t_6

EXERCISE 17.2 Wavelength of audible sound

Given that the speed of sound waves in dry air is 343 m/s, determine the wavelengths at the lower and upper ends of the audible frequency range (20 Hz–20 kHz).



SOLUTION The wavelength is equal to the distance traveled in one period. At 20 Hz, the period is $1/(20\text{ Hz}) = 1/(20\text{ s}^{-1}) = 0.050$ s, so the wavelength is $(343\text{ m/s})(0.050\text{ s}) = 17$ m. ✔ The period of a wave of 20 kHz is $1/(20{,}000\text{ Hz}) = 5 \times 10^{-5}$ s, so the wavelength is $(343\text{ m/s})(5.0 \times 10^{-5}\text{ s}) = 17$ mm. ✔

The wave pulse in Figure 17.8 is longitudinal—the air molecules are displaced in the same direction as that in which the wave propagates. In bulk gases and liquids that have no internal friction, there can be no transverse waves because such gases and liquids do not exert elastic forces in the transverse direction. Notice the similarity between the wave pulse shown in Figure 17.8 and the longitudinal wave pulse propagating through a coil spring shown in Figure 16.5.

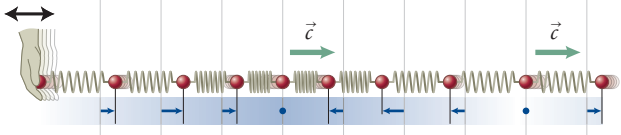


Figure 17.9a shows a chain of identical beads coupled together by springs, which can serve as a simple

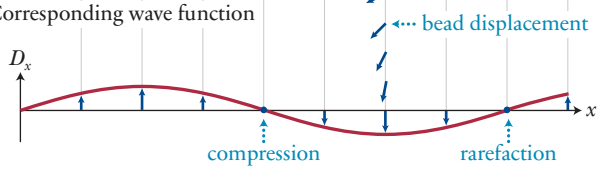
Figure 17.9 A simple mechanical model for longitudinal waves.



(*a*) Identical beads coupled by springs

(*b*) Snapshot of longitudinal wave propagating along chain

(*c*) Corresponding wave function

CONCEPTS

mechanical model for studying longitudinal waves. A snapshot of a harmonic longitudinal wave propagating through the chain is shown in Figure 17.9*b*. The leftmost bead is made to oscillate back and forth harmonically. Because each bead executes, in turn, the same longitudinal oscillation, a compressional wave propagates along the chain. Although the beads move in the same direction as the wave, there is no permanent displacement of beads in that direction. What are transported along the chain, however, are energy (as kinetic energy of the beads and elastic potential energy of the springs) and momentum.

17.3 Does the wave speed along the chain shown in Figure 17.9 increase or decrease when (*a*) the spring constant of the springs is increased and (*b*) the mass of the beads is increased?

From Section 16.1, you know that a snapshot of a transverse wave gives us the wave function directly. Things are not so simple with longitudinal waves, however. Because with these waves the displacement of the medium is along the axis of wave propagation, it is cumbersome to interpret any wave snapshots. The wave function shown in Figure 17.9*c*, however, provides an alternative representation of the wave and reveals its harmonic nature, which is not immediately obvious in Figure 17.9*b*. This graph is obtained by plotting the displacement of each bead from its equilibrium position versus the bead's equilibrium position. To create Figure 17.9*c*, the displacement vector of each bead in Figure 17.9*b* is rotated 90° counterclockwise and its tail placed on the x axis at the *equilibrium* position of the bead given in Figure 17.9*a*.

The perception of sound

The human ear is capable of detecting longitudinal waves transmitted through a gas, liquid, or solid medium in what is called the *audible frequency range*. This range, which varies with age and also from person to person, extends from about 20 Hz to 20 kHz. The sensitivity of the ear varies greatly over this range, however, peaking at about 3 kHz. Waves outside this range cause no auditory nerve signals in humans, although large-amplitude waves of very low frequency, called *subsonic waves* (such as earthquakes), can be felt. Some animals, such as bats, can detect longitudinal waves of frequencies up to 120 kHz, called *ultrasonic waves* because they are above the audible frequency range for humans.

The perception of sound is a complicated and subjective matter. The mechanical part of this process, which is determined by the physiology of the ear, is well understood. A sound wave that reaches the ear propagates through a complex system of solid and liquid parts of the outer and middle ear to the inner ear, where the wave causes *hair cells* to oscillate. These oscillations cause the auditory nerve to send signals to the brain.

The neurological processing of these signals by the brain is not yet fully understood. The properties of sound are typically described using terms such as *loudness*, *pitch*, and *timbre* or *tonal quality*. These terms are subjective, however, and so there is no simple correlation between them and the parameters used to describe waves in physics (amplitude, frequency, harmonic content).

Loudness: The perception of loudness is connected to sound wave energy and therefore amplitude. Because the ear is capable of detecting waves over a large range of wave energies—from the very faint sound of a pin drop to the loud roar of an airliner taking off—the response is highly nonlinear (discussed in Section 17.5). The correlation between loudness and energy is complicated by the fact that the perception of loudness also depends on frequency: A 1-kHz wave sounds louder than a 200-Hz wave of equal energy (see Figure 17.26).

Pitch: The sensation of pitch is related to the physical property of frequency. The correlation is nonlinear; if the frequencies of two sound waves differ by a factor of 2, their pitches are said to be an *octave* apart. Sounds at 256 Hz and 512 Hz are one octave apart, but so are sounds at 3 kHz and 6 kHz. The perceived pitch also depends on the amplitude of the sound wave. Above 3 kHz, pitch increases with increasing sound wave amplitude; below 2 kHz, pitch decreases with increasing amplitude.

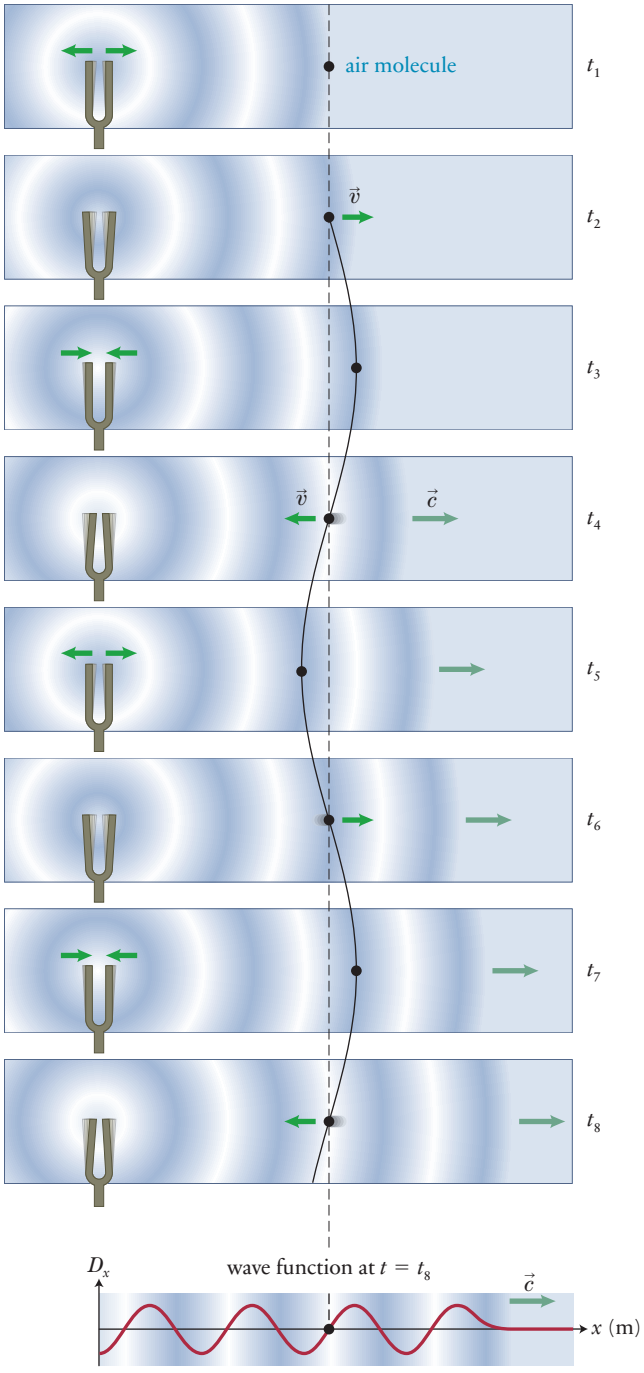
Timbre: We can readily distinguish two musical instruments even when they emit tones of identical pitch because they produce different mixtures of harmonics. The pitch is typically related to the lowest, or fundamental, frequency in the series of harmonics, and two instruments playing the same pitch usually produce the same fundamental. They differ, however, in the content of the higher harmonics, which is what determines the timbre of the instrument. Even though the ear and the brain constitute a remarkable Fourier analyzer in the sense that they can distinguish sounds of different harmonic contents, we cannot characterize timbre with a precise statement about measurable parameters. (An alternative term you might run across for timbre is *tonal quality*.)

17.4 (*a*) Plot the velocity of the beads along the chain in Figure 17.9*b* as a function of their equilibrium position x. (*b*) Plot the linear density (number of beads per unit length) as a function of x.

As Checkpoint 17.4 suggests, we can also represent the wave in Figure 17.9 by plotting the linear density versus position. Comparing the linear density curve of Figure S17.4*b* with the $D_x(x)$ curve of Figure S17.4*a* (see the Solutions to Checkpoints near the back of this book) gives us some important information:

The compressions and rarefactions in longitudinal waves occur at the locations where the medium displacement is zero.

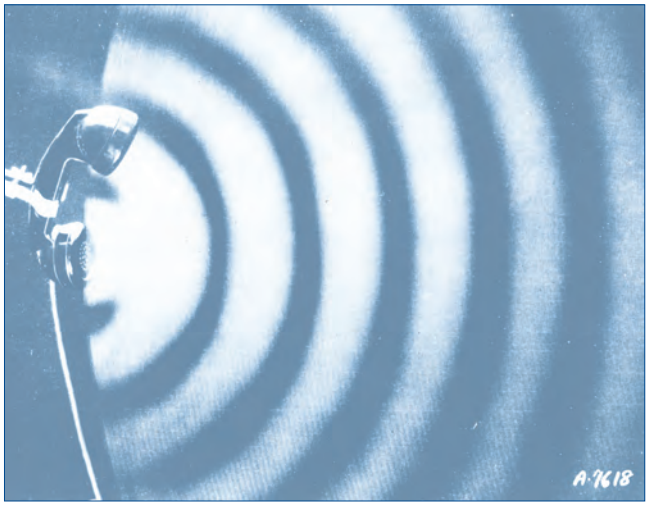
(You can get this same information by comparing Figures 17.9*b* and *c*.)



The propagation of sound through a medium is very similar to that of a compressional wave through the chain in Figure 17.9. Disturbed molecules in a solid, liquid, or gas are subject to intermolecular forces that tend to return the molecules to their equilibrium positions. For small displacements, the restoring force is proportional to the displacement. It is this restoring force that is responsible for the propagation of the disturbance caused by the piston in Figure 17.8.

When not confined to a tube, a compressional wave traveling through air spreads out in three dimensions because, unlike beads along a string, air molecules interact with the surrounding molecules in all three directions. Consequently, sound waves tend to form spherical wavefronts. **Figure 17.10** shows a sound wave generated by an oscillating tuning fork. A series of spherical shells of compression and rarefaction travel outward from the fork. Each molecule in the air executes a sinusoidal back-and-forth movement as successive shells travels by; the sine curve in the figure shows the position versus time of one molecule.

The displacements of air molecules disturbed by a sound wave are very small. At a distance of a few hundred meters, for example, the deafening roar of an airliner taking off causes displacements of only 10^{-6} m—about one-hundredth of the width of a hair. These small displacements coupled with the high speed at which sound waves travel make it impossible to directly see the compressional wavefronts that accompany sound. Only under special laser illumination is it possible to observe these wavefronts (**Figure 17.11**).

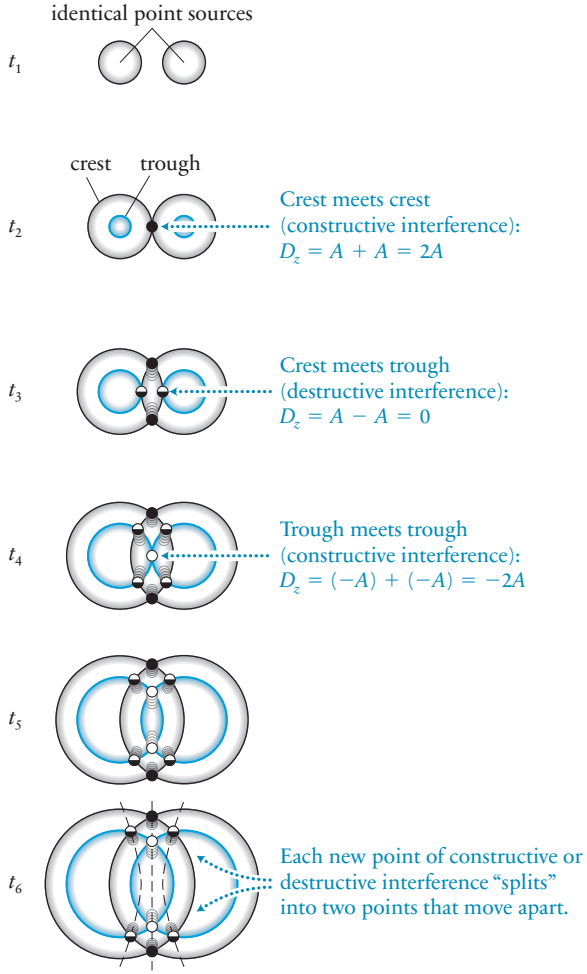


Notice how the wavefronts shown in Figures 17.10 and 17.11 resemble the circular wavefronts of a surface wave, such as the one represented in Figure 17.2. The compressions correspond to crests, and the rarefactions correspond to troughs. When we draw circles to represent the spherical wavefronts of sound waves, which are longitudinal waves, the circles represent not crests and troughs but rather compressions and rarefactions.

Figure 17.10 The periodic wave emitted by a tuning fork causes a series of outward-traveling spherical wavefronts. The dot represents an air molecule that oscillates about its equilibrium position as the wavefronts pass by.

CONCEPTS

Figure 17.11 Image of the spherical compressional wavefronts produced by sound waves emanating from a telephone. This image was obtained using laser illumination. *Reused with permission of Nokia Corporation and AT&T Archives.*



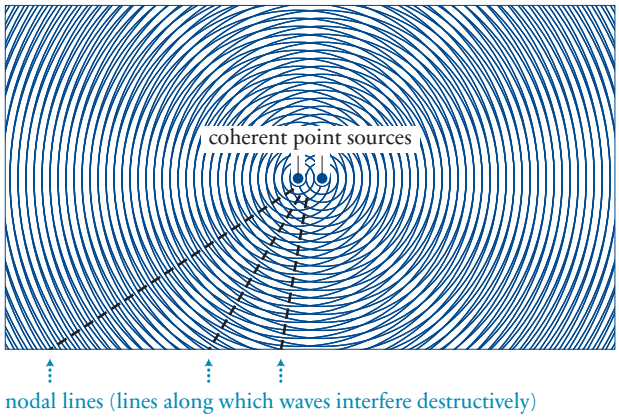
17.5 Even though the sound of a common type of loudspeaker carries in all directions, the loudness in front of the speaker is considerably greater than the loudness behind it. What is the shape of the wavefronts produced by such a loudspeaker?

17.3 Interference

The superposition of overlapping waves in two and three dimensions leads to a number of interesting phenomena. Consider first the situation illustrated in **Figure 17.12**, where two identical circular wave pulses traveling on a liquid surface cross as they expand. At t_2 the two crests meet at a point midway between the two sources, giving rise to constructive interference. At this point the displacement of the liquid surface is twice as great as that due to the individual pulses. As the pulses continue to expand, this point of overlap splits into two points, one moving upward and the other moving downward. At t_3 the crest of each pulse meets the trough of the other pulse, leading to destructive interference. Because the height of the crest is equal to the depth of the trough, the vector sum of the medium displacement is zero.* Each of these points splits into two points that move vertically away from each other. At t_4 the two troughs meet and reinforce each other, giving rise to constructive interference again. At this point the depression of the medium is

*The waves do not cancel exactly close to the sources because the amplitudes of the two waves differ due to the $1/\sqrt{r}$ factor in the wave amplitude. Far from the sources, however, this difference is negligible.

Figure 17.12 Interference of two identical sets of circular wave pulses expanding on a liquid surface.



doubled. Note that, as shown at t_6, the points of constructive interference move along a straight line perpendicular to the line that connects the two sources, while the points of destructive interference move along curved paths.

Let us now apply these ideas to the overlapping of periodic surface waves. When periodic circular waves from two nearby sources cross each other, the crests and troughs overlap in many places, giving rise to a complex interference pattern. **Figure 17.13** on the next page shows the circular wavefronts for two sources separated by a distance equal to three wavelengths and emitting waves of the same amplitude and frequency. In addition, the two sources always have the same phase and are therefore said to be *in phase*. Sources that are emitting waves that have a constant phase difference are said to be **coherent.** The pattern produced by the overlapping circles in Figure 17.13, called a *moiré pattern*, creates the illusion of a number of bands radiating out from the center of the figure (*moiré* is the French word for the wavy finish seen in some fabrics). As we shall see shortly,

CONCEPTS

Figure 17.13 Moiré pattern formed by the overlapping wavefronts of two closely spaced, coherent wave sources (located at the centers of the two concentric sets of circles). The center of each band in the pattern corresponds to a nodal line.

the centers of these bands correspond to **nodal lines**—lines where the two waves cancel each other and the vector sum of the medium displacement is always zero.

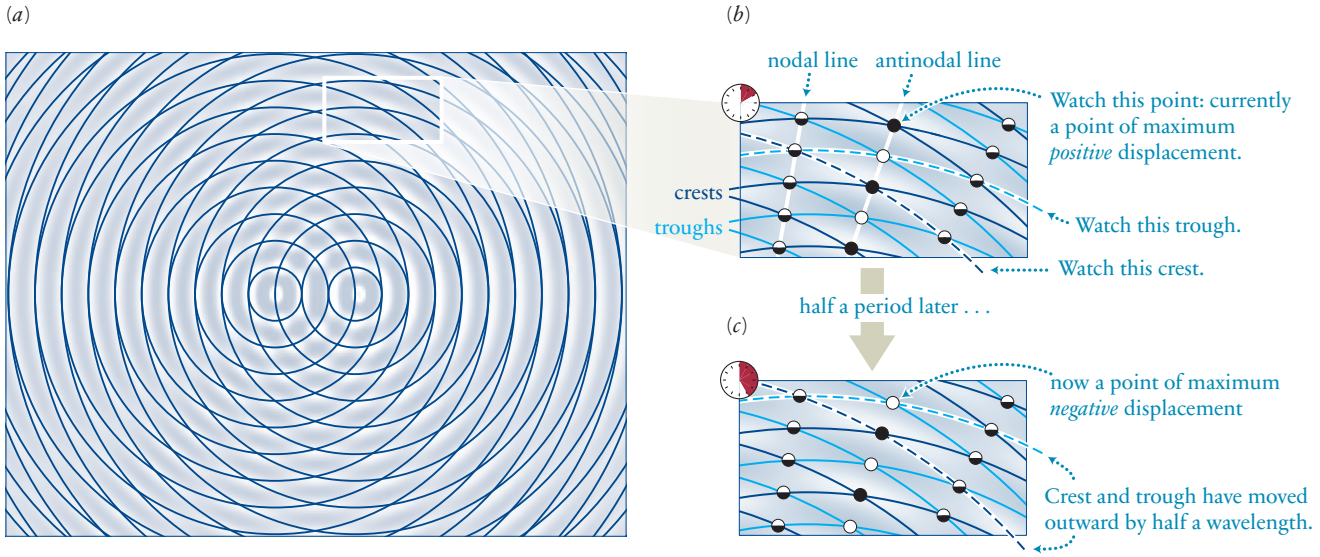


Figure 17.14*a* shows a magnified view of the central portion of Figure 17.13 overlaid on a picture of the interference pattern. White areas in the picture correspond to areas where the medium displacement is greatest—regions where two crests reinforce each other (comparable to t_2 in Figure 17.12). Bright blue areas also correspond to areas where the medium displacement is greatest—regions where two troughs reinforce each other (t_4 in Figure 17.12). Pale blue areas correspond to regions where the surface is undisturbed because the waves interfere destructively. If you look at the picture from a glancing angle, you can see that these pale blue areas form outward radiating bands. The bands coincide with the positions where the wavefronts of one source fall halfway between the wavefronts of the other (which gives the illusion of bands in the moiré pattern in Figure 17.13).

Figure 17.14*b* shows a detail of the interference pattern. In addition to the solid dark blue arcs that indicate wavefronts marking the crests of the waves generated by each source, bright blue arcs indicate the locations of the troughs halfway between each pair of neighboring crests. Figure 17.14*c* shows the same region half a period later. All wavefronts have advanced by half a wavelength, and the nodes (◒) and antinodes (● and ○) have moved along with the wavefronts. See, for example, the node at the intersection of the dashed dark blue crest from the left source and the dashed bright blue trough from the right source—in Figure 17.14*b* it is the second node from the top; in Figure 17.14*c* it is the uppermost. In addition, all white and bright blue areas are interchanged, as are all filled and unfilled circles (see, for example, the highlighted filled and open circles in Figure 17.14*b* and *c*). Where two crests initially reinforced each other, two troughs now meet. (Of course, the nodal lines stay in place, by definition.)

17.6 (*a*) What is the medium displacement at a point halfway between a filled circle and a neighboring open circle in Figure 17.14*b*? (*b*) Sketch the variation of this displacement as a function of time. (*c*) What is the medium displacement at all points between two neighboring half-filled circles? (*d*) Sketch the variation of this displacement as a function of time at the midpoint between two neighboring half-filled circles.

CONCEPTS

Figure 17.14 Details of the interference pattern in the central region of Figure 17.13. White and blue regions represent, respectively, areas of maximum positive and maximum negative medium displacement. The intermediate regions of zero displacement line up to form the gray nodal bands seen in Figure 17.13.

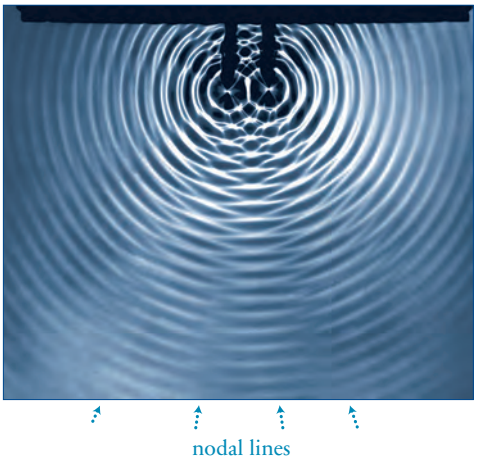
The half-filled circles line up to form a path, and as Checkpoint 17.6 demonstrates,* *all* points along this path remain undisturbed and are therefore nodes. The line that connects the half-filled circles is thus a nodal line, and the pale blue bands that appear in Figure 17.13 are thus centered on nodal lines. The filled and open circles line up to form what are called **antinodal lines.** Points on these antinodal lines have the greatest amplitude of oscillation; in other words, these points are antinodes.

17.7 Is a point halfway between a filled and a neighboring open circle in Figure 17.14*b* a node?

The interference pattern formed by overlapping waves in two dimensions can readily be observed for waves generated on a water surface (**Figure 17.15**). The nodal lines are clearly visible in the picture. All waves in more than one dimension—sound waves, light waves, x-ray waves, radio waves—set up interference patterns that contain nodal and antinodal lines. For example, two loudspeakers that are some distance apart and that emit sound waves of the same frequency set up an interference pattern that is not very different from the ones for circular water waves. By adjusting your position in front of the speakers, you can find regions where the destructive interference occurs, causing the loudness of the sound to be low.

The existence of nodal regions has a number of consequences. Consider, for example, the interference pattern shown in **Figure 17.16*a***. Two coherent sources S_1 and S_2 emit circular waves. The waves cause the medium displacement at point P to vary, but at point Q, located on a nodal line, the medium displacement *remains zero*. If you were standing at that location, you could not tell whether the sources were emitting waves or not! Each source separately, however, does emit waves in the direction of Q. Figure 17.16*b* shows that, with S_1 is turned off, the wavefronts from S_2 that reach Q are not interfered with. In other words, if you were standing at Q, you would hear sound when S_1 is turned off but not when both sources are on. So, *removing* a source *increases* the amplitude of the wave at Q! Conversely, adding a second source (in other words, returning to the situation in Figure 17.16*a*) decreases (or even eliminates) the wave amplitude in certain regions. So:

Figure 17.15 Photograph of the interference pattern caused by overlapping circular waves on a water surface.



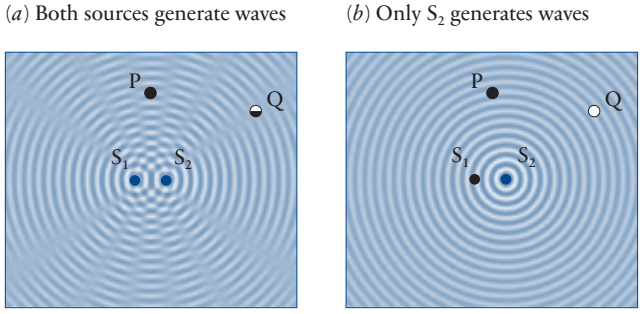


Figure 17.16 Less can be more. (*a*) When both sources generate waves, point Q lies on a nodal line and thus never experiences displacement of the medium (because the waves from the two sources interfere destructively there). If these were sound waves, there would be silence at Q. (*b*) However, when only one source generates waves, Q experiences their full effect.

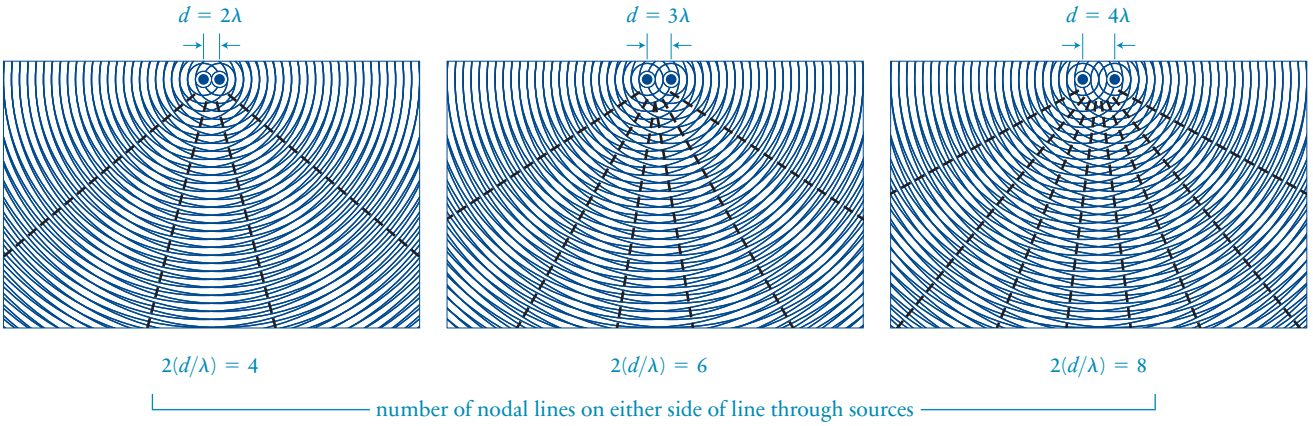
When the waves from two coherent sources interfere, the amplitude of the sum of these waves in certain directions is less than that of a single source.



17.8 (*a*) If the amplitude of the wave generated by each source in Figure 17.16 is *A* at points P and Q, what is the overall amplitude at P in Figure 17.16*a*? In Figure 17.16*b*? (*b*) Given that the wave energy that passes Q in Figure 17.16*b* becomes zero when S_1 is turned on, do you expect the energy that passes P to increase or decrease? (*c*) Use your answer to part *a* to determine by what factor the amount of energy that passes P changes, and reconcile your answer with your answer to part *b*.

Just what a given interference pattern looks like is determined by the wavelength and the spacing between the two sources. The greater the source separation relative to the wavelength, the greater the number of nodal lines. We determine the number of nodal lines in a pattern by imagining a straight line running through

CONCEPTS

*I cannot overstress the importance of doing Checkpoint 17.6. By completing this checkpoint, you will be teaching yourself the key feature of interference of waves in more than one dimension.

Figure 17.17 The effect of changing the separation between two point sources.

the centers of the two sources and then counting the number of nodal lines on either side of this line:

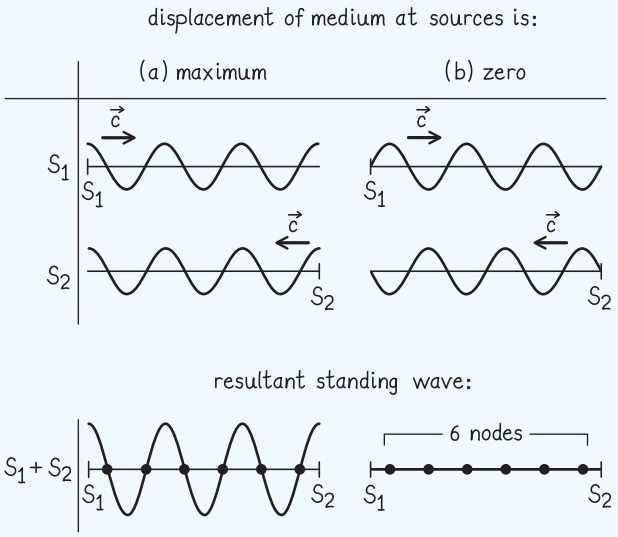
> **If two coherent sources located a distance d apart emit identical waves of wavelength λ, then the number of nodal lines on either side of a straight line running through the centers of the sources is the greatest integer smaller than or equal to $2(d/\lambda)$.**

You can study the appearance of nodal lines as the separation between the sources is varied in **Figure 17.17**.

17.9 By how many wavelengths are the sources in Figure 17.16*a* separated?

EXAMPLE 17.3 Nodes

For the situation shown in Figure 17.16*a*, how many nodes are there along the line segment S_1S_2 that connects the centers of the two sources?



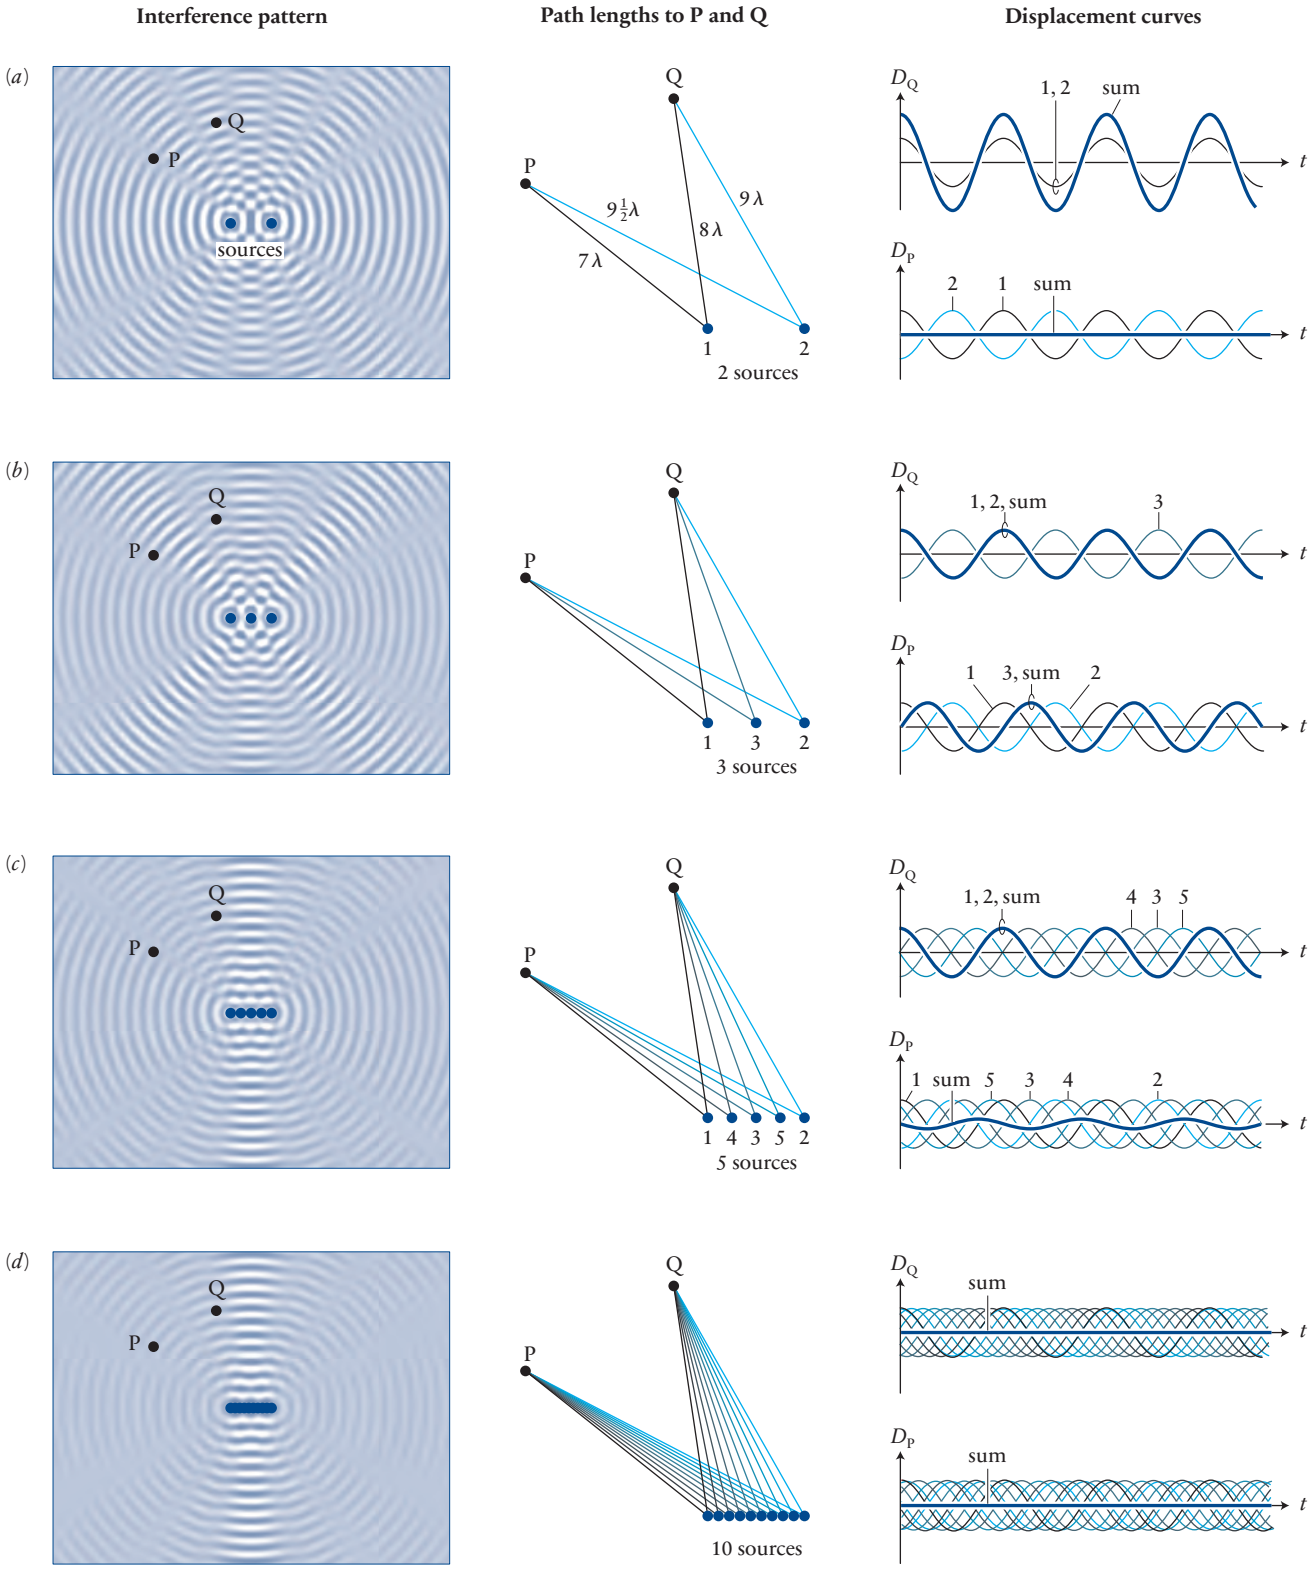
1 GETTING STARTED The sources are coherent and so send identical waves in opposite directions along S_1S_2. This means there is a standing wave (see Section 16.6) along that segment. From Figure 17.16*b* I can tell that exactly three wavelengths fit between S_1 and S_2.

2 DEVISE PLAN The two sources are in phase, so I can determine the number of nodes by plotting the amplitudes of the waves due to each source along S_1S_2 at two instants and then adding those amplitudes. The nodes occur wherever the amplitude of the combined wave remains zero.

3 EXECUTE PLAN **Figure 17.18*a*** shows, for the instant at which the medium displacement at both sources is maximum, the medium displacement caused by S_1 and S_2 and the sum of the two. Figure 17.18*b* shows the displacements one-quarter cycle later. Comparing the two graphs, I see that six positions along line segment S_1S_2 (denoted by the black dots in the bottom graphs) remain stationary, indicating six nodes. ✔

4 EVALUATE RESULT Because the sources are separated by a distance equal to three wavelengths and because there is one node for each half-wavelength (see Section 16.6), my answer makes sense.

Figure 17.18



Example 17.3 shows us why there are twice as many nodes and therefore twice as many nodal lines as there are wavelengths between the sources. Each node corresponds to a nodal line, and so you now see why there is a connection between the number of nodal lines and the source spacing.

17.10 Along the leftward and rightward extensions of the straight line joining S_1 and S_2 in Figure 17.16, why are there no nodes to the left of S_1 and to the right of S_2?

Figure 17.19 shows what happens when additional coherent sources are added between the two sources of Figure 17.14. Let us focus our attention on the two points P and Q. When just two sources are present (Figure 17.19*a*), P is on a nodal line and Q is on an antinodal line. The path length diagram in Figure 17.19*a* shows the waves arriving at P and Q.

CONCEPTS

Figure 17.19 When additional coherent sources are added between the two sources spaced by three wavelengths, the interference pattern changes: The greater the number of sources, the more the waves are concentrated along the axis perpendicular to the sources. The displacement curves show the displacements at P and Q for each source and the sum of these displacements (bold curve).

The distance from source 1 to P is 7λ; the distance from source 2 to P is $9\frac{1}{2}\lambda$. Consequently the two waves *always* arrive at P out of phase—they cause medium displacements in opposite directions and so always cancel. The distance from source 1 to Q is 8λ; the distance from source 2 is 9λ. So the two waves arrive in phase at Q and always reinforce each other.

Figure 17.19*b* shows how the addition of a single source halfway between the two original sources redistributes the flow of wave energy and concentrates the waves in fewer triangular areas. The phase of the wave arriving from the additional source is approximately halfway between that from sources 1 and 2. In other words, source 3 is about $8\frac{1}{4}\lambda$ from P and $8\frac{1}{2}\lambda$ from Q. Because the waves from 1 and 2 cancel each other at P, the wave from 3 arrives undisturbed at P, so P is no longer on a nodal line. At Q, the additional wave from 3 arrives out of phase with those from 1 and 2, so the additional source diminishes the wave amplitude at Q.

If two additional sources are added, almost all the wave energy becomes concentrated in a narrow cone perpendicular to the straight line that connects the sources (Figure 17.19*c*). The phases of the waves are such that, even though there are five sources instead of two, the amplitude of the waves arriving at Q is *smaller* than before and that of the waves arriving at P is very small.

With ten coherent sources, all the waves are concentrated in a cone along the direction perpendicular to the straight line that joins the sources (Figure 17.19*d*). Outside of this cone, the waves—all arriving at any given point, including P and Q, with a different phase—cancel each other. **Figure 17.20** shows what happens when 100 coherent sources are placed close together, now forming a row 10λ wide: A *beam* of nearly straight wavefronts emanates in a direction perpendicular to the row of sources. There are hardly any waves outside the beam because the waves from all the different sources tend to cancel each other. Summarizing:

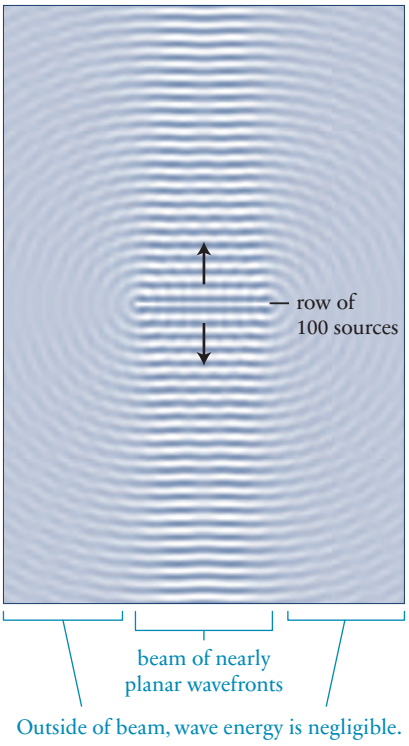
When many coherent point sources are placed close together along a straight line, the waves nearly cancel out in all directions except the direction perpendicular to the axis of the sources.

17.11 How does the wave amplitude along the beam of wavefronts in Figure 17.20 change with distance from the row of sources?

17.4 Diffraction

The nearly straight wavefronts that emanate from continuous rows of coherent sources suggest that *any* wavefront may be regarded as having originated from a collection of many closely spaced, coherent point sources emitting waves in all directions. The waves cancel in all directions except the direction perpendicular to the wavefront. This picture of wavefronts consisting of closely spaced, coherent point sources is called **Huygens' principle** after the 17th-century Dutch physicist Christiaan Huygens.

Figure 17.20 A 10λ-wide row of 100 coherent sources produces nearly planar wavefronts. The flow of energy is entirely along a beam perpendicular to the row of sources.



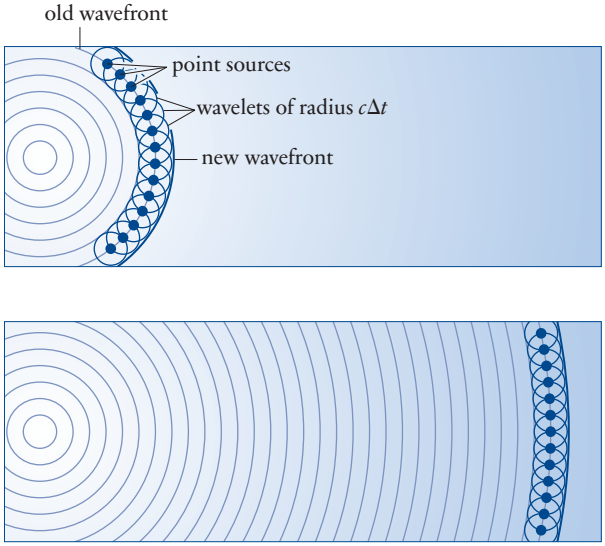


Figure 17.21 illustrates how Huygens' principle can be used to construct a future wavefront given the wavefront at a certain instant. We begin by dividing the original wavefront into a series of closely spaced point sources. All those point sources emit in phase because they are all on the same wavefront. After a short time interval Δt, each source has emitted a small circular wavefront, called a *wavelet*, of radius $c\Delta t$. Wavelets of neighboring sources overlap in such a way that they interfere destructively with each other except in the forward direction. All these forward-moving wavelets combine to form the wavefront we aim to construct, labeled "new wavefront" in Figure 17.21.*

Huygens' principle also helps explain how waves spread around corners. If you stand near an open window, you hear sounds from the street even if you are

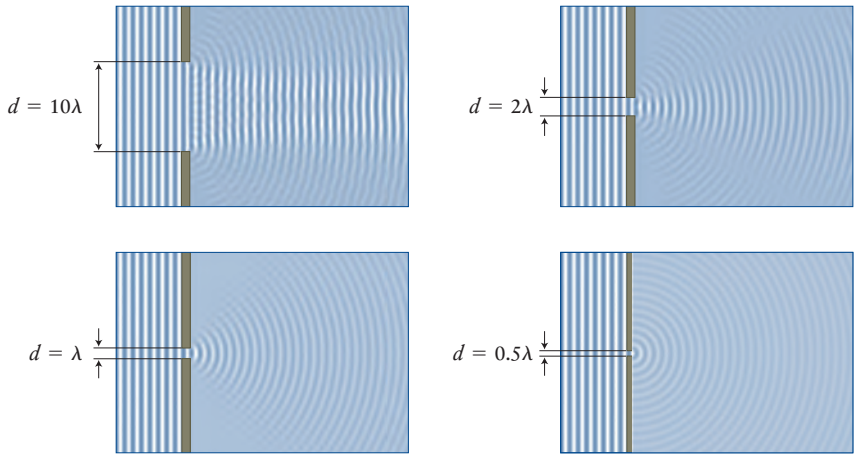
*For a *single* row of coherent point sources, wavefronts emanate in *two* directions along a line perpendicular to the straight line connecting the sources (Figure 17.20). When additional rows of coherent point sources are added in front of or behind this row and these sources are given the proper phases, the amplitude of the resulting waves in one of the two directions is suppressed by interference.

CONCEPTS

Figure 17.21 According to Huygens' principle, any wavefront can be regarded as a collection of closely spaced, coherent point sources. Advancing wavefronts can then be constructed by drawing circular wavelets centered at points along an earlier wavefront.

not standing directly in front of the window. Likewise, if you stand behind a tree, you can hear sounds coming from in front of the tree because the sound waves spread around the tree.

Figure 17.22 shows nearly planar wavefronts incident on gaps of various size. If the gap is much larger than the wavelength, the gap lets through a *beam* of wavefronts with very little spreading. As the gap gets narrower, the waves beyond the gap spread out more and more, so that what gets through the gap no longer constitutes a beam. When the gap width is smaller than the wavelength, the wavefronts beyond the gap spread out in all directions—in essence, the gap now acts like a single point source. This spreading, called **diffraction,** is another characteristic feature that distinguishes waves from objects: Waves spread out when going through a narrow opening, but objects do not. If you throw a handful of pebbles through an opening, for instance, the "beam" of pebbles doesn't spread out after passing the opening.



The reason waves diffract is directly related to the observation that many coherent point sources in a row give rise to waves in just one direction because the waves emitted by each source cancel in all but the forward direction (Figure 17.20). Here we see the opposite occurring: As the number of point sources is reduced (the gap is narrowed in our example), the cancellation of waves along directions away from the straight line perpendicular to the line of sources becomes less complete and spreading occurs. As the width of the gap becomes comparable to the wavelength, the gap acts like a point source, leading to spreading of the wave in all directions.

Obstacles or apertures (openings) whose width is smaller than the wavelength of an incident wave give rise to considerable spreading of that wave.

The amount of spreading depends strongly on the wavelength. For a given aperture, low-frequency sounds diffract more strongly than higher-frequency ones. If a band marches by below your window and you are not standing directly in the window opening, you hear the low-frequency drone of drums and tubas more than the high-frequency sounds of cymbals and piccolos. Move near the window and the sound of the band turns from dull to sharp as the high-frequency sounds emitted by it now also reach your ears.

CONCEPTS

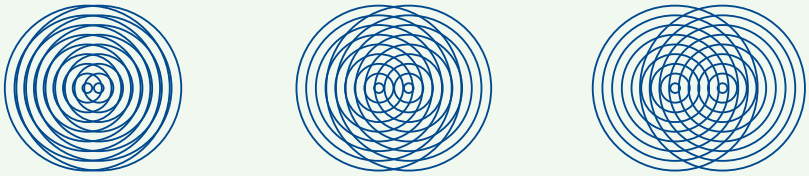
Figure 17.22 When a planar wavefront passes through a gap, some spreading, called diffraction, occurs. The smaller the gap, the greater the amount of spreading. When the width d of the gap is smaller than the wavelength λ, the gap acts like a point source.

A direct consequence of wave diffraction is that it is impossible to create a beam of waves that is narrower than the wavelength of the waves. This means that diffraction limits the ability of waves to locate objects. For example, it is very difficult for a person to locate small objects by detecting reflected sound waves because, with their relatively long wavelengths (0.02 m to 20 m), these waves diffract around most objects. We therefore locate objects using visible light, whose wavelength is in the range of 4×10^{-7} m to 7×10^{-7} m (less than one-hundredth the width of a human hair). Only objects and apertures that are smaller than the wavelength of visible light diffract light.

Bats can detect ultrasonic waves of frequencies up to 120 kHz. The wavelength of these waves is about 3 mm. By emitting such waves and detecting their reflections, bats can locate small insects. Ultrasonic waves are also used for diagnostic purposes in medicine. Because of their short wavelength, it is possible to emit a narrow beam of ultrasonic waves. The beam is rapidly scanned across a sample to create an image from the reflections of the beam that occur inside the sample (**Figure 17.23**).

17.12 Suppose the barriers in Figure 17.22 were held at an angle to the incident wavefronts. Sketch the transmitted wavefronts for the case where the width of the gap is much smaller than the wavelength of the incident waves.

Figure 17.23 Ultrasound image of a three-month-old fetus in utero. The 2-MHz waves (1 megahertz = 1 MHz = 10^6 Hz) used to obtain this picture have a wavelength of 0.7 mm.

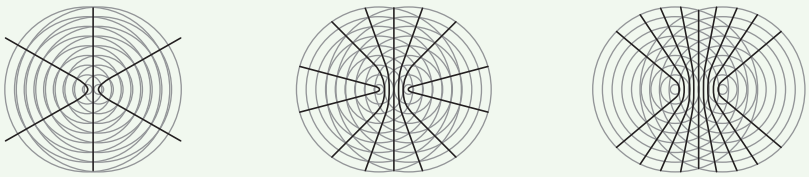


CONCEPTS

Self-quiz

1. A circular wave travels such that a crest occurs at radius r_1 at instant t_1. The same crest has a radius $r_2 = 2r_1$ at $t_2 = 2t_1$. (*a*) What is the wave speed? (*b*) Where is the crest at $t_3 = 3t_1$? (*c*) What is the ratio (energy per unit length at t_3)/(energy per unit length at t_1)?
2. A spherical wave travels such that a crest occurs at radius r_1 at instant t_1. The same crest has a radius $r_2 = 2r_1$ at $t_2 = 2t_1$. (*a*) What is the wave speed? (*b*) Where is the crest at $t_3 = 3t_1$? (*c*) What is the ratio (energy per unit area at t_3)/(energy per unit area at t_1)?
3. Two circular wavefronts interfere as shown in **Figure 17.24**. (*a*) Draw the antinodal lines. (*b*) Is the medium displacement along these lines constant?

Figure 17.24



4. Two coherent sources are placed two wavelengths apart. Point P lies on a nodal line in the interference pattern of the two sources, and point Q lies on an antinodal line. (*a*) If one source is turned off, does the energy arriving at P increase, decrease, or remain the same? (*b*) If one source is turned off, does the energy arriving at Q increase, decrease, or remain the same? (*c*) Do your answers depend on which source is turned off?
5. Because sound waves diffract around an open doorway, you can hear sounds coming from outside the doorway. You cannot, however, see objects outside the doorway unless you are directly in line with them. What does this observation imply about the wavelength of light?

Answers

1. (*a*) The speed is the distance traveled divided by the time interval over which the motion occurs: r_1/t_1. (*b*) At $3t_1$ the crest is at $3r_1$. (*c*) The energy per unit length at r_1 is proportional to $1/r_1$. That at r_3 is proportional to $1/r_3 = 1/3r_1$. The ratio of the energies per unit length at the two instants is thus $1/3$.
2. (*a*) The speed is r_1/t_1. (*b*) The crest is at $3r_1$. The answers to parts *a* and *b* to this and the preceding question have to do with only the speed of the waves, not their dimensionality. (*c*) The energy per unit area at r_1 is proportional to $1/r_1^2$. That at r_3 is proportional to $1/r_3^2 = 1/(3r_1)^2$. The ratio of the energies per unit area at the two instants is $1/9$.
3. (*a*) See **Figure 17.25**. (*b*) No. The medium displacement at any point on an antinodal line varies as a function of time.

Figure 17.25

4. (*a*) Being on a nodal line, P initially receives no energy. After one source is turned off, it receives energy from the other source, and so the energy P receives increases. (*b*) Being on an antinodal line, Q receives four times the energy of a single source because the amplitude at Q is twice that of a single source. When one source is turned off, Q receives only the energy from a single source, and so the energy received at Q decreases. (*c*) It does not matter which source is turned off. The interference pattern exists only when both sources are on, and each point receives the energy from only a single source when the second source is turned off.
5. Because light does not diffract as it travels through the doorway, this observation implies that the wavelength of the light must be smaller than the width of the doorway. Given that visible light has wavelengths between 4×10^{-7} m and 7×10^{-7} m and most doorways are about 1 m wide and 2 m tall, this is indeed the case.

17.5 Intensity

As we saw in Section 17.1, the propagation of waves in more than one dimension causes the wave energy to be diluted over a larger and larger region. For waves in three dimensions, we define the **intensity** I as the energy delivered by the wave per unit time per unit area normal to the direction of propagation. Because the energy delivered per unit time is the definition of power, we can say

$$I \equiv \frac{P}{A}, \tag{17.1}$$

where P is the power delivered by the wave over an area A. For three-dimensional waves, the SI unit of intensity is thus $\mathrm{W/m^2}$.

Consider a point source sending out waves uniformly in all directions. If there is no dissipation of energy, all the energy generated by the source must cross an imaginary sphere centered on the source. If the power delivered by the source is P_s, the intensity is

$$I = \frac{P_s}{A_{\text{sphere}}} = \frac{P_s}{4\pi r^2} \quad \text{(uniformly radiating point source)}, \tag{17.2}$$

and so we see that the intensity of a wave in three dimensions is proportional to $1/r^2$, as we concluded in Section 17.1.

For a two-dimensional surface wave, the intensity is defined as the energy incident per unit time per unit *length* normal to the direction of propagation. For a surface wave that delivers a power P over a length L,

$$I_{\text{surf}} \equiv \frac{P}{L}. \tag{17.3}$$

Consequently the SI unit of the intensity of a surface wave is W/m because we must replace the area of a sphere in Eq. 17.2 by the circumference of a circle: $I = P_s/(2\pi r)$. The intensity of two-dimensional waves is thus proportional to $1/r$.

EXAMPLE 17.4 Sound wave energy

The minimum intensity audible to the human ear is called the *threshold of hearing*. For a 1.0-kHz sound wave, this threshold is approximately 10^{-12} $\mathrm{W/m^2}$. The maximum tolerable intensity, called the *threshold of pain*, is about 1.0 $\mathrm{W/m^2}$ for a 1.0-kHz sound wave. (*a*) For a 1.0-kHz sound wave, estimate the amount of energy delivered to the ear in 1.0 s at the threshold of hearing and at the threshold of pain. (*b*) If the sound is produced by a loudspeaker 1.0 m away from the ear, what is, in each case, the power emitted by the loudspeaker?

❶ **GETTING STARTED** I am given two intensities, which give the power per unit area, and asked in part *a* to calculate the energy arriving at the ear in 1.0 s for each intensity. Because energy per unit time is power, part *a* reduces to identifying the area over which the energy is delivered. For part *b*, I am given a loudspeaker-to-ear distance, and I need to calculate the power for each loudspeaker at that distance.

❷ **DEVISE PLAN** For part *a*, to estimate the energy delivered to the ear in 1.0 s, I have to estimate the surface area of the ear. I can then use Eq. 17.1 to calculate the power delivered to the ear. To obtain the energy delivered, I multiply the power by the time interval. For part *b*, I assume that the loudspeaker is a point source that radiates sound uniformly in all directions. With this assumption, I can use the given intensities and source-to-ear distance in Eq. 17.2 to calculate the power emitted by the speaker.

QUANTITATIVE TOOLS

3 EXECUTE PLAN (*a*) The surface area of the outer ear is approximately $(0.030\ \text{m})^2 \approx 9.0 \times 10^{-4}\ \text{m}^2$, so the power delivered to the ear at the threshold of hearing is about

$$P = IA = (10^{-12}\ \text{W/m}^2)(9.0 \times 10^{-4}\ \text{m}^2) = 9.0 \times 10^{-16}\ \text{W}$$

$$= 9.0 \times 10^{-16}\ \text{J/s}.$$

In 1.0 s, a mere 9.0×10^{-16} J—about a millionth of a billionth of a joule—gets delivered to the ear when a sound source emits at an intensity equal to the threshold of hearing. ✔

At the threshold of pain, the power delivered to the ear is

$$(1.0\ \text{W/m}^2)(9.0 \times 10^{-4}\ \text{m}^2) = 9.0 \times 10^{-4}\ \text{W},$$

and so 0.90 mJ is delivered to the ear in 1.0 s. ✔

(*b*) For the power emitted by the loudspeaker at the two thresholds, Eq. 17.2 gives

threshold of hearing:

$$P_s = I(4\pi r^2) = (10^{-12}\ \text{W/m}^2)[4\pi(1.0\ \text{m})^2]$$

$$= 1.3 \times 10^{-11}\ \text{W}\ ✔$$

threshold of pain:

$$P_s = (1.0\ \text{W/m}^2)[4\pi(1.0\ \text{m})^2] = 13\ \text{W}.\ ✔$$

4 EVALUATE RESULT The energies delivered at the threshold of hearing are very small, and I have no good way of evaluating those. I do know that the ear can detect sounds made by the tiniest of movements—the rustle of a leaf, for example—and these movements cannot transmit much energy, so at least I know that the values I obtained are not unreasonably large. I know that headphones and loudspeakers can easily emit power levels at the threshold of pain. The fact that headphones can be powered with tiny batteries tells me that the 0.9-mW answer I obtained in part *a* is not unreasonable. Most stereo systems are rated at tens to hundreds of watts, so the 13 W in part *b* is also in the right range.

As Example 17.4 illustrates, the human ear is capable of handling sound waves over a tremendous range of intensities—intensities that differ by as much as a factor of 10^{12}. To deal conveniently with such an enormous intensity range, it is common to use a logarithmic scale for intensity. For example, if the intensity I increases by a factor of 10^{12}, as it does when going from the threshold of hearing to the threshold of pain, the common logarithm (see Appendix B), $\log I$, increases by only 12. The intensity of a sound wave can then be expressed as part of a ratio that also includes the intensity I_{th} at the threshold of hearing:

$$\log\left(\frac{I}{I_{\text{th}}}\right). \tag{17.4}$$

The reference level ($I_{\text{th}} = 10^{-12}\ \text{W/m}^2$) is chosen to coincide with human hearing, and the quantity $\log(I/I_{\text{th}})$, even though it is unitless, is given an artificial unit. This unit is the *bel* (B), in honor of the American scientist Alexander Bell (1847–1922). It is customary to express intensity levels of sound in **decibels** (dB), one-tenth of a bel: 1 dB = 0.1 B. The **intensity level** β of a sound, measured in decibels, is thus defined as

$$\beta \equiv (10\ \text{dB}) \log\left(\frac{I}{I_{\text{th}}}\right). \tag{17.5}$$

Figure 17.26 Average auditory response of the human ear. The ear is sensitive to longitudinal waves in air ranging in frequency from 20 Hz to 20 kHz. The sensitivity is greatest at 3 kHz, where the threshold of hearing is lowest. The curves give the intensity levels required to produce harmonic tones of the same perceived loudness.

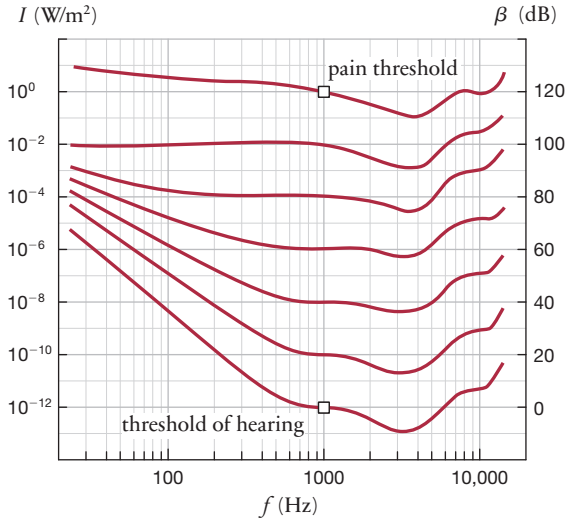


Table 17.1 Approximate intensity levels

Source	distance (m)	β (dB)	Description
Jet engine	50	140	pain
Pneumatic hammer	10	110	
Shout	1.5	100	very loud
Car horn	10	90	
Hair dryer	0.2	80	loud
Automobile interior		70	
Conversation	1	60	moderate
Office background		50	
Library background		40	
Suburban bedroom		30	quiet
Whisper	1	20	
Normal breathing	5	10	barely audible

At the threshold of hearing, where the intensity is $I = 10^{-12}\ \text{W/m}^2$, we have $\log(I/I_{\text{th}}) = \log(1) = 0$, and so the intensity level $\beta = (10\ \text{dB}) \times (0) = 0\ \text{dB}$. At the threshold of pain, where the intensity is $I = 1\ \text{W/m}^2$, we have $\log[(1\ \text{W/m}^2)/(10^{-12}\ \text{W/m}^2)] = 12$, and so the intensity level is $\beta = (10\ \text{dB})(12) = 120\ \text{dB}$.

As Figure 17.26 illustrates, the thresholds for hearing and pain vary with frequency. The five curves between the two threshold curves give the intensity required to produce harmonic sounds that a listener perceives as all being equally loud. For example, a sinusoidal 200-Hz tone of intensity $10^{-8}\ \text{W/m}^2$ and a sinusoidal 1-kHz tone of intensity $10^{-10}\ \text{W/m}^2$ are perceived to have the same loudness by the average listener. The right vertical scale gives the corresponding intensity level in decibels. Table 17.1 gives the intensity levels in decibels of a number of common sound sources.

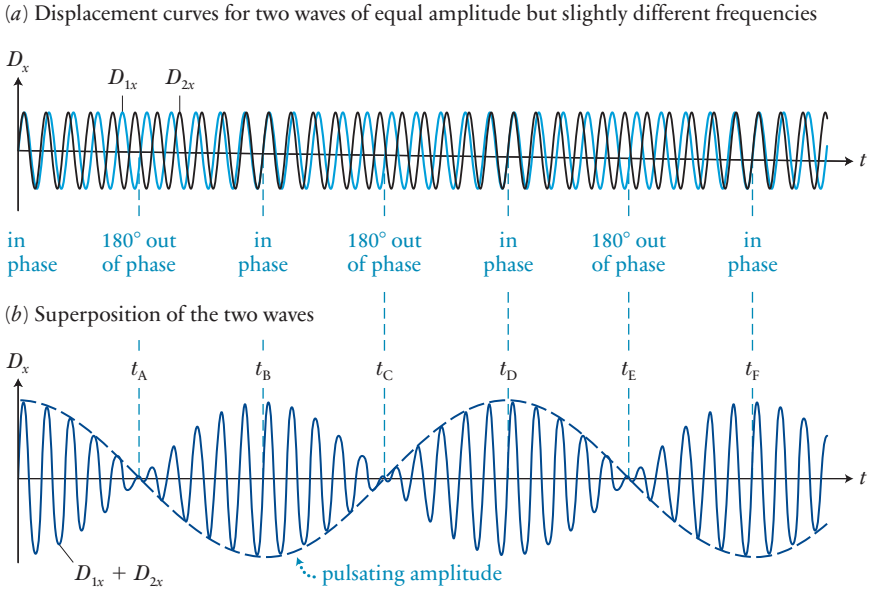
EXERCISE 17.5 Doubling the intensity

A clarinet can produce sound waves of intensity level about 70 dB. By how much does the intensity level increase if a second clarinet is played at the same time?

SOLUTION If the intensity of the sound produced by one clarinet is I_c, the intensity level of one clarinet is

$$\beta_1 = (10\ \text{dB}) \log\left(\frac{I_c}{I_{\text{th}}}\right) = 70\ \text{dB}.$$

The second clarinet doubles the intensity, so the intensity level becomes



$$\beta_2 = (10\ \text{dB}) \log\left(\frac{2I_c}{I_{\text{th}}}\right) = (10\ \text{dB})\left[\log 2 + \log\left(\frac{I_c}{I_{\text{th}}}\right)\right]$$
$$= (10\ \text{dB})\log 2 + \beta_1,$$

where I have used the logarithmic relationship $\log AB = \log A + \log B$. Because $\log 2 \approx 0.3$, the intensity level increases to $\beta_2 \approx (10\ \text{dB})(0.3) + 70\ \text{dB} = 73\ \text{dB}$. So, even though the intensity doubles, the intensity *level* increases by only 3 dB. ✔

17.13 In Exercise 17.5, how many clarinets must play at the same time in order to increase the intensity level from 70 dB to 80 dB?

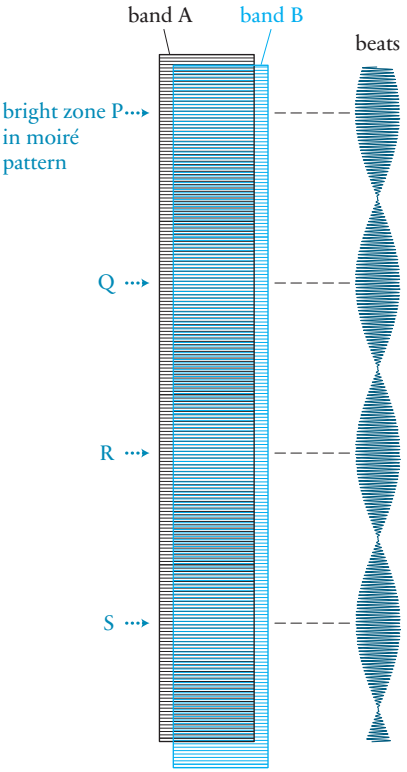
QUANTITATIVE TOOLS

Figure 17.27 When two sources emit waves of equal amplitude but slightly different frequencies, the waves superpose to produce a wave that has a pulsating amplitude (dashed line). We call this phenomenon *beating*.

17.6 Beats

In the first part of this chapter, the only type of interference we considered was interference between sources that emit waves of the same frequency. Let us now consider two sources that emit waves of equal amplitude but slightly different frequencies f_1 and f_2. Let the medium displacements caused by the individual waves at some fixed location be given by

$$D_{1x} = A \sin(2\pi f_1 t) \tag{17.6}$$



$$D_{2x} = A \sin(2\pi f_2 t). \tag{17.7}$$

These displacements are plotted in **Figure 17.27*a***. Note that because the frequencies are different, the phase relationship between the two sources is not constant. At $t = 0$, the displacements are in phase, but over time they get out of phase, with the phase of one wave getting ahead of the other. At some instants the two waves are in phase ($0, t_B, t_D, \ldots$), and at these instants their crests coincide, giving rise to oscillations of double amplitude. At other instants, however, the waves are 180° out of phase ($t_A, t_C, \ldots$), and at these instants the crests and troughs of the two waves cancel each other.

The medium displacement that results from the superposition of the two waves is shown in Figure 17.27*b*. The resultant wave is an oscillation that changes amplitude with time. At instants 0, t_B, t_D, and t_F the amplitude is maximal; at instants t_A, t_C, and t_E the amplitude is zero. This phenomenon, called **beating**, can be heard clearly with two tuning forks that oscillate at slightly different frequencies. Each maximum in the amplitude (at $0, t_B, t_D, \ldots$) corresponds to what sounds like a *beat*. When both tuning forks simultaneously produce sound, you hear a tone whose intensity periodically fades in and out.

This phenomenon is similar to the moiré pattern in **Figure 17.28**, produced by two striped bands that have slightly different line spacings. At some places the lines of the two bands overlap, producing bright regions (labeled P, Q, R, S), while at others the lines fall precisely in between one another, producing dark regions.

Figure 17.28 Moiré pattern showing beating between two patterns with slightly different line spacings.

17.14 The lines in band A in Figure 17.28 are more closely spaced than those in band B. (*a*) How many more lines does band A have between points P and S? (*b*) Describe what happens to the pattern if band B is displaced downward by one-half the spacing between its lines.

EXAMPLE 17.6 Lapping rounds

You and a friend are running laps around a race track. You begin together, and both of you run at constant speed, but you run faster than she does. Because the time interval T_y you take to complete one lap is smaller than the time interval T_f your friend takes to complete one lap, you finish the first lap ahead of her. Each lap you get farther ahead, until eventually you overtake your friend after she has run n laps (Figure 17.29). What is the frequency $f_{overtake}$ at which you overtake her? Express your answer in two ways: first in terms of T_y and T_f and then in terms of the frequencies f_y and f_f at which each of you completes one lap.

1 GETTING STARTED Regardless of how many laps my friend has run, when I overtake her I have completed exactly one lap more than she has. So, if she has completed n laps, I have completed $(n + 1)$ laps. At that instant, the process starts over, and I overtake her again when I have completed another $(n + 1)$ laps. Note that n need not be a whole number of laps; for example, if I first overtake my friend after 8.2 laps (she having completed 7.2 laps) and we both keep running at constant speed, the next overtaking occurs when I have completed 16.4 laps.

2 DEVISE PLAN The frequency at which I overtake my friend is the reciprocal of the time interval it takes me to overtake her. I know that she completes n laps, each of duration T_f, at the same instant I complete $(n + 1)$ laps, each lap of duration T_y. From this information I can determine n and the instant at which I first overtake her. The frequency at which I overtake her is the reciprocal of the period between that instant and the beginning of the race.

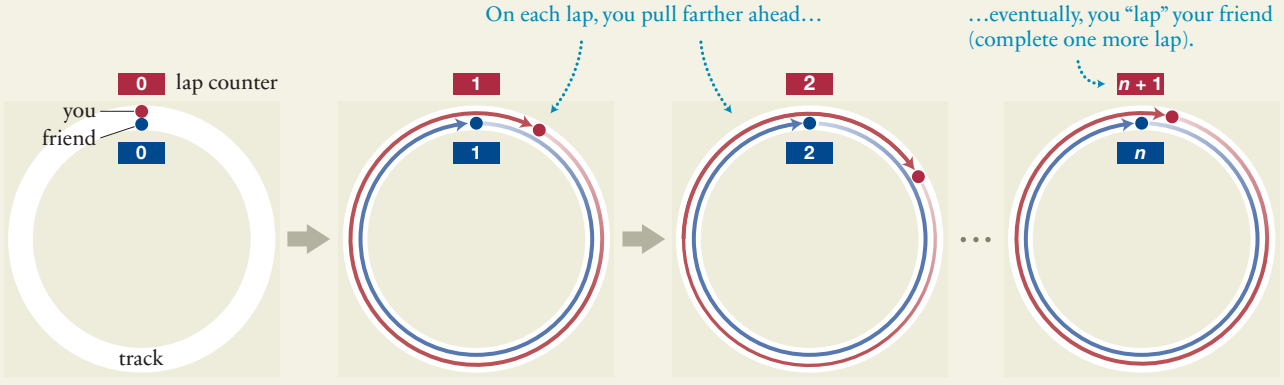
3 EXECUTE PLAN At the instant I first overtake my friend, I have run for a time interval $(n + 1)T_y$ and she has run for a time interval nT_f. Because we started at the same instant, I have $nT_f = (n + 1)T_y$, giving me

$$n = \frac{T_y}{T_f - T_y}.$$

The instant at which the first overtake occurs is

$$t_{overtake} = nT_f = \frac{T_y T_f}{T_f - T_y},$$

and so the overtaking frequency is



$$f_{overtake} = \frac{1}{t_{overtake}} = \frac{T_f - T_y}{T_y T_f}. \checkmark$$

To express $f_{overtake}$ in terms of f_y and f_f, I use $f_y = 1/T_y$ and $f_f = 1/T_f$ and write

$$f_{overtake} = \frac{T_f - T_y}{T_y T_f} = \frac{1}{T_y} - \frac{1}{T_f} = f_y - f_f. \checkmark$$

4 EVALUATE RESULT Because $f_y > f_f$, the overtaking frequency is positive, as I expect. My result shows that if both of us run laps at the same frequency, $f_y = f_f$, the overtaking frequency is zero. That makes sense because, running at the same rate, we never overtake each other. Another limiting case is when my friend remains at rest. In that case f_f is zero and so the overtaking frequency is equal to the frequency at which I complete laps. My answer makes sense in the limiting cases, which gives me confidence it is correct.

Figure 17.29 Example 17.6.

Suppose that in Example 17.6 your friend had run faster than you. In that case we could apply the same reasoning, but the indices y and f would now have been switched and the end result would have been $f_{overtake} = f_f - f_y$. (Because $f_y < f_f$, the overtaking frequency is again positive.) The general result, in case we do not know which frequency is greater, is thus $f_{overtake} = |f_f - f_y|$.

We can apply the reasoning I used in solving this example to the beating of two waves: The phases of the two waves catch up each time the wave of higher frequency has completed one more full oscillation than the other wave. If the wave frequencies are f_1 and f_2, then the frequency at which the beats occur, called the **beat frequency,** must, in analogy to the result from Example 17.6, be

$$f_{\text{beat}} \equiv |f_1 - f_2|. \tag{17.8}$$

We can reach the same conclusion by adding the expressions for the displacements of the two waves given by Eqs. 17.6 and 17.7:

$$D_x = D_{1x} + D_{2x} = A(\sin 2\pi f_1 t + \sin 2\pi f_2 t). \tag{17.9}$$

The sum of two sine functions can be written using the identity

$$\sin\alpha + \sin\beta = 2\cos\tfrac{1}{2}(\alpha - \beta)\sin\tfrac{1}{2}(\alpha + \beta), \tag{17.10}$$

so

$$D_x = 2A\cos\tfrac{1}{2}[2\pi(f_1 - f_2)t]\sin\tfrac{1}{2}[2\pi(f_1 + f_2)t]. \tag{17.11}$$

Because $\cos\theta = \cos(-\theta)$, we can replace the term $(f_1 - f_2)$ in Eq. 17.11 by $(f_2 - f_1)$ when $f_1 < f_2$. If we write $\Delta f = |f_1 - f_2|$ for the absolute value of the difference in frequency and $f_{\text{av}} = \frac{1}{2}(f_1 + f_2)$ for the average frequency, we can rewrite Eq. 17.11 in the form

$$D_x = 2A\cos\left[2\pi\left(\tfrac{1}{2}\Delta f\right)t\right]\sin(2\pi f_{\text{av}}t). \tag{17.12}$$

This expression tells us that the resulting wave has a frequency that is the average of the two original frequencies and an amplitude that varies with time. The factor $2A\cos\left[2\pi(\frac{1}{2}\Delta f)t\right]$ corresponds to the dashed curve in Figure 17.27*b*. It represents the slow variation in the amplitude of the combined wave.

The frequency of the amplitude variation is $\frac{1}{2}\Delta f = \frac{1}{2}|f_1 - f_2|$. However, *two* beats occur in each cycle of this amplitude variation. In Figure 17.27, one cycle in the amplitude variation lasts from $t = 0$ to $t = t_{\text{D}}$ (look at the dashed curve in Figure 17.27*b* and notice how it returns to its starting value at t_{D}). During this period *two* beats occur, one at t_{A} and the other at t_{C}. The beat frequency is therefore *twice* the amplitude variation frequency $\frac{1}{2}|f_1 - f_2|$, and so we see that the beat frequency is indeed equal to the absolute value of the difference in the frequencies of the two waves: $f_{\text{beat}} = |f_1 - f_2|$.

EXERCISE 17.7 Tuning a piano

Your middle-C tuning fork oscillates at 261.6 Hz. When you play the middle-C key on your piano together with the tuning fork, you hear 15 beats in 10 s. What are the possible frequencies emitted by this key?

SOLUTION The beat frequency—the number of beats per second—is equal to the difference between the two frequencies (Eq. 17.8). I am given the frequency of the tuning fork, $f_{\text{t}} = 261.6$ Hz, and the beat frequency, $f_{\text{B}} = (15\text{ beats})/(10\text{ s}) = 1.5$ Hz. I do not know, however, whether the frequency f_{p} of the struck middle-C piano key is higher or lower than that of the tuning fork.

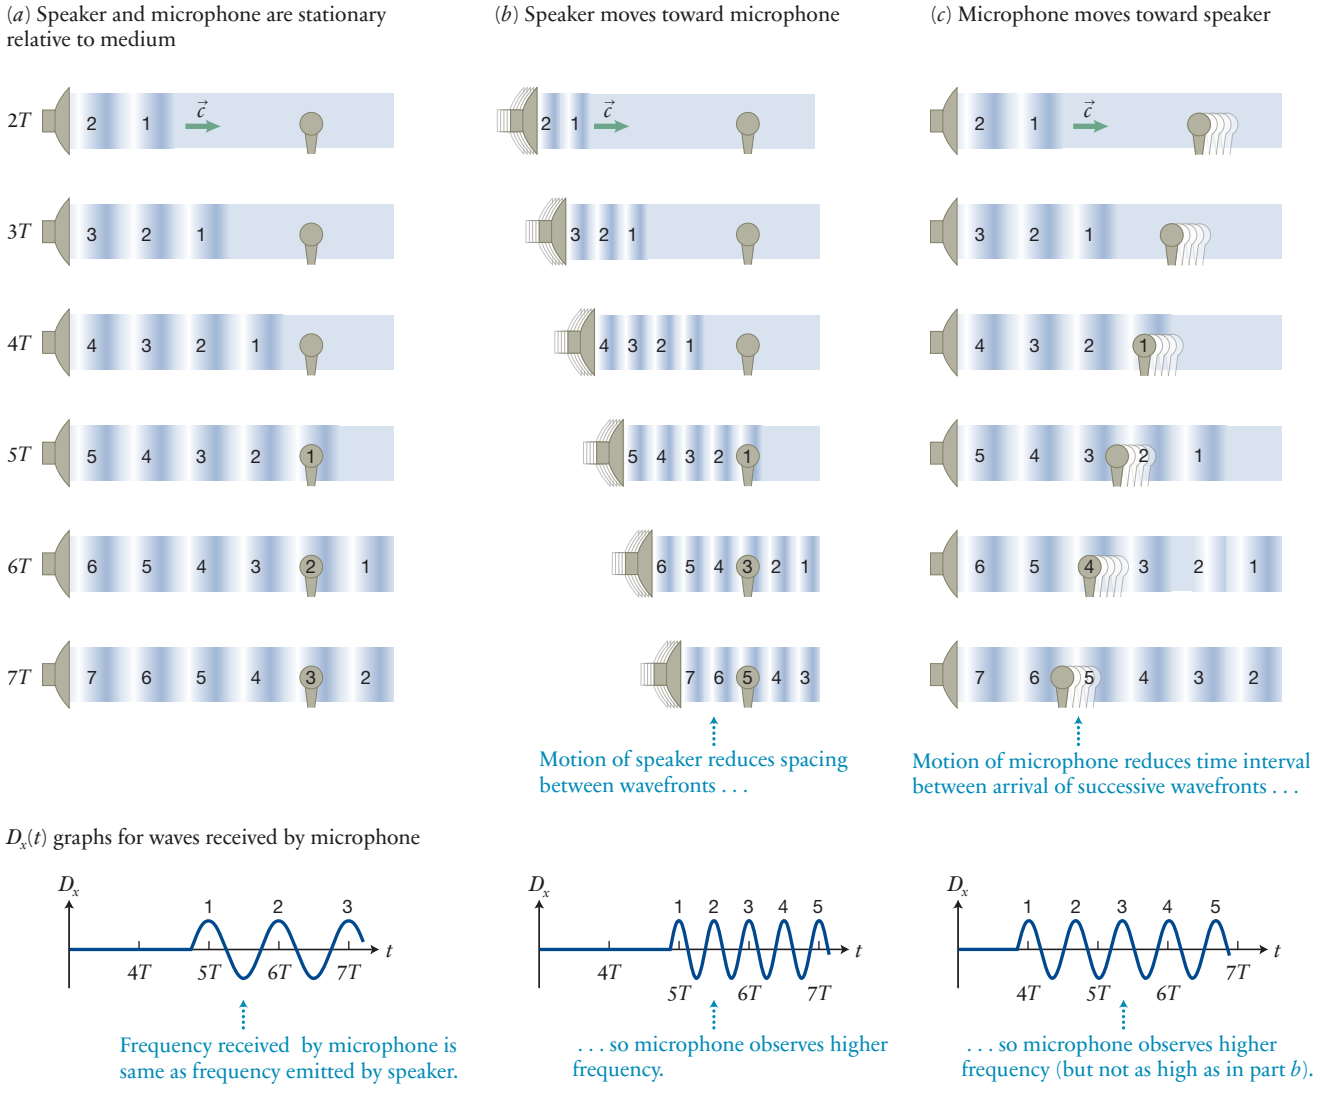
If it is higher, I have $f_{\text{B}} = f_{\text{p}} - f_{\text{t}}$.

If it is lower, then $f_{\text{B}} = f_{\text{t}} - f_{\text{p}}$.

So

$$f_{\text{p}} = f_{\text{t}} \pm f_{\text{B}} = 261.6\text{ Hz} \pm 1.5\text{ Hz}$$

and the possible frequencies emitted by the out-of-tune middle-C key are 260.1 Hz and 263.1 Hz. ✔



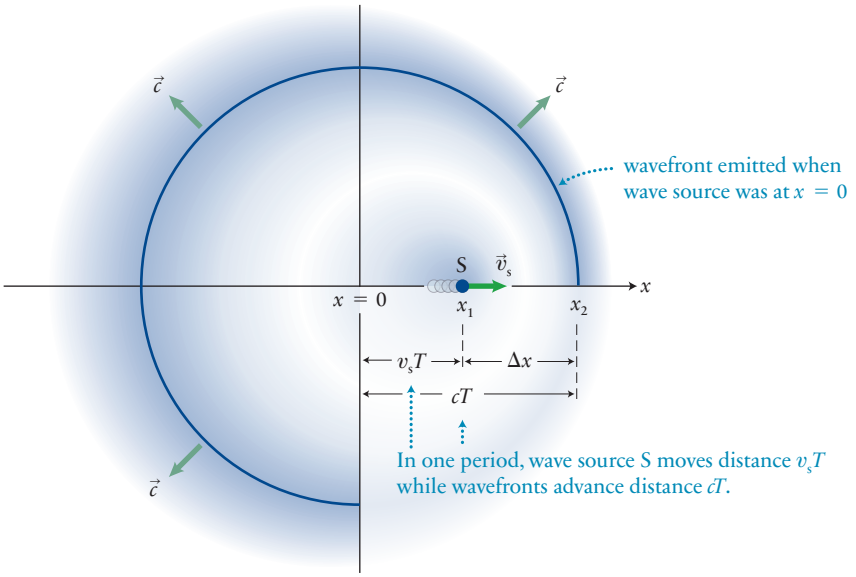
17.15 Do two sound waves of slightly different frequencies and *different* amplitudes cause beats?

17.7 Doppler effect

When an observer and a source of waves move relative to each other, the observed wave frequency is not the same as the frequency emitted by the source. When observer and source move toward each other, the observed frequency is higher than the emitted frequency; when they move away from each other, the observed frequency is lower than the emitted frequency. This phenomenon is called the **Doppler effect.**

Let us determine how the observed frequency deviates from the actual frequency of the source, depending on the speeds of source and observer relative to the medium through which the waves propagate. In **Figure 17.30*a***, a loudspeaker that is stationary relative to a medium emits a sound wave that is detected by a microphone that is also stationary relative to the medium. The period of the wave is T, and so one wavefront of a given phase (a crest, for example) leaves the loudspeaker each period T. Once the first wavefront reaches the microphone, it thereafter receives one wavefront each period T, and so the frequency received by the microphone is identical

Figure 17.30 The Doppler effect demonstrated by a speaker and a microphone. Notice that motion of the speaker toward the microphone and motion of the microphone toward the speaker both cause the frequency received by the microphone to increase—but not by the same amount. The two situations are not symmetrical because motion of the speaker shortens the wavelength of the propagating sound, whereas motion of the microphone does not.



QUANTITATIVE TOOLS

to the frequency emitted by the loudspeaker. The graph at the bottom of Figure 17.30*a* shows the longitudinal medium displacement caused by the sound wave at the location of the microphone as a function of time.

Figure 17.30*b* shows what happens when the loudspeaker emits the same sound wave while moving at constant velocity toward the microphone. Because of the motion of the loudspeaker, each wavefront is emitted closer to the previous wavefront than if the loudspeaker were stationary. Because the speed of the wavefronts, which is determined by the properties of the medium (air in this case), does not depend on the motion of the loudspeaker, the more closely spaced wavefronts generated by the moving loudspeaker reach the microphone at shorter time intervals than those of the stationary loudspeaker. For example, between $t = 5T$ and $t = 7T$ only two cycles between wavefronts 1 and 3 pass the microphone when the source is stationary (Figure 17.30*a*), but four wave cycles between wavefronts 1 and 5 pass the microphone when the source is moving (Figure 17.30*b*). So the frequency detected by the microphone for the moving source is $(4 \text{ cycles})/(7T - 5T) = (4 \text{ cycles})/(2T)$, or two cycles per period instead of one cycle per period; in other words, the frequency heard by the microphone is twice the frequency emitted by the moving loudspeaker.

To obtain a general expression for the frequency received from a source S moving at speed v_s, let us evaluate the spacing between wavefronts. **Figure 17.31** shows the motion of the source during one period. (For now we consider the case when the source moves more slowly than the wave, $v_s < c$; in the next section we consider what happens when $v_s > c$.) The labeled wavefront was emitted when the source was at $x = 0$. During the time interval T, the source has moved from $x = 0$ to $x_1 = +v_sT$, at which point it emits the next wavefront. The first wavefront meanwhile has moved from $x = 0$ out to a radius $x_2 = cT$. To an observer somewhere to the right of Figure 17.31, the distance between the two wavefronts is decreased: $\Delta x = x_2 - x_1 = cT - v_sT = (c - v_s)T$. The period T_o of the wave that reaches this observer is equal to the time interval between the arrival of two

Figure 17.31 Doppler effect for a source moving toward an observer. The observer is off to the right and not shown.

successive wavefronts and is thus equal to the distance Δx divided by the speed of the waves:

$$T_o = \frac{\Delta x}{c} = \frac{c - v_s}{c} T \quad \text{(source approaching observer, } v_s < c\text{)}. \quad (17.13)$$

The frequency of the approaching source heard by the observer is thus

$$f_o \equiv \frac{1}{T_o} = \frac{c}{c - v_s} \frac{1}{T}$$

$$= \frac{c}{c - v_s} f_s \quad \text{(source approaching observer, } v_s < c\text{)}, \quad (17.14)$$

where f_s is the frequency emitted by the source. Note that because v_s is positive, $[c/(c - v_s)] > 1$, so the observed frequency is higher than the emitted frequency, as expected.

Now let us consider an observer on the opposite side of Figure 17.31. To this observer, the source is receding and the distance between wavefronts is increased: $\Delta x = (c + v_s)T$. Consequently the minus sign in front of v_s becomes a plus in Eqs. 17.13 and 17.14:

$$f_o \equiv \frac{1}{T_o} = \frac{c}{c + v_s T} \frac{1}{} = \frac{c}{c + v_s} f_s \quad \begin{matrix}\text{(source receding} \\ \text{from observer)}\end{matrix} \quad (17.15)$$

and the observed frequency is now lower than the emitted frequency, as we expect. Contrary to the situation described by Eq. 17.14, there is no limit on the speed of the source in this case.

EXAMPLE 17.8 Moving train

Standing alongside a straight section of railroad track as a train passes, you record the sound of the train's horn. By analyzing the recording, you determine that the frequency of the sound was 483 Hz as the train approached and 405 Hz after it passed. At what speed was the train moving? Use 343 m/s for the speed of sound in air. Assume that the train starts out coming almost straight at you and ends up moving almost directly away from you.

❶ **GETTING STARTED** I am given two frequencies for one sound source, so I know this problem is about a Doppler shift. I assume the train moved at constant velocity and denote its unknown speed by v. Because the horn—that is, the sound source—was on the train, v is also the speed at which the horn moved, and I know I can use some Doppler equation to calculate this speed. The wave speed is given as $c = 343$ m/s.

❷ **DEVISE PLAN** As the train approaches, the frequency I hear is given by Eq. 17.14. After it passes, the frequency is given by Eq. 17.15. This gives me two equations with two unknowns, f_s (the frequency of the source) and v, so I can solve for v.

❸ **EXECUTE PLAN** As the train approaches, the observed frequency is given by Eq. 17.14:

$$f_1 = \frac{c}{c - v_s} f_s = \frac{c}{c - v} f_s. \quad (1)$$

After the train passes, the observed frequency is given by Eq. 17.15:

$$f_2 = \frac{c}{c + v_s} f_s = \frac{c}{c + v} f_s. \quad (2)$$

Solving Eq. 2 for f_s and substituting the result into Eq. 1, I obtain

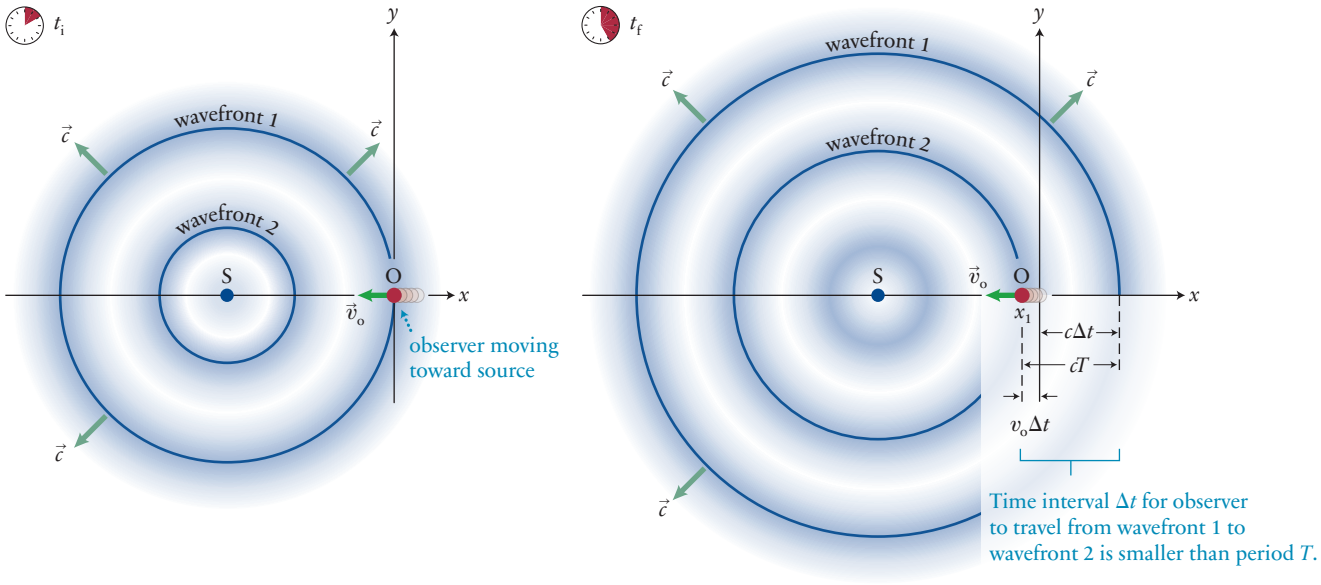
$$f_1 = \frac{c}{c - v}\left(\frac{c + v}{c} f_2\right) = \frac{c + v}{c - v} f_2.$$

Multiplying both sides by $(c - v)$ gives

$$f_1(c - v) = f_2(c + v)$$

$$v(f_1 + f_2) = c(f_1 - f_2).$$

Therefore



$$v = \frac{f_1 - f_2}{f_1 + f_2} c = \frac{483 \text{ Hz} - 405 \text{ Hz}}{483 \text{ Hz} + 405 \text{ Hz}} (343 \text{ m/s}) = 30 \text{ m/s}. \checkmark$$

❹ **EVALUATE RESULT** This is about 110 km/h or 70 mi/h, not unreasonable for a train.

17.16 In Example 17.8, what is the frequency of the sound the horn makes?

QUANTITATIVE TOOLS

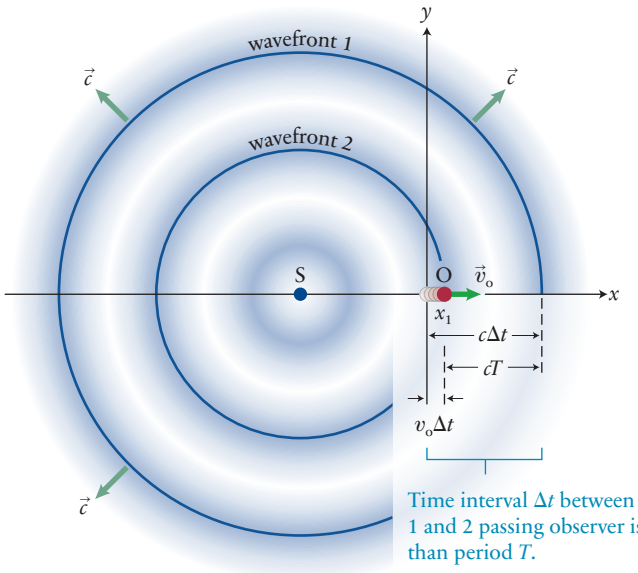
Figure 17.32 Doppler effect for an observer moving toward the source.

Applications of the Doppler effect range from measuring the speed of blood flow by reflecting a beam of ultrasound waves from red blood cells to measuring the speed of water molecules in a storm using radar. The latter uses electromagnetic waves (see Chapter 30), which, like sound waves, exhibit a Doppler effect.

Any movement by an observer also affects the frequency of sound waves. When an observer is moving toward a stationary source, as in Figure 17.30*c*, the observer travels through the oncoming wavefronts and consequently observes more of them per unit time than if she or he were at rest. Between $t = 4T$ and $t = 6T$ in Figure 17.30*c*, for example, three wave cycles pass the microphone, and so the observed frequency is $(3 \text{ cycles})/(6T - 4T) = (1.5 \text{ cycles})/T = 1.5f_s$. Because the microphone moves toward the loudspeaker, each subsequent wavefront has to travel a shorter distance to reach the microphone, and so the observed frequency is higher than the emitted frequency.

Figure 17.32 allows us to relate the increase in frequency to the speed v_o of an observer O who is moving toward the source S. At t_i the observer is at $x = 0$ just as wavefront 1 passes her. At t_f the observer meets wavefront 2 at position x_1, and so she detects one complete cycle (that is, two wavefronts) in $\Delta t = t_f - t_i$. During that time interval, wavefronts 1 and 2 have moved a distance $c\Delta t$. From the figure we see that the sum of the distances traveled by the wavefront and the moving observer is equal to the distance between wavefronts, so $c\Delta t + v_o\Delta t = cT$. The time interval at which successive wavefronts reach the observer is thus

$$\Delta t = \frac{cT}{c + v_o}. \tag{17.16}$$



The frequency she observes is

$$f_o \equiv \frac{1}{\Delta t} = \frac{c + v_o}{c}\frac{1}{T} = \frac{c + v_o}{c}f_s \quad \text{(observer approaching source)}. \tag{17.17}$$

Because $(c + v_o) > c$, the observed frequency is higher, as expected.

Let us now consider an observer who moves away from the source at a speed that is smaller than the speed of sound, $v_o < c$. (If the observer were

Figure 17.33 Doppler effect for an observer moving away from the source at a speed $v_o < c$.

to move away at a greater speed, the sound would never catch up with the observer.) Again, we take the observer to be at $x = 0$ just as wavefront 1 passes him at t_i. **Figure 17.33** shows the situation at t_f when wavefront 2 catches up with the observer at position x_1. In the time interval $\Delta t = t_f - t_i$ the observer hears a complete cycle. During that time interval, wavefronts 1 and 2 have moved a distance $c\Delta t$. From the figure we see that the distance between wavefronts is equal to the difference between the distances traveled by the wavefront and the moving observer, so $c\Delta t - v_o\Delta t = cT$. The time interval at which successive wavefronts reach the observer is thus

$$\Delta t = \frac{cT}{c - v_o}. \tag{17.18}$$

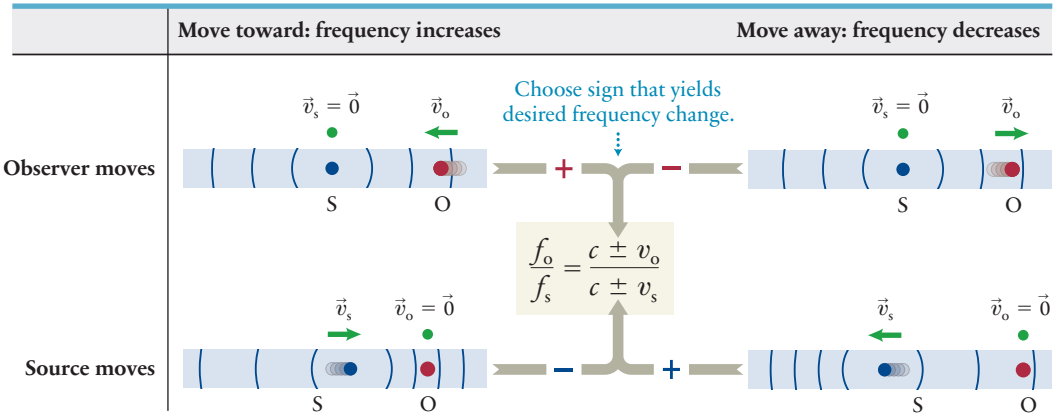
Consequently the plus sign in front of v_o in Eq. 17.17 becomes a minus, and the observed frequency is thus

$$f_o \equiv \frac{1}{\Delta t} = \frac{c - v_o}{c}\frac{1}{T}$$

$$= \frac{c - v_o}{c} f_s \quad \text{(observer receding from source, } v_o < c\text{)}. \tag{17.19}$$

Because $(c - v_o) < c$, the observed frequency is lower, as expected.

If both source and observer are moving, the two effects multiply—the moving source causes wavefronts to be spaced differently, giving rise to the observed frequency given in Eqs. 17.14 and 17.15, and the moving observer detects the wavefronts at a different rate, as indicated by Eqs. 17.17 and 17.19. The two effects can be combined in one equation:



$$f_o = \left(\frac{c \pm v_o}{c}\right)\left(\frac{c}{c \pm v_s}\right) f_s = \frac{c \pm v_o}{c \pm v_s} f_s, \tag{17.20}$$

which can be written in the more symmetrical form

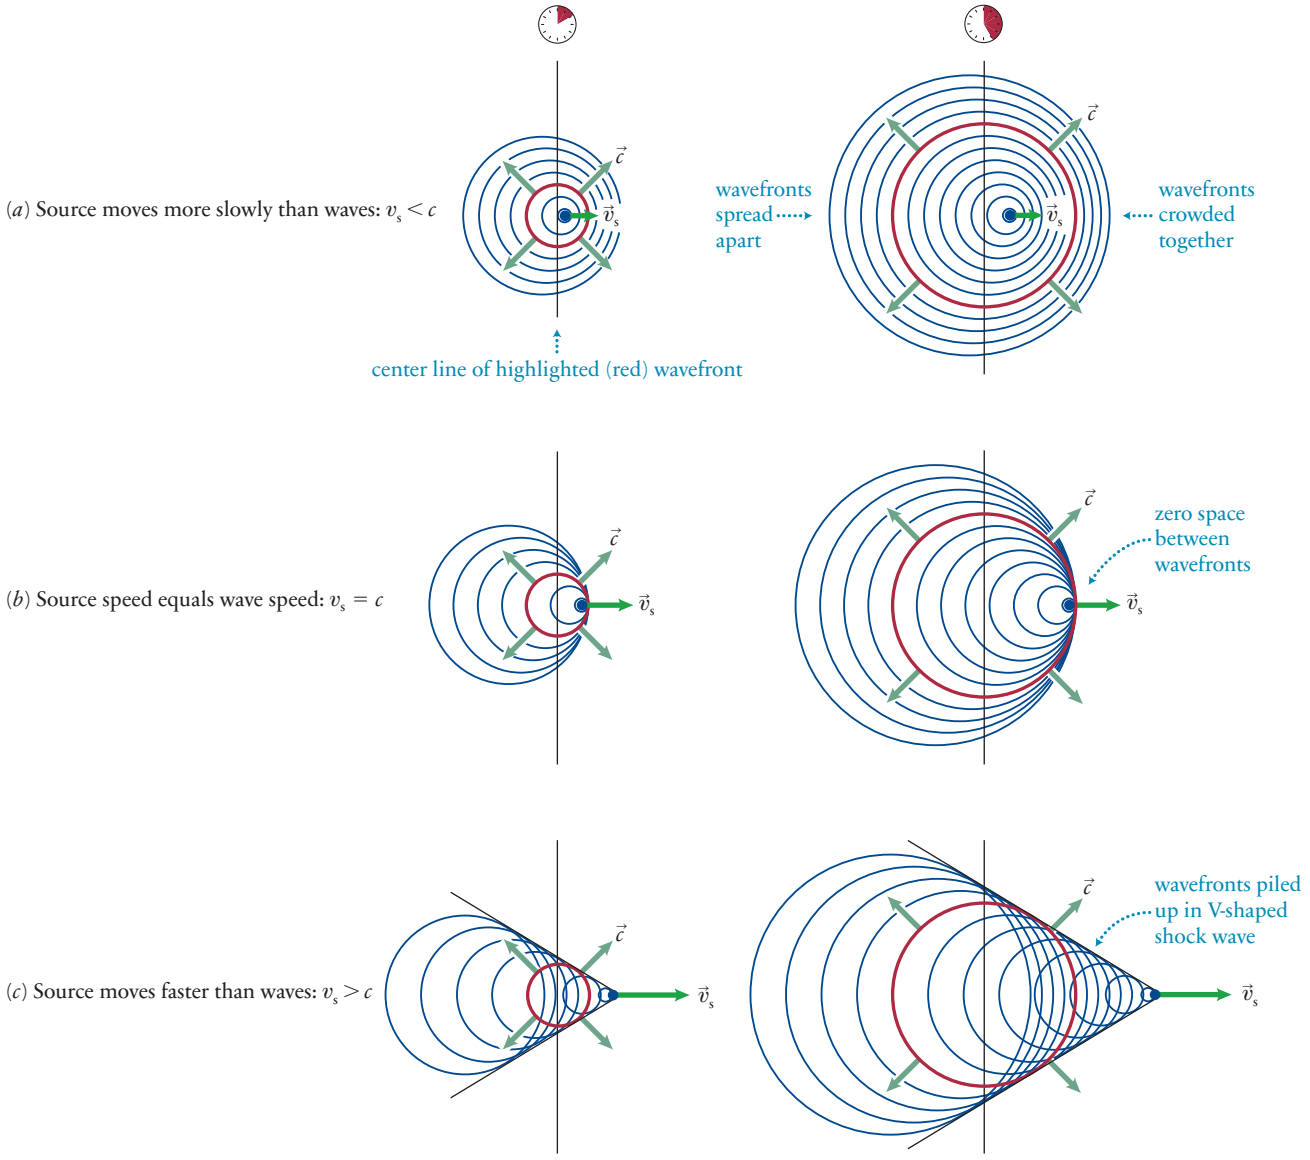
$$\frac{f_o}{f_s} = \frac{c \pm v_o}{c \pm v_s}. \tag{17.21}$$

QUANTITATIVE TOOLS

Figure 17.34 To use the general Doppler equation, the key thing you need to remember is that the observed frequency increases when source and observer move toward each other and decreases when they move apart.

Keep in mind that in Eqs. 17.20 and 17.21 the speeds of the observer and source are measured relative to the medium. Also, these expressions are subject to the same conditions as in Eqs. 17.14 and 17.19: when the source is approaching the observer $v_s < c$, and when the observer is receding from the source $v_o < c$.

Rather than trying to remember the correct choices for the signs in front of v_o and v_s in this expression, it is easiest to remember that the observed frequency increases when source and observer move toward each other and decreases when they move apart. For example, the top left of **Figure 17.34** shows an observer approaching a stationary source ($v_s = 0$). The observed frequency is higher and therefore you select the plus sign in front of v_o in Eq. 17.21. When the observer moves away from the stationary source (top right of Figure 17.34), the observed frequency is lower and so you select the minus sign in front of v_o in Eq. 17.21. The bottom left of Figure 17.34 shows a source moving toward an observer who is at rest relative to the medium ($v_o = 0$). The observed frequency is higher, and therefore you select the minus sign in front of v_s in Eq. 17.21. In the bottom right of Figure 17.34 the source moves away from the stationary observer; the observed frequency is now lower and you select the plus sign in front of v_s in Eq. 17.21.



17.17 (*a*) Suppose an observer moves at half the speed of sound toward a stationary source of sound waves. By what factor does the observed frequency differ from the emitted frequency? (*b*) By what factor does the observed frequency differ if, instead of the observer moving, the source moves toward the stationary observer at half the speed of sound? (*c*) Why is there a difference?

17.8 Shock waves

The observed frequency f_o given by Eq. 17.14 becomes infinite when the speed of the source approaches the speed of sound. As can be seen in **Figure 17.35a** on the next page, the wavefronts in front of a source moving at a speed $v_s < c$ crowd together. When a source moves at the speed of sound, *all* wavefronts in the forward direction travel with the source, and so the spacing between them is reduced to zero. A source traveling *faster* than the speed of sound overtakes the wavefronts it has generated. The wavefronts then pile up to form a wavefront that is wedge-shaped in two dimensions and cone-shaped in three dimensions.

Figure 17.35 The formation of a shock wave as the speed of a source reaches and then exceeds the speed of sound in the medium.

This wedge- or cone-shaped wavefront, called a **shock wave,** occurs whenever the speed of any object moving through a medium is higher than the the speed of sound in the medium, *even if the object emits no sound*. A bullet moving faster than the speed of sound in air, for example, creates a shock wave (**Figure 17.36**) even though the bullet emits no sound. Air piles up in front of the speeding bullet like snow in front of a snowplow, and this piling up of the air creates a compression in front of the bullet. This compression then moves outward at the speed of sound, just as the compression in Figure 17.8 does, and forms the wedge- or cone-shaped shock wave, which trails the bullet like a water wake trailing behind a ship.

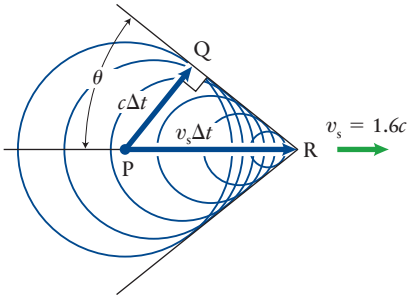
When a shock wave sweeps over your ears, the piled-up wavefronts sound like an explosion, just as a small boat gets jolted when struck by the wake of a passing speedboat. For a small object, such as a bullet, the shock wave produces a sharp, cracking sound. The crack of a long whip is a shock wave produced when the tip of the whip is made to move faster than the speed of sound. For large objects, the shock wave sounds like a thunderous boom called a *sonic boom*. The sonic boom of a supersonic

Figure 17.36 Shock wave produced by a bullet traveling through air.

airplane (a plane with a speed higher than the speed of sound) reaches the pain threshold of the human ear even at a distance of 20 km. For this reason, supersonic transport is not feasible over land. The cone-shaped shock wave dragging behind the plane would break windows on the ground even at its maximum flying altitude of about 20 km.

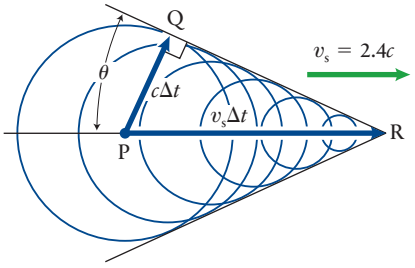
17.18 Does an observer moving at twice the speed of sound toward a stationary sound source detect a sonic boom?

As can be seen in **Figure 17.37**, the higher the source speed, the narrower the wedge or cone formed by the shock wave. From the right-angle triangle PQR, we see that the angle the shock wave makes with the direction of motion is given by



$$\sin\theta = \frac{c}{v_s} \quad (v_s > c). \tag{17.22}$$

For motion through air, the ratio v_s/c is called the *Mach number*. A plane flying at Mach 1.8, for example, has a speed of 1.8 times the speed of sound.



17.19 Estimate the speed of the bullet in Figure 17.36.

Figure 17.37 The shape of a shock wave depends on the speed of the source. The higher the source speed, the smaller the angle θ and so the sharper the cone or wedge.

(*a*) Lower source speed v_s: wider angle θ

(*b*) Higher source speed v_s: narrower angle θ

Chapter Summary

Characteristics of waves in two and three dimensions (Sections 17.1, 17.4, 17.5)

Concepts A **wavefront** is a curve or surface in a medium on which all points of a propagating wave have the same phase.

A **planar wavefront** is a flat wavefront that is either a plane or a straight line.

A **surface wave** is a wave that propagates in two dimensions and has circular wavefronts. A **spherical wave** is a wave that propagates in three dimensions and has spherical wavefronts.

According to **Huygens' principle,** any wavefront may be regarded as a collection of many closely spaced, coherent point sources.

Diffraction is the spreading out of waves either around an obstacle or beyond the edges of an aperture. The effect is more pronounced when the size of the obstacle or aperture is about equal to or smaller than the wavelength of the wave.

Quantitative Tools If no energy is dissipated, the amplitude A of a wave originating at a point source decreases with increasing distance r from the source as

$$A \propto \frac{1}{\sqrt{r}} \quad \text{(surface wave)}$$

or

$$A \propto \frac{1}{r} \quad \text{(spherical wave)}.$$

The **intensity** I (in W/m^2) of a spherical wave that delivers power P to an area A oriented normal to the direction of propagation is

$$I \equiv \frac{P}{A}. \tag{17.1}$$

If a point source emits waves uniformly in all directions at a power P_s and no energy is dissipated, the intensity a distance r from the source is

$$I = \frac{P_s}{4\pi r^2}. \tag{17.2}$$

The intensity I_{surf} (in W/m) of a surface wave that delivers power P to a length L oriented normal to the direction of propagation is

$$I_{surf} \equiv \frac{P}{L}. \tag{17.3}$$

Sound waves (Sections 17.2, 17.5)

Concepts **Sound** is a longitudinal *compressional* wave propagating through a solid, liquid, or gas. The wave consists of an alternating series of *compressions* (where the molecules of the medium are the molecules are spaced far apart). The frequency range of *audible* sound is 20 Hz to 20 kHz.

The speed of sound c depends on the density and elastic properties of the medium. In dry air at 20 °C, the speed of sound is 343 m/s.

Quantitative Tools The *threshold of hearing* I_{th} is the minimum sound intensity audible to humans. For a 1.0-kHz sound,

$$I_{th} \approx 10^{-12}\ \text{W/m}^2.$$

For a sound of intensity I, the **intensity level** β in decibels is

$$\beta \equiv (10\ \text{dB}) \log\left(\frac{I}{I_{th}}\right). \tag{17.5}$$

Interference effects (Sections 17.3, 17.6)

Concepts Two or more sources emitting waves that have a constant phase difference are called **coherent sources.** If that constant phase difference is zero, the sources are said to be *in phase*.

Along **nodal lines,** waves cancel each other, and so the displacement of the medium is zero. Along **antinodal lines,** the displacement of the medium is a maximum.

The superposition of two waves of equal amplitude but slightly different frequencies results in a wave of oscillating amplitude. This effect is called **beating.**

Quantitative Tools When two waves of frequencies f_1 and f_2 result in **beating,** the **beat frequency** is

$$f_{beat} \equiv |f_1 - f_2|, \tag{17.8}$$

and the displacement D_x of the particles of the medium is

$$D_x = 2A \cos\left[2\pi\left(\tfrac{1}{2}\Delta f\right)t\right] \sin(2\pi f_{av} t), \tag{17.12}$$

where $\Delta f = |f_1 - f_2|$ and $f_{av} = \frac{1}{2}(f_1 + f_2)$.

The effects of motion on sound (Sections 17.7, 17.8)

Concepts The **Doppler effect** is a change in the observed wave frequency caused by the relative motion of a wave source and an observer.

A **shock wave** is a conical (wedge-shaped) disturbance caused by the piling up of wavefronts from a source moving at a speed greater than or equal to the wave speed in the medium.

Quantitative Tools If a source moving with speed v_s relative to the medium produces sound of frequency f_s, the **Doppler effect** causes an observer moving with speed v_o relative to the medium to observe the sound as having a frequency f_o given by

$$\frac{f_o}{f_s} = \frac{c \pm v_o}{c \pm v_s}. \tag{17.21}$$

The $\pm$ signs are chosen so that $f_o > f_s$ when the source and observer approach each other and $f_o < f_s$ when they move apart.

As a shock wave propagates at speed c, the angle θ it makes with the direction in which the source moves is given by

$$\sin\theta = \frac{c}{v_s} \quad (v_s > c), \tag{17.22}$$

where v_s is the speed of the source relative to the medium. The ratio v_s/c is the *Mach number*.

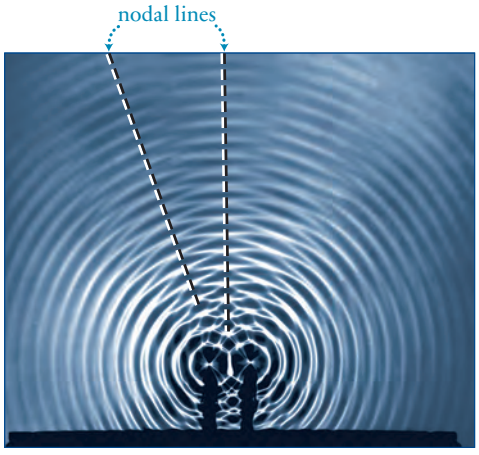
Questions and Problems

For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

17.1 Wavefronts

1. A neat trick for determining whether or not a train is coming is to press your ear to a railroad track. Why is this much more effective than listening for the train's sound carried by air? •
2. Suppose a material is stiffer in the x direction than in the y direction. Draw the wavefronts emanating from a point source embedded in this material and radiating in these two directions. ••
3. Your professor delivers a lecture. Does the amplitude of sound waves in the classroom decrease like $1/r$, where r is the distance from the professor to you? ••
4. A cannon is fired some distance away from you, and you wish to estimate that distance by determining how much sound energy enters your ear. (*a*) How does the sound energy depend on the distance between the cannon and your ear? (*b*) Now you use the dependence you described in part *a* to judge how far away the cannon is. First you estimate the distance assuming that none of the energy in the sound waves is dissipated (into, say, random motion of the molecules that make up the air), and then you repeat the estimate assuming that some of the sound energy is dissipated. Is your first estimate higher or lower than your second estimate? ••
5. One form of whispering gallery is an elliptical room where a person standing at one focus can hear quite clearly someone speaking very quietly at the other focus. Use your knowledge of ellipses to explain how this works. •••



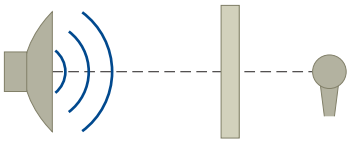
17.2 Sound

6. Describe the pressure of particles at points in a sound wave where the gas is (*a*) compressed at maximum, and (*b*) minimally compressed. •
7. Because the audible range in bats is about 10 kHz to more than 120 kHz, these animals are oblivious to normal human conversation, which is at frequencies of typically several hundred hertz. If you shout, though, you may in fact startle a bat. Why? ••
8. Standing waves (see Section 16.6) can form when sound traveling inside a closed tube reflects from each end. These waves have a node at each (immovable) end. Standing waves can also form in a tube with open ends. In this case, the waves have antinodes rather than nodes at the ends. Use the requirement of antinodes at the tube ends to determine the relationship between wavelength and tube length for the fundamental and the next two harmonics for standing waves in a tube that is open at both ends. ••
9. Sketch the three lowest-frequency harmonic wave function patterns for standing waves in the air in a tube that is open at both ends, (*a*) representing *displacement* nodes and antinodes and (*b*) representing *pressure* nodes and antinodes. Your sketches should be similar to the pattern in Figure 17.9*c*. ••

17.3 Interference

10. If the frequency of the sources in Figure P17.10 is increased, do the nodal lines get farther apart, get closer together, or remain unchanged? •

Figure P17.10



11. What happens to the nodal lines in Figure P17.10 if the phase of one of the sources is shifted by 180°? •
12. Are stable nodal lines formed by two sources that emit waves that have the same amplitude but different frequencies? ••
13. Speaker manufacturers often discourage placing speakers in front of curtains or drapes because having an uncovered wall behind the speakers often alleviates dead listening spots in the room. Explain why a wall helps. ••
14. How many nodal lines are created by two point sources that are separated by a distance equal to 2.5λ? ••
15. Vibration in a car can create concentric ripples on the surface of a cup of coffee sitting on the dashboard. What kind of waves are the ripples, and why are they circular? ••
16. Two sound sources emitting at the same wavelength λ are placed a distance d_s apart and a perpendicular distance d_m away from a row of microphones. Show that the distances Δx between those microphones that experience maximum variations in loudness are given by $\Delta x = d_m\lambda/d_s$ in the limit $d_m \gg d_s$. •••
17. Two coherent sources of water waves of frequency f and speed c are a distance d apart and equal in amplitude. Nodal lines exist where the path lengths from the sources differ by an odd number of half wavelengths (where the contributions are 180° out of phase). (*a*) Far from the sources (where we can treat wavefronts from each source as parallel), what are the angles between the nodal lines in the water and the perpendicular to the line joining the sources? (*b*) If you introduce a phase difference ϕ between the sources, how do the directions of the nodal lines shift? •••
18. Three equally spaced, coherent sources of water waves of frequency f are in a line with a distance d separating each adjacent pair. All three sources have the same amplitude. Nodal lines exist where the separate waves from the three sources cancel each other. Far from the sources, where we can treat the wavefronts from each source as parallel, what are the angles between the nodal lines in the water and the perpendicular to the line joining the sources? •••

17.4 Diffraction

19. When your mother shouted at you to come inside when you were a kid, how could you hear her when you were around a corner? •
20. The speaker in Figure P17.20 faces a narrow obstructing panel made of sound-absorbing material. A microphone is placed dead center behind the panel. Does the microphone pick up sound or not? ••

Figure P17.20

21. Two very small, coherent sources are separated by $d = 2\lambda$, where λ is the wavelength of the circular waves created by each source. (*a*) Use Huygens' principle to construct a dozen wavefronts from each source, six troughs and six crests. Mark antinodes with blue lines and mark nodes with red lines, starting each line at least two wavelengths from either source. (*b*) Repeat for the case when the two sources are not coherent, so that waves from one source are exactly one-half wavelength out of phase with waves from the other. (*c*) Compare your diagrams. Are the original antinodes still antinodes? Are the original nodes still nodes? ••
22. Phasors (see Section 15.5) are useful for adding waves that are out of phase. For example, assume you have two sources, 1 and 2, that emit sound waves of the same frequency f. At your detector, the waves from source 1 have an amplitude of 1.00×10^{-8} m, and those from source 2 have an amplitude of 0.600×10^{-8} m and a phase of $+\pi/3$ relative to the phase of the source 1 waves. If the phase of the waves from source 1 is arbitrarily assigned to be $\phi_1 = 0$, what are the amplitude and phase of the combined waves? (Hint: It will help to draw the two waves as phasors.) •••

17.5 Intensity

23. You measure the sound intensity of a sound wave to be 1.50 W/m^2 at 2.60 m away from a point source. Calculate the power output of the source. •
24. Radio Station DXYZ has a power output of 128 W. While listening at home, you measure the intensity of the sound to be 3.40×10^{-6} W/m^2. How far away from your home is the radio station? ••
25. One mosquito emits a sound of intensity level 15 dB, as measured on a decibel meter 0.50 m away. What is the intensity level of the sound emitted by 100 mosquitoes at the same distance? •
26. If ten screaming children on the playground produce a sound for which the intensity level is 80 dB, how many children do you need to produce an 82-dB sound? •
27. A sound source at the center of a cubical room radiates uniformly in all directions. What is the difference in decibels between the intensity level at a ceiling corner of the room and the intensity level at the center of one of the walls? Ignore reflections. ••
28. At a distance of 3.0 m from your stereo system with two speakers, what power output must your stereo amplifier have in order for the intensity level to be 80 dB? Assume that all the energy from the amplifier goes into producing sound. ••
29. A satellite orbiting Earth at an altitude of 450 km emits a radio signal that has a power level of 12 W when it reaches Earth. The signal is beamed in such a way that it covers an area of 8.0 m^2 on Earth's surface. What power is received by a ground-based antenna if the surface area of the antenna is 400 mm^2? ••
30. At a basketball game in an enclosed arena, you happen to sit next to a screaming baby. If the baby's yell arrives at your ear with an intensity level of 75 dB, and the music that reaches your ear from the loudspeakers during the teams' warm-up is at 80 dB, (*a*) what is the intensity I of the overall sound you hear and (*b*) what is the intensity level of the sound you hear? ••
31. The intensity level from a directional loudspeaker at your position at a political rally is 95 dB. (*a*) What is the intensity I of the sound in watts per square meter? (*b*) What is the

power output of the loudspeaker if you are 20 m from the speaker and it emits sound into one hemisphere only? ••

32. You are on the design team for a new airport. The developer wants to build a hotel as close to the airport as possible. The intensity level of a large jet during takeoff is 140 dB at 50 m from the jet. The developer wants to build the hotel such that the intensity level heard by guests is not higher than 50 dB inside the hotel rooms and not higher than 125 dB in the parking lot of the hotel. (*a*) How far from the airport would you suggest the developer build the hotel? (*b*) What is the maximum allowable intensity I of the sound in the hotel rooms? ••
33. The intensity level at the front of a library reading room is 70 dB when 120 students are in the room and 20 dB when the room is empty. What do you expect the intensity level to be when 60 students are in the room? ••
34. A typical car horn has an intensity level of 90 dB at a distance of 1.0 m. (*a*) What is the intensity level of 16 cars all honking their horns at an intersection on a city street? (*b*) What is the power output of the combined horns at a distance of 5.0 m? (*c*) What is the intensity level three city blocks away? Assume 100 m for the length of each block. ••
35. On a whale-watching expedition, your underwater sound detector picks up a whale sound that has an intensity of 9.0 μW/m^2. (*a*) What is the intensity level β of this sound? (*b*) If your detector tells you that you are 2.3 km from the whale, what is the power of the emitted signal? (*c*) How many whales, emitting sound at the same intensity $I = 9.0\ \mu$W/m^2, are needed to produce an intensity level of 100 dB at your location? ••
36. A frequency generator (a device that produces sinusoidal signals whose frequency and amplitude can be independently set) is used to power a horn. The frequency is set to 2000 Hz, and for a particular amplitude the sound intensity is measured to be 0.050 W/m^2 at a distance of 12 m. (*a*) What is the power output of the horn in this case? (*b*) If the power output is increased to 92 W, what is the new intensity reading? ••
37. Suppose that two coherent, spherical sound sources, 1 and 2, each generate the same amount of power P. The distance between the sources is 2λ. Point R is on a line of maximum destructive interference, and the distance between R and source 1 is equal to 9λ. Point Q is on a line of maximum constructive interference, and the distance between Q and source 1 is 6λ. Obtain expressions for the intensity at points R and Q. •••
38. Your bedroom is 8.0 m away from the living room. When requested by your parents to turn down your stereo, you do, and the intensity level where they are sitting in the living room drops from 50 dB to 45 dB. What is the change in the power of the sound emitted by your stereo? •••

17.6 Beats

39. Examine each situation for two waves and determine if audible beats can be produced. Two wave with (*a*) the same amplitude; (*b*) the same frequency; (*c*) slightly different amplitude; and (*d*) slightly different frequency. ••
40. Two stationary tuning forks with frequencies of 246 Hz and 252 Hz are struck simultaneously. Calculate the frequency of the resulting sound. •
41. Two violin players are next to each other on a theater's stage. One plays a 350-Hz note, while the other simultaneously plays a 353-Hz note. (*a*) What is the beat frequency heard by the audience? (*b*) How many beats does the audience hear in a minute? ••
42. Two tuning forks are struck simultaneously, the first one having a frequency of 762 Hz. If a nearby listener hears 20 beats per second, determine the possible frequency or frequencies of the other tuning fork. ••
43. You have four electronic audio generators, A, B, C, and D, all producing tones near 1200 Hz that are easily audible but not distinguishable by ear. When you increase the frequency of generator A a little, the beat frequencies between A and B, A and C, and A and D all increase. When you increase the frequency of generator B a little, the B-C beat frequency increases and the B-A and B-D beat frequencies decrease. Rank the generators by frequency, from lowest to highest. ••
44. One tuning fork vibrates at a frequency of 528 Hz, and a second one vibrates at 524 Hz, but you don't know which is which. After applying a small piece of modeling clay to the end of one fork, you notice that the beat frequency has increased. On which fork did you put the clay? ••
45. Three tenors are giving a concert at an outdoor amphitheater. What are the possible beat frequencies if tenor 1 holds a 262-Hz note while tenor 2 holds a 264.3-Hz note and tenor 3 holds a 258-Hz note? ••
46. When two frequencies are added together, the beat frequency and the average frequency are an octave apart. What is the ratio of the original frequencies? ••
47. Two violin strings, each having a linear mass density of 0.0014 kg/m and under the same 100-N tension, have the same fundamental frequency of 660 Hz. If the tension in one of the strings is changed to 102 N and both strings vibrate in their fundamental nodes, what is the beat frequency? ••
48. During a fire drill in your dormitory, you notice that the sound waves from the two alarms on your floor interfere with each other; you hear five beats every two seconds. (*a*) If the average of the two frequencies is 3500 Hz, what are the frequencies of the two alarms? (*b*) If your room is 15 m from each alarm, what is the intensity I of the sound if the power output is 60 W for each alarm? ••

17.7 Doppler effect

49. Describe the pitch of an approaching siren if it is (*a*) coming close to you and (*b*) after it passes you. •
50. While driving down the road, you spot a friend standing on the sidewalk. You honk your horn at him while driving 70 km/h. Your horn emits a frequency of 360 Hz. What frequency does your friend hear (*a*) as you approach and (*b*) after you pass by? •
51. The electric bells at your school buzz with a frequency of 400 Hz. If you are late for class and riding your bike down a hill toward the school at a constant speed of 4.47 m/s, what is the frequency of the sound you hear? •
52. A stationary mechanical motor generates 8.0 Hz water waves moving at 3.0 m/s. What is the frequency of these waves as observed by a person in a motorboat that approaches the source at 12 m/s? •

53. How fast do you have to travel away from a stationary sound source in order for the frequency to be shifted by (*a*) 1%, (*b*) 10%, and (*c*) a factor of 2? ••
54. While you watch a parade, a band on a float passes you. You detect the frequency of a note played on a flute to be 352 Hz when the float is coming toward you and 347 Hz after the float passes you. At what speed is the float traveling? ••
55. You and a friend are riding bikes, you moving at 9.72 km/h and she moving at 7.20 km/h. She is behind you and turns on her electric horn, which has a frequency of 300 Hz. (*a*) What frequency do you hear? (*b*) What frequency is heard by a person who is standing alongside your route after you both have passed him? ••
56. While you are driving on a straight road at 97 km/h, a police car traveling in the opposite direction comes toward you with the siren blaring, and the frequency you hear is 310 Hz. Starting when the two of you are 200 m apart, it takes you 3.00 s to pass the police car. What is the frequency of the siren? ••
57. A car traveling west at 90 km/h along a road running parallel to a railroad track approaches a train traveling east at 65 km/h. If the train's whistle emits a frequency of 400 Hz, what is the frequency heard by the driver of the car (*a*) as the car approaches the train and (*b*) after the two vehicles have passed each other? ••
58. A foghorn that emits a frequency of 150 Hz is mounted on a buoy in the bay. If a ship approaches the buoy at 21.2 km/h, (*a*) what frequency does the captain of the ship hear? (*b*) Hearing the foghorn is a signal for the captain to slow his ship. After passing the buoy, the captain hears the horn again, but the frequency he detects is now 149 Hz. What is the new speed of the ship? ••
59. Two airplanes simulating a dogfight are headed right for each other, plane A moving at 285 km/h and plane B moving at 295 km/h. The electronic machine gun on A can emit 300 rounds per minute, with each round accompanied by a sound pulse. (*a*) How many pulses does the pilot in B hear during a burst that lasts 10 s according to observer A? (*b*) How long does the burst last for the pilot in B? ••
60. You stand in your yard and hold a battery-powered buzzer that is emitting a frequency of 560 Hz as a friend stands next to you. (*a*) What frequency does your friend hear if you throw the buzzer away from you with a speed of 18.0 m/s? (*b*) You and your friend now get on a flat railroad car that begins to travel at 12.0 m/s, and you throw the buzzer in the direction opposite the direction of the car's velocity. What frequency does your friend hear? (*c*) What frequency would a person standing alongside the tracks hear? ••
61. A dog whistle has a frequency of 21 kHz, which is above the high end of the audible range for humans. At what minimum speed and in what direction must you travel in order to just hear the whistle? ••
62. During trials of a new submarine, its speed is measured with an underwater sonar gun anchored to the ocean floor. The gun emits sound waves at a frequency f, and these waves reflect off the surface of the submarine and return to the source at a frequency $f' \neq f$. If the submarine is receding from the sonar gun at speed v, derive an expression for f' in terms of f, v, and c (the speed of the waves through water). •••
63. A device that both emits and receives sound waves is traveling at 80 km/h. The emitted waves have a frequency of 700 Hz. If the waves are reflected off a stationary flat surface in front of the device, what frequency is detected by the device? •••
64. Two students standing 54.9 m apart are tossing around footballs designed to whistle while they are airborne. (*a*) When student A throws her football toward student B at 16.0 m/s, it emits a frequency of 680 Hz. What frequency is heard by student B? (*b*) When student B throws his football toward student A at 15.0 m/s, it emits a frequency of 670 Hz. What frequency is heard by student A? (*c*) If the two footballs are thrown simultaneously, what is the beat frequency? •••

17.8 Shock waves

65. A jet ski travelling across the surface of water creates a shockwave that makes an angle of 39° with the horizontal. If the waves it creates in the water have a speed of 9.5 m/s, how fast is the jet ski moving? •
66. A military jet is flying at 420 m/s horizontally. Take the speed of sound to be 344 m/s. What is the apex half angle of the conical shock wave it created? •
67. A speedboat traveling at 73.0 km/h causes a shock wave that makes an angle of 14.3° with the path of the boat. At what speed are the waves moving through the water? •
68. Two jets flying at the same altitude pass over your head simultaneously, one traveling at Mach 1.5 and the other at Mach 2.5. Which plane's sonic boom do you hear first? ••
69. While attending an air show, you observe a fighter jet traveling horizontally at a speed of Mach 1.30. At the instant you hear the sonic boom, what is the angle between your line of sight to the jet and the horizontal? ••
70. Many years ago, test pilots accelerating through Mach 1 reported that the ride was pretty rough just before Mach 1 but smoothed out suddenly as Mach 1 was breached. How can you account for this? ••
71. Concerned about being disturbed by sonic booms, residents near an Air Force base located along a seacoast submit a petition asking that all jet aircraft from the base head out to sea before attaining Mach 1 and proceed inland only after they have reached supersonic speed. What do you think of the physics reasoning behind this idea? ••
72. A woman standing on the ground observes a jet directly overhead flying at an altitude of 20,000 m. If the jet has a speed of Mach 2 and its shock wave makes an angle of 30° with the horizontal, how long will it be until she hears the sonic boom? ••
73. At a pistol range, a microphone is placed between a shooter and the target so that when a bullet is fired we can hear its sonic boom. A bullet passes by the microphone at a speed of Mach 2.1. The microphone picks up the sonic boom 0.0021 s after the bullet passes above the microphone. (*a*) What is the angle of the shock wave? (*b*) What is the vertical distance between bullet and microphone? ••

74. A jet flying directly over you at an altitude of 3000 m produces a shock wave. If the angle of the shock wave is 42°, (*a*) how long will it be until the sonic boom reaches you, and (*b*) how far does the jet travel during this time interval? ●●
75. At White Sands, New Mexico, a car powered by a rocket engine passes you while you are standing still. If you hear the sonic boom 0.045 s after the car passes and the angle of the shock wave is 37.0°, what is your perpendicular distance from the path of the car? ●●●

Additional Problems

76. What does an observer hear on the ground before and after a sonic boom caused by a jet passing overhead? ●
77. Is a second sonic boom generated when a plane reaches a speed of Mach 2? ●
78. Two test pilots are flying in a jet trainer going faster than Mach 1. Can the pilot in the front of the cockpit hear the pilot in back? ●●
79. Two guitar strings, 1 and 2, plucked simultaneously produce standing waves described by

$$D_1 = A\sin(ax)\cos(bt)$$
$$D_2 = A\sin(qx)\cos(dt),$$

with $a = 14.5\ \text{m}^{-1}$, $b = 2512\ \text{s}^{-1}$, $q = 19.3\ \text{m}^{-1}$, and $d = 2575\ \text{s}^{-1}$. (*a*) What is the frequency of each wave? (*b*) What is the beat frequency of the combined wave? ●●
80. A race car traveling at 350 km/h passes a spectator in the stands. If the spectator has an air horn that emits a sound of frequency 400 Hz, what is the range of frequencies of the sound heard by the driver of the car? ●●
81. Which type of conic section (circle, ellipse, parabola, or hyperbola) is formed by the nodal-line pattern produced by two coherent sources of two-dimensional waves? (Hint: For a given nodal line, the difference in distance between any point on it and the two sources is the same for all points.) ●●
82. Why is the high-frequency "tweeter" on a stereo speaker usually much smaller than the low-frequency "woofer"? ●●
83. You are standing beneath a Ferris wheel when two children riding in cars on opposite sides of the wheel both scream at 600 Hz. Your well-trained ears notice a beat frequency that is maximum when one child is moving directly toward you and the other is moving directly away from you. The Ferris wheel takes 24.0 s to complete one rotation, and its diameter is 27.0 m. You begin to wonder whether a Doppler shift could produce observable beats under these circumstances. ●●● CR
84. You have tickets for an outdoor rock concert, fourth row from the stage. However, at that distance the intensity level is 100 dB, too loud to be enjoyable. You decide to move to a row where the intensity level is a more moderate 80 dB. Fortunately, turning around and counting the right number of rows back (assuming that the distance between rows is uniform), you see that the seats you want are available. ●●● CR
85. You want to build a portable device that can detect pirate radio stations broadcasting at about 50 W of power a few miles from your beachfront home. You have a 0.60-m diameter bowl you might use as an antenna dish, but you are worried that your amplifier input will require a signal of at least 0.10 μW. ●●● CR
86. Your car is third in line at a railroad crossing as a train moving at a constant speed approaches, with its whistle blowing constantly. To keep yourself from going crazy with the noise, you begin thinking about the relative difference between the frequency you hear and the frequency the engineer hears. Surely this must depend on the angle that your line of sight to the engine of the train makes with the perpendicular to the track. ●●● CR

18.5 Pressure and gravity
18.6 Working with pressure
18.7 Bernoulli's equation
18.8 Viscosity and surface tension

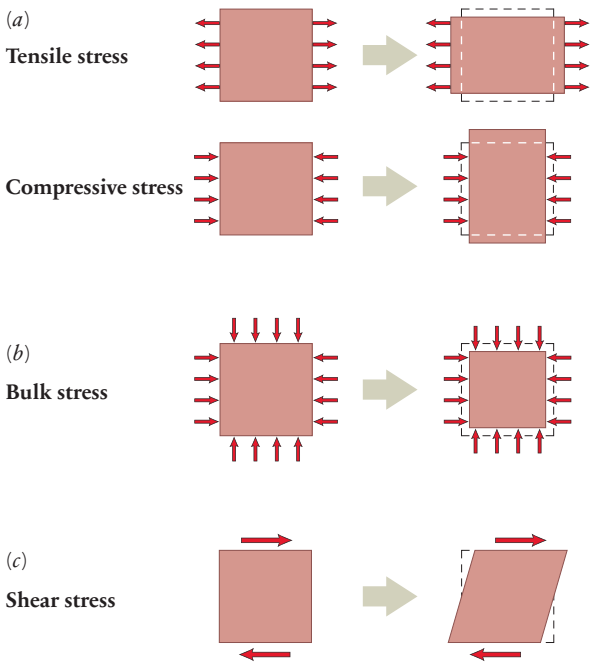
In earlier chapters we dealt with the motion and behavior of solid objects mostly. In the next few chapters we extend our description to include two other states of matter: liquids and gases (Figure 18.1). The internal forces exerted on the atoms in a solid keep each atom at a particular location in the solid. Because the atoms can move only slightly relative to one another, a solid material free of external forces has a definite size and shape. In a liquid, the forces exerted on the particles* are not strong enough to keep them from moving relative to one another. Consequently a liquid sample has a definite volume but adjusts to the shape of its container. In a gas, the particles are far apart. They move about randomly and freely, and so a sample of gas has neither a definite volume nor a definite shape.

Liquids and gases are collectively called **fluids** because they flow.

Because fluids flow and change shape, we cannot describe their behavior in the same way we described the behavior of solids. When you look at the flow of water in a river, for example, it makes no sense to speak of "the velocity of the water" because the water may move fast in one spot and more slowly in another, or it may be flowing in one direction at one location and in another direction a bit farther downstream. Unlike a solid object, in other words, water in a river cannot be characterized by a simple set of kinematic quantities—the motion of its center of mass and rotation about that center. However, you can specify its velocity at a specific location.

Figure 18.1 States of matter.

*Both liquids and gases can be made up of either atoms or molecules. From now on, we'll use the generic term *particle* to refer to either atoms or molecules in a liquid or gas.



In general, therefore, describing the motion of fluids requires an approach in which we associate quantities such as velocity not with a body of fluid as a whole but with a position within the body of fluid.

18.1 Forces in a fluid

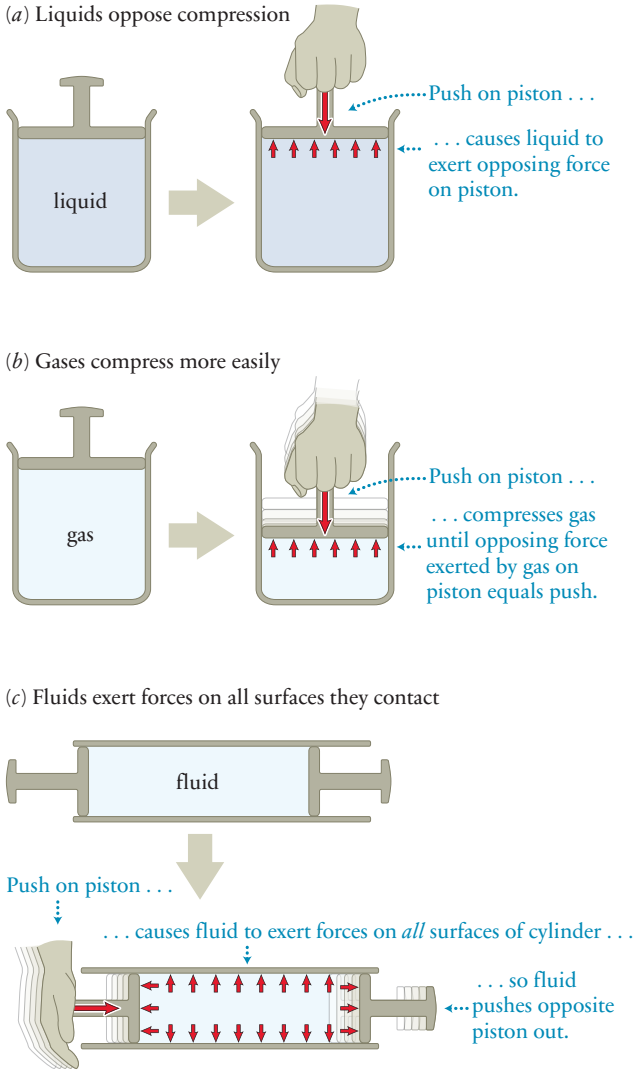
The result of exerting forces on fluids is very different from the result when forces are exerted on solids. To better understand this difference, let us begin by examining how a solid object at rest responds to a set of forces whose vector sum is zero. Because the vector sum is zero, the object remains at rest, but because no solid material is perfectly rigid, the object deforms when opposing forces are exerted on it. Such opposing forces are said to cause a *stress*. A solid object that returns to its original shape when the stress is removed is said to be *elastic* (see Section 8.6). Beyond the elastic limit, the object deforms permanently, and still greater forces may cause the object to fracture. Within the elastic range, the amount of deformation caused by a given stress depends on the properties of the material and typically obeys Hooke's law (see Section 8.9) for small deformations; that is, the deformation is linearly proportional to the magnitude of the applied forces.

Because the atoms in a solid are at fixed positions, a solid object can withstand forces applied to its surface in a number of ways. A set of opposing forces along the same line of action (Figure 18.2a) causes either *tensile stress*, which stretches the object, or *compressive stress*, which compresses it. Under such stress, the object's dimensions perpendicular to the line of action of the forces also change to compensate for the stretching or

Figure 18.2 Different types of stresses caused by equal forces applied in opposite directions to solid objects.

CONCEPTS

compressing along the line of action. In spite of this compensating change, however, precise measurements show that the object's volume increases by a small amount when the object is stretched and decreases by a small amount when the object is compressed.



When opposing forces are exerted perpendicular to all surfaces of a solid object (Figure 18.2*b*), the atoms are pushed closer together in all directions, resulting in what is called *bulk stress*. Such a stress causes the volume of the object to decrease.

A third type of stress, *shear stress*, occurs when opposing forces are exerted tangent to the surfaces of a solid object (Figure 18.2*c*). For small forces, the object's shape changes—turning a rectangular face into a parallelogram, say—but the volume of the object does not change.

Let us now examine how a fluid responds to these same three types of stresses: tensile/compressive, bulk, and shear. If you put your hands under water parallel to each other and some distance apart and then move them toward each other, you feel resistance. Your moving hands exert a force on the water and, because forces always come in interaction pairs, the water, in turn, exerts a force on your hands. Once your hands stop moving, however, this force exerted by the water on them disappears. In addition, when you remove your hands, the water molecules don't flow back to where they were before you moved your hands. In other words, water is not elastic the way some solid materials are. If you compress an elastic solid—a foam rubber ball, say—the way you "compress" the water by bringing your hands together, you must keep exerting the force if you want to keep the ball compressed. Once you remove your hands, the ball returns to its original shape. This is not true for most liquids (water, rubbing alcohol, and gasoline, for instance) or for all gases under ordinary circumstances; these fluids are not elastic. You can easily verify that they also cannot support static tensile or shear stresses. Such fluids are said to be *nonviscous*. Liquids such as jelly or tar, which do not behave the way water does in response to a shear stress, can support a shear stress and are said to be *viscous*.

Let us next look at how fluids behave when subjected to bulk stress. If you exert forces on a fluid so as to cause a bulk stress, as in Figure 18.2*b*, the fluid resists being compressed. Imagine putting water in a cylinder fitted with a piston and pushing down on the piston (**Figure 18.3*a***). Because the water has nowhere to go and because the water molecules are already as close together as they can get, a very large force is required to change the volume of the water, and so you feel a rapidly growing resistive force exerted by the water on the piston. If, instead of water, you put a gas in the cylinder, the gas compresses easily as you push on the piston because gas particles are far apart and can easily be pushed closer together. As the gas is compressed, however, it exerts on the piston a force of increasing

Figure 18.3 All fluids resist bulk stresses, but liquids don't compress much, whereas gases are easily compressed.

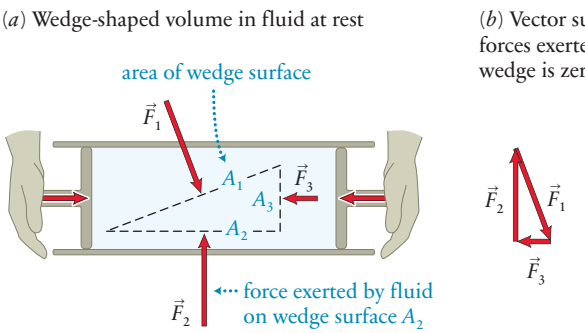
magnitude. Once that force is equal in magnitude to the force you exert on the piston, the system reaches mechanical equilibrium (Figure 18.3*b*). The greater the force you exert, the more the gas is compressed.

So, a fluid can sustain forces that are perpendicular to its surfaces, provided the forces are exerted simultaneously on *all* its surfaces. If you pushed the left piston in Figure 18.3*c* inward without also pushing the right piston inward, for example, you would simply push the water and the right piston out of the tube. Likewise, if you replaced a section of either the top or bottom wall of the cylinder in Figure 18.3*c* with a piston and again pushed on the left piston, you would also need to push both the right piston and the newly added piston inward in order to keep the water contained. From these observations we conclude that, in mechanical equilibrium, a fluid in a container exerts a (normal) force that is distributed along *all* surfaces of the container that are in contact with the fluid, and those

CONCEPTS

surfaces exert on the fluid a force that is of equal magnitude but in the opposite direction.

The main difference between gases and liquids is that gases tend to compress easily, often greatly changing the volume and therefore the mass density (mass per unit volume, see Section 1.6), whereas the volume and mass density of a liquid do not change easily. For simplicity, from now on we shall assume that the liquids we deal with are *incompressible*; that is, their mass density and volume are fixed.



When a gas is subjected to bulk stress, its mass density and volume change easily. When a liquid is subjected to bulk stress, its mass density and volume can be considered unchanged.

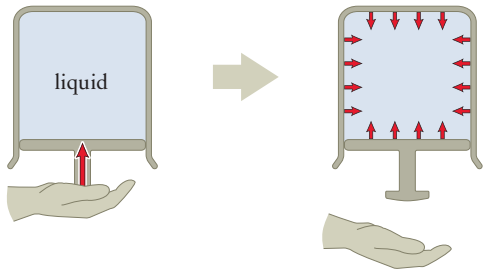
18.1 In Figure 18.3*c*, suppose you push the left piston rightward with a force of magnitude 10 N. (For now, ignore normal forces.) (*a*) To keep the water in the cylinder at rest, what force must you exert on the (identical) right piston? (*b*) How does the force $\vec{F}^{c}_{wr}$ exerted by the water on the right piston compare to the force $\vec{F}^{c}_{pl}$ exerted by you on the left piston?

The two pistons in Checkpoint 18.1 are identical. Suppose we divide the right piston in Figure 18.3*c* into two pistons, each having half the surface area of the original piston. As you might expect, to keep the water in the cylinder at rest while pushing the left piston rightward with a force of magnitude 10 N, you would need to exert on each half-piston a force of magnitude 5 N, which suggests a linear proportionality between surface area and force.

To examine this relationship in more detail, consider a fluid at mechanical equilibrium in a cylinder (**Figure 18.4**). Forces are exerted on the two pistons so that the fluid is subject to a compressive stress. Now imagine a wedge-shaped volume of the fluid. Because liquids cannot sustain any shear stresses (resulting from forces tangent to the wedge surfaces) exerted on the wedge, the forces exerted by the surrounding fluid on the wedge must be perpendicular to the three wedge surfaces. Because the wedge is at rest, the vector sum of these forces must be zero. Let the three wedge surfaces have areas A_1, A_2, and A_3. Each of these areas is proportional to the length of the corresponding side of the dashed triangle in Figure 18.4*a*, and each is subject to a normal force exerted by the surrounding fluid. Let us denote these forces by $\vec{F}_1$, $\vec{F}_2$, and $\vec{F}_3$. Because these vectors add up to zero, we can arrange them in a triangle as shown in Figure 18.4*b*. Because the vectors are perpendicular to the sides of the dashed triangle in Figure 18.4*a*, the triangle in Figure 18.4*b* is similar to the dashed triangle, and so the ratio of the force magnitudes $F_1{:}F_2{:}F_3$ is the same as the ratio of the lengths of the sides of the dashed triangle. Because the dimension of the wedge in the direction perpendicular to the plane of the drawing is fixed, the area A of each side of the wedge is proportional to its length. Therefore $F_1{:}F_2{:}F_3 = A_1{:}A_2{:}A_3$, or $F_1/A_1 = F_2/A_2 = F_3/A_3$. In other words, the ratio of the magnitude of the force exerted by the fluid on a surface and the area of that surface is constant. This ratio is called **pressure,** denoted by the symbol P. Pressure is a scalar and is taken to be positive when a fluid is under compression.

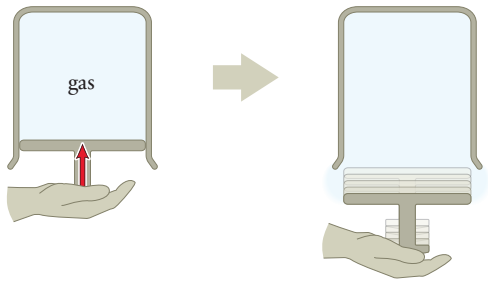
Figure 18.4 Forces exerted on the sides of a wedge-shaped volume of fluid.

It is important to distinguish pressure from force. The two are related because forces exerted on the fluid cause the pressure in a fluid. Force, however, is a vector, while pressure is a scalar. In addition, forces of the same magnitude can cause very different pressures depending on the surface area over which these forces are exerted. Imagine, for example, exerting a force of 10 N on your skin first with the tip of a pin and then with the cover of a book. Even though the force is the same in both cases, the effect is very different. At the tip of the pin, the pressure caused by the 10-N force is very great because the surface area of the pin is small. The pressure caused by the pin is likely to cause pain, and the pin might penetrate into your skin. The book, however, spreads that same 10-N force out over a much greater surface area, and so the resulting pressure is much smaller.



Another important point to keep in mind is that because forces always come in interaction pairs, the force exerted by a container wall on a fluid (which causes the pressure in the fluid) and the force exerted by the fluid on the container wall form an interaction pair. The pressure in a fluid therefore causes the fluid to exert forces on anything that is in contact with it. Because of the mobility of the particles in a fluid, pressure is transmitted in all directions to all parts of the fluid. However, because fluids cannot sustain shear stresses, the forces exerted by the fluid on any surfaces that contain the fluid are always exerted perpendicular to the surface.

In gases, pressure can be only positive. Liquids, however, can sustain negative pressures. For example, if you hold the container of Figure 18.3*a* upside down, as shown in **Figure 18.5*a*** on the next page, and pull down on the piston, you feel a large resistive force, which tells you that the liquid pulls the piston inward. The water molecules exert an attractive force on one



CONCEPTS

Figure 18.5 Liquids can sustain negative pressures, whereas pressures in a gas can be positive only.

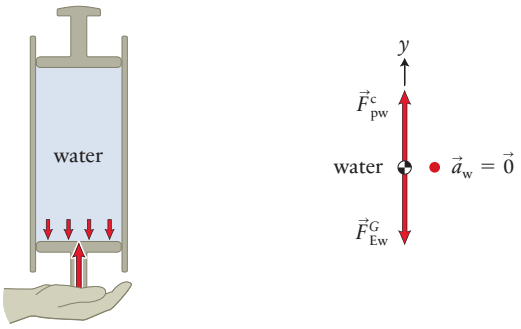
(*a*) Because liquid particles exert attractive forces on each other and on the container walls, liquid can hold piston up against force of gravity

(*b*) Gases expand to fill any volume and therefore cannot sustain negative pressures

another and on the surfaces of the container, pulling them inward as you pull the piston down. So, just as a liquid under compression causes an outward push that we associate with a positive pressure, we find that a "stretched" liquid causes an inward pull that we associate with a negative pressure.

(You can easily try this yourself. Fill a glass to the top with water, place an index card on top of the glass, making sure no air is left between the water surface and the card, and then turn the glass upside down while holding the card in place with the palm of your hand. If you slowly remove your hand from the card, the water remains in the glass.)

Gas particles are so far apart that they interact only when they collide, and so a gas always expands to fill whatever container it is placed in. A gas can therefore not sustain negative pressure, and a piston just falls out of a gas container that is held upside down (Figure 18.5*b*).



18.2 Consider a plastic cup full of water. (*a*) Is the water exerting a force on the bottom of the cup? (*b*) On the sides of the cup? (*c*) Is the water pressure negative, zero, or positive?

The answers to Checkpoint 18.2 may have surprised you. What causes the pressure in the water if the top surface of the water is open to the environment and no piston is pushing down on that top surface? The cause

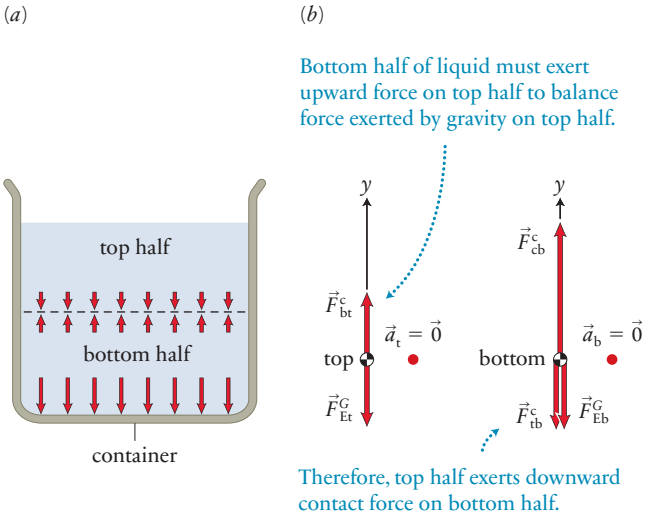
Figure 18.6 Gravity exerts a downward force on a volume of fluid.

(*a*) You must exert upward force on bottom piston to keep water from falling out

(*b*) Free-body diagram for water

is gravity. Imagine the column of water in the glass as being a stack of thin "layers" of water. Gravity exerts a force on each layer, which means that each layer pushes down on the layer underneath it, just as a book presses down on the surface of a table because of gravity. At the top of the water column, the atmosphere presses down on the surface, our imaginary top layer.

To examine the effect of gravity on the pressure in a fluid, consider again a water-filled tube fitted with identical pistons on either end, but now we orient the tube vertically (**Figure 18.6*a***). Even with no force exerted on the top piston, you have to exert an upward force on the bottom piston to prevent the water from falling out of the tube. As the free-body diagram in Figure 18.6*b* shows, when you are not pressing down on the top piston, the water is subject to two forces: a downward force of gravity and an upward force of equal magnitude exerted by the bottom piston.* So the pressure at the top of the water is zero (no force exerted on the surface), whereas the pressure at the bottom of the tube is nonzero.



Now imagine dividing a liquid in a container into two equal parts, as shown in **Figure 18.7*a***. Ignoring any force exerted at the top surface (we'll return to this issue in a bit), we see from the free-body diagrams in Figure 18.7*b* that the top half must be supported against the pull of gravity by the bottom half. The bottom of the container, in turn, must support both halves. Consequently the pressure at the bottom of the container is greater than the pressure at the center.

18.3 How does the pressure in the liquid vary with height above the bottom of the container in Figure 18.7?

*As we shall see later, the atmosphere exerts a force on each piston, but the combined effect of these two forces is negligible. For simplicity, we also ignore the mass of the pistons, which means there is no gravitational force exerted on them and so the top piston exerts no force on the water.

CONCEPTS

Figure 18.7 Pressure increases with distance below the surface because liquid layers at the top press down on lower layers of liquid.

The conclusion you reached in Checkpoint 18.3 holds for any liquid that is at rest in a container of any shape:

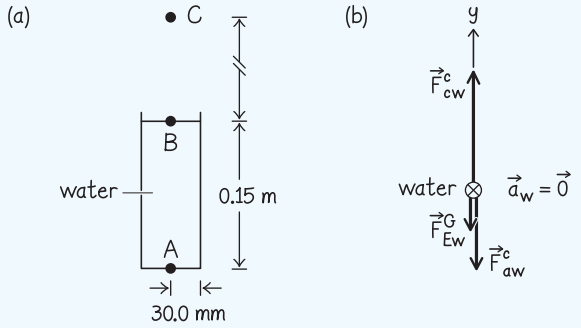
The pressure in a liquid at rest in a container decreases linearly with height, regardless of the shape of the container.

In a gas, the pressure also decreases with height, but the effect is much less pronounced because gases are much less dense than liquids. Also, because gases are compressible, gas density varies with height and so the decrease in pressure with height is not linear. Air, for example, is densest at sea level, where it is compressed by all the air above. At the cruising altitude of most airplanes (10 km), the mass density of the air is one-third of its value at sea level, and the atmospheric pressure is just one-quarter of its value at sea level.

At sea level, you are at the bottom of an "ocean" of air. The mass of a column of air that has a cross section the size of a fingernail is approximately 1 kg. In other words, at sea level the atmosphere exerts on each fingernail-sized area of your body a force that is equivalent to the force of gravity on a 1-kg object. If we were to add up the magnitudes of the forces exerted on the entire surface area of your body, you would obtain a force equal to the force of gravity exerted on 2×10^4 kg! The force with which the atmosphere pushes down on the surface of your orange juice at breakfast is more than four times the force with which this book presses down on your lap.

Given that the average atmospheric pressure at sea level is 1×10^5 N/m^2, it is clear that we cannot ignore the pressure at the top of the liquid in Figure 18.7. As you saw in Checkpoint 18.1, any force exerted at one surface of a liquid is transmitted to any other part of the liquid. This means that if we change the pressure in a container of liquid at any location, the change in pressure is the same throughout the liquid. This is called **Pascal's principle:**

A pressure change applied to an enclosed liquid is transmitted undiminished to every part of the liquid and to the walls of the container in contact with the liquid.



Consequently, if atmospheric pressure at the top of a column of water in a container open to the atmosphere is 1×10^5 N/m^2, the pressure in the water near that surface must also be 1×10^5 N/m^2. Below the surface, the pressure in the water increases with greater depth as more water pushes down due to gravity. The next example gives you some feel for pressure variation with height in both water and air.

EXAMPLE 18.1 Water and air pressure

Consider a cylindrical container that has a radius of 30.0 mm and is filled with water to a height of 0.150 m. If the container is at sea level, what is the pressure (*a*) at the water surface and (*b*) at the bottom of the container? (*c*) How far above the water surface is the decrease in atmospheric pressure the same as the pressure decrease between the bottom and top of the water? The mass densities of air and water are 1.20 kg/m^3 and 1.00×10^3 kg/m^3, respectively.

1 GETTING STARTED I begin by making a sketch of the situation (**Figure 18.8*a***). The problem deals with the pressure at three locations: at the bottom of the container (point A), at the water surface (B), and at some location above the surface (C). Because 0.150 m is a negligible distance in the context of this problem, the pressure at B is essentially equal to the atmospheric pressure at sea level. At A the pressure should be greater than at B because of the force of gravity exerted on the water. At C the pressure should be smaller than at B because the volume of air above C pressing down on C is smaller than the volume of air above B pressing down on B.

Figure 18.8

2 DEVISE PLAN The pressure at A is equal to the magnitude of the force $\vec{F}^c_{cw}$ exerted by the container bottom on the water divided by the area of the container bottom. To determine the magnitude of this force, I make a free-body diagram for the water (Figure 18.8*b*). The forces exerted

(Continued)

CONCEPTS

on the water are the force of gravity $\vec{F}^G_{Ew}$, the downward force $\vec{F}^c_{aw}$ exerted by the atmosphere, and the upward force exerted by the container bottom, which I need to determine. Because the water is at rest, the vector sum of these forces must be zero, and so the magnitude of the force exerted by the container bottom on the water is $F^c_{cw} = F^G_{Ew} + F^c_{aw}$. The force $\vec{F}^c_{aw}$ is determined by atmospheric pressure. To calculate $\vec{F}^G_{Ew}$ I need to know the mass of the water, which I can obtain by multiplying the volume of the water by the mass density of water.

Because the difference in pressure between A and B is the same as that between B and C, I know that the mass of the air column between B and C must be equal to the mass of the water column between A and B. The ratio of the distances between these locations must therefore be equal to the ratio of the volumes, which is equal to the inverse of the ratio of the mass densities (assuming that the density of air is approximately constant over that column of air).

3 EXECUTE PLAN (*a*) The pressure at B is essentially equal to atmospheric pressure at sea level, which I can look up: $P_B = 1.01325 \times 10^5\ \text{N/m}^2$. ✔

(*b*) Dividing both sides of $F^c_{cw} = F^G_{Ew} + F^c_{aw}$ by the bottom surface area A, I get $P_A = F^G_{Ew}/A + P_{atm}$ because $P_A = F^c_{cw}/A$ and $P_{atm} = P_B = F^c_{aw}/A$. The volume of the water is $V = Ah$, and so the mass of the water is this volume times the mass density of water: $m_{water} = Ah\rho$. The magnitude of the force of gravity exerted on the water is $F^G_{Ew} = m_{water}g = Ah\rho g$, and this force is exerted over the bottom surface area A of the container. The pressure at point A is thus

$$P_A = \frac{F^G_{Ew}}{A} + P_{atm} = \frac{Ah\rho g}{A} + P_{atm} = h\rho g + P_{atm}$$
$$= (0.150\ \text{m})(1.0 \times 10^3\ \text{kg/m}^3)(9.8\ \text{m/s}^2) + 1.01325 \times 10^5\ \text{N/m}^2 = 1.03 \times 10^5\ \text{N/m}^2. \checkmark$$

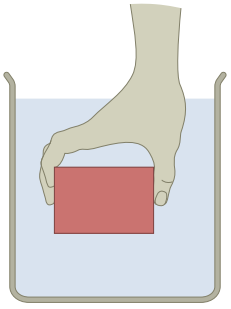
(*c*) The ratio of the distances is $\overline{AB}/\overline{BC} = \rho_{air}/\rho_{water} = (1.20\ \text{kg/m}^3)/(1.00 \times 10^3\ \text{kg/m}^3) = 1.20 \times 10^{-3}$. I am given $\overline{AB} = 0.150\ \text{m}$, so $\overline{BC} = (0.150\ \text{m})/(1.20 \times 10^{-3}) = 1.25 \times 10^2\ \text{m}$. ✔

4 EVALUATE RESULT The answer I obtained in part *b* shows that the pressure difference between the top and bottom of the container is very small. That makes sense—I know from experience that my ears, which are very sensitive to pressure, don't experience any pressure difference when I swim a mere 0.15 m under the surface of water.

The answer to part *c* tells me that the distance above sea level I would have to climb in order to obtain the same pressure difference is about three orders of magnitude greater than the distance from B to A (0.15 m versus 120 m). Again, I know from experience that I don't experience any detectable pressure difference when going up 120 m in air, so my answer is not unreasonable.

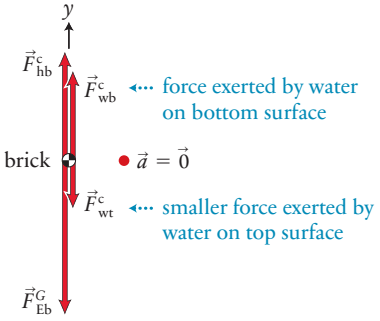
18.4 How far below the surface of a deep body of water is the pressure twice what it is at the surface?

18.2 Buoyancy



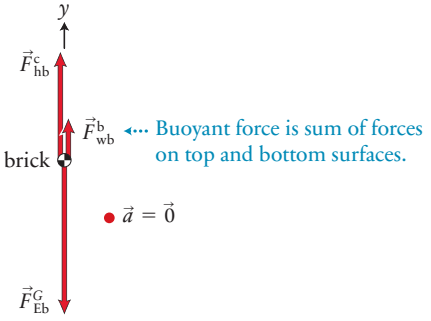
The decrease in pressure with height is responsible for the **buoyant force,** an upward force experienced by objects when they are either fully or partially submerged in a fluid. The tendency of certain objects to float in air or water, called *buoyancy*, is due to this force.

If you hold a brick under water with its top surface parallel to the surface of the water, as illustrated in Figure 18.9*a*, the pressure in the water at the bottom of the brick is greater than the pressure at the top, so the upward force exerted by the water on the bottom surface of the brick is greater than the downward force the water exerts on the top surface of the brick. The free-body diagram for the brick in Figure 18.9*b* shows the forces exerted on the brick: a downward gravitational force, an upward force exerted by your hand, an upward force exerted by the water on the bottom surface, and a downward force exerted by the water on the top surface. Because the pressure is greater at the bottom of the brick than at the top, the two forces exerted by the water on the brick add up to an upward buoyant force



CONCEPTS

Figure 18.9 Cause of the buoyant force experienced by objects that are partly or fully submerged in a fluid.



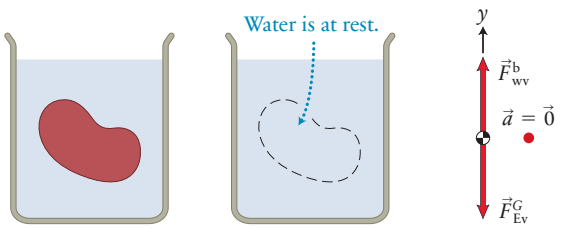
(*a*) Brick held under water

(*b*) Free-body diagram that separates force exerted by water on brick's top and bottom surfaces

(*c*) Free-body diagram showing buoyant force exerted by water on brick

(Figure 18.9*c*). Buoyant forces are denoted by a superscript b. (We can ignore the sideways forces exerted by the water on the brick because they cancel out.)

18.5 (*a*) What happens to the pressure difference between the top and bottom of the brick in Figure 18.9*a* when the brick is held deeper in the water? (*b*) What happens to the pressure difference when the pressure at the surface of the water is increased? (*c*) What is the effect of the pressure in the water on the vertical sides of the brick? (*d*) Consider the same brick held in the air. Does the air exert a buoyant force on the brick? If so, in which direction is this force?



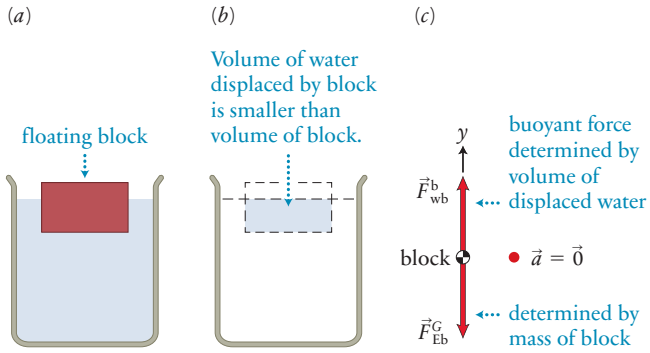
How large is the buoyant force that is exerted on an object submerged either fully or partially in a fluid? For an object that has a rectangular cross section, such as the brick in Figure 18.9*a*, we can determine the pressures at the top and bottom of the object, multiply the pressures by the surface area to get the two force magnitudes, and then take the difference of these magnitudes to obtain the buoyant force. However, many objects do not have a rectangular cross section. Consider, for example, the fully submerged object in **Figure 18.10*a***. Even if we know the pressure at every location on the surface of the object, calculating the buoyant force exerted by the water on the object is a complicated matter. We know, however, that if we remove the object from the water, water fills the space previously occupied by the object (Figure 18.10*b*). This volume of water within the boundary defined by the object is said to be *displaced* by the object when the object is fully submerged. Figure 18.10*c* shows the free-body diagram for this displaced volume of water. Because all the water is at rest, we know that the vector sum of the forces exerted on the volume of water within the boundary must be zero. Two forces are exerted on this volume of water: a downward force of gravity exerted by Earth and a buoyant force exerted by the surrounding water. Given that the vector sum of these two forces is zero, we know that the buoyant force exerted on the water within the boundary must be upward and equal in magnitude to the magnitude of the force of gravity exerted by Earth on the water within the boundary.

Because the buoyant force exerted by the surrounding water on the boundary in Figure 18.10*a* cannot depend on the nature of the material inside the boundary, we have a way of determining the buoyant force exerted on an object of arbitrary shape:

> **An object submerged either fully or partially in a fluid experiences an upward buoyant force that is equal in magnitude to the magnitude of the force of gravity exerted on the fluid displaced by the object. The volume of the displaced fluid is equal to the volume of the submerged portion of the object.**

This statement is called **Archimedes' principle.** Note that there is no reference to the shape or composition

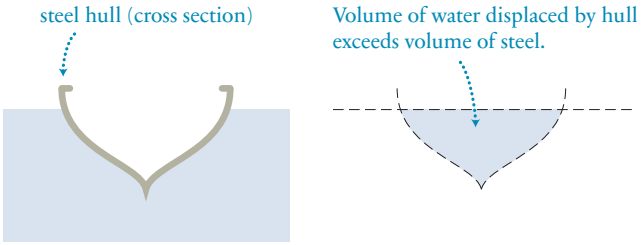
Figure 18.10 The force exerted by gravity on the volume of liquid *displaced* by a submerged object is equal in magnitude to the buoyant force exerted by the liquid on the object.



of the submerged object: The only factor that comes into play is the volume of the displaced fluid.

18.6 If the buoyant force exerted on an object is always equal in magnitude to the force of gravity exerted on the fluid displaced by the object, why does a brick placed in a barrel of water sink?

Now that we know how to determine the buoyant force exerted on an object, we can understand why some objects float and others sink. As Checkpoint 18.6 shows, a brick sinks because the force of gravity exerted by Earth on it is greater than the force of gravity exerted by Earth on an equal volume of water (equal in magnitude to the buoyant force). Because the vector sum of these two forces is directed downward, the brick sinks unless it is held up.



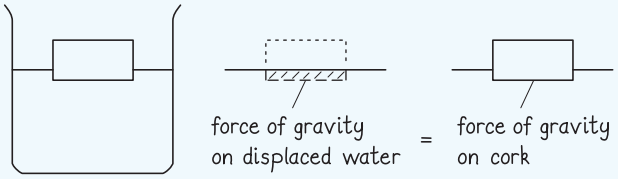
When the buoyant force is greater in magnitude than the force of gravity exerted on an object fully submerged in water, the object accelerates toward the surface of the water when you release it. A block of wood released under water, for example, accelerates to the surface, so the force of gravity exerted by Earth on the block is smaller than the force of gravity exerted on an equal volume of water (**Figure 18.11*a***). Once it floats at the surface, only part of the block is submerged, and so now the volume of displaced water is smaller than the volume of the block (Figure 18.11*b*). Because the block

Figure 18.11 The concept of displaced volume can be used to determine the buoyant force on floating as well as submerged objects.

CONCEPTS

Figure 18.12 Steel ships can float even though steel sinks. The ship's hollow interior means that the volume of water displaced by the ship is larger than the volume of steel. Thus, the upward buoyant force exerted on the ship is greater than the downward gravitational force exerted on the steel.

is at rest at the surface, the force of gravity exerted by Earth on it and the buoyant force exerted by the water must be equal in magnitude, as shown in Figure 18.11*c*.



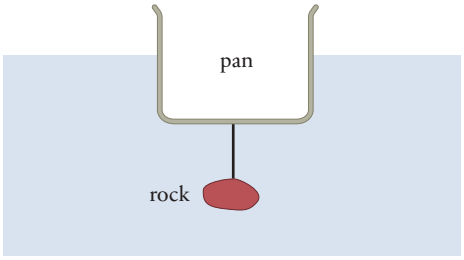
Objects made out of materials that normally sink can be made to float by designing the objects in such a way that the buoyant force is great enough to offset the force of gravity exerted on them. For example, a steel ship floats even though a block of steel sinks. The reason for this is illustrated in **Figure 18.12**: As long as the force of gravity exerted on the ship is smaller than the force of gravity exerted on the volume of water displaced by the ship, the buoyant force is great enough to keep the ship floating. Because the hull of a ship is hollow, the volume of displaced water is much greater than the volume of steel.

EXAMPLE 18.2 Mass densities

When a piece of cork floats in water, three-quarters of its volume is above the water surface. How does the mass density of cork compare with the mass density of water?

❶ **GETTING STARTED** I begin by making a sketch of the situation. Because one-quarter of the cork's volume is under water, I know that the cork displaces a volume of water equal to one-quarter of the volume of the cork. This also tells me that the force of gravity exerted on the whole cork $m_{\text{cork}}g$ is equal to the force of gravity exerted on the displaced water $m_{\text{disp}}g$ (**Figure 18.13**), which means that the mass of the displaced water is equal to the mass of the cork.

Figure 18.13



❷ **DEVISE PLAN** The mass density of an object is equal to the amount of mass per unit volume. Because I know how the volumes of equal masses of cork and water compare (Figure 18.13), I can compare the mass densities of cork and water.

❸ **EXECUTE PLAN** The volume of a piece of cork of a certain mass is four times greater than the volume of an equal mass of water, and so the mass density of cork is one-quarter that of water. ✔

❹ **EVALUATE RESULT** A "light" material such as cork has less mass per unit volume and therefore a smaller mass density than water, as I expect.

18.7 A pan with a rock in it is floating in water. Suppose you remove the rock and use a very lightweight string to suspend it from the bottom of the pan (**Figure 18.14**). If the combination still floats, is the volume of water displaced when the rock is suspended greater than, equal to, or smaller than the volume of water displaced when the rock is in the pan?

Figure 18.14 Checkpoint 18.7.

18.3 Fluid flow

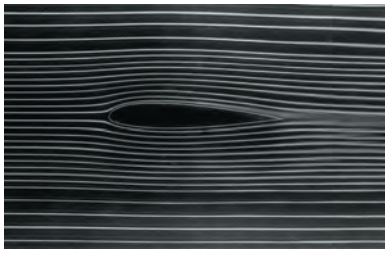
We have so far restricted our study to fluids at rest. Now we turn our attention to fluids in motion; such motion is usually referred to as *fluid flow*. When the flow is such that the velocity of the fluid at any given location is constant, such as when water moves through a pipe, the flow is said to be **laminar.** Not all fluid flow is laminar, however. For example, the motion of rising smoke or the motion of water in the wake of a large ship is characterized by chaotic changes. Such flow is said to be **turbulent.**

To better understand fluid flow, we introduce the concept of **streamlines,** which are lines drawn to represent the paths taken by the particles in a fluid in motion. Streamlines can be made visible by injecting smoke into a flow of gas (**Figure 18.15**) or ink into a flow of liquid

Figure 18.15 Streamline flow over a car.

CONCEPTS

Figure 18.16 Streamline flow around an airplane wing.



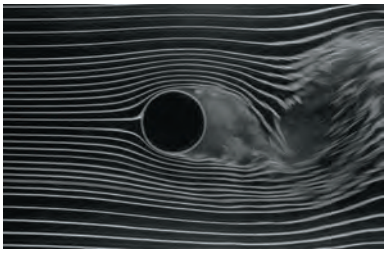


Figure 18.17 Turbulent flow around a cylinder.

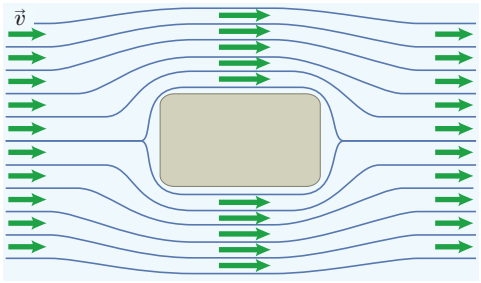

(**Figure 18.16**). When flow is laminar, as in Figures 18.15 and 18.16, streamlines maintain their shape and position. In turbulent flow, streamlines are erratic and often curl into whirling, circularly moving regions of fluid called *vortices* (singular *vortex*, **Figure 18.17**).

Whether a flow of fluid past a stationary object is laminar or turbulent depends on the speed of the flow, the shape of the object, and the fluid's resistance to shear stress (its *viscosity*). For a fluid that has zero viscosity and that has no friction when flowing past surfaces, streamlines just bend around a blunt object (**Figure 18.18*a***). Except where the fluid has to move out of the object's way, the flow speed is the same everywhere. In such situations, the streamline pattern in regions downstream from the object is the same as the streamline pattern upstream of the object. (Although such "totally nonviscous" fluids don't exist, examining these models provides useful insights.)

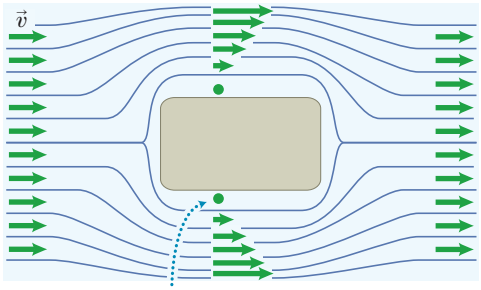

Figure 18.18*b* shows the flow pattern for a fluid that has nonzero viscosity when that fluid is moving at a very low speed. The streamlines have the same general shape as for the nonviscous fluid of Figure 18.18*a*, but the pattern of speeds is very different in the two cases. At the object's surface, the viscous fluid in Figure 18.18*b* is stationary because of friction between the fluid and the surface. Far above and below the object, the flow is unaffected by the presence of the object. Between those two extremes, the flow speed increases from layer to layer. Because the viscosity is nonzero, adjacent layers of fluid exert shear forces on each other, with faster-moving layers trying to speed up slower-moving layers and slower-moving layers

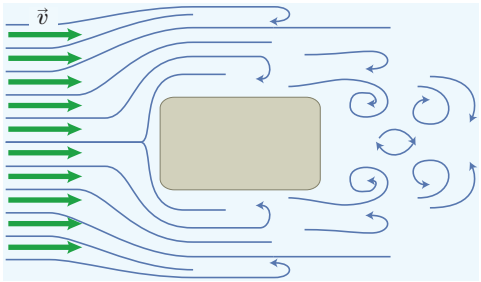
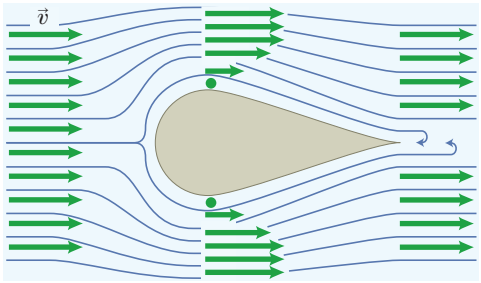
Figure 18.18 Whether the flow of fluid past a stationary object is laminar or turbulent depends on the fluid's speed and viscosity and on the object's shape.



(*a*) Low flow speed, zero viscosity



(*b*) Low flow speed, nonzero viscosity

(*c*) High flow speed, turbulence

(*d*) High flow speed, streamlined object

CONCEPTS

slowing down faster-moving ones. The resulting "rubbing" of layers of fluid causes energy dissipation.

As flow speed is increased, the torques caused by the forces that adjacent layers exert on each other become so great that the flow develops vortices and becomes turbulent (Figure 18.18*c*). The turbulent wake alongside and downstream from the object is erratic and causes significant energy dissipation.

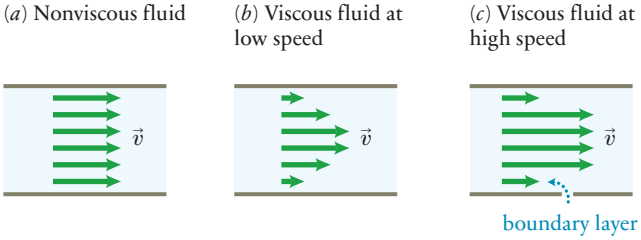
18.8 Instead of laminar fluid flow past a stationary object as in Figure 18.18*a*, consider the motion of an object moving at constant velocity through a stationary fluid. Do you expect the flow pattern surrounding the object to be the same as in Figure 18.18*a* or different?

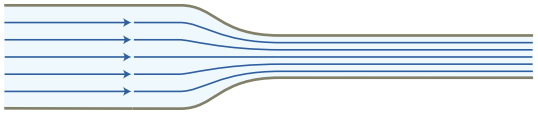
To prevent turbulence and minimize energy dissipation at high flow speeds, it helps to *streamline* objects, which means to adjust their shape so as to maintain streamline flow around them. For example, when an object has a rounded upstream end and a long, tapered downstream tail, as in Figure 18.18*d*, the turbulent wake is very narrow and the flow pattern is similar to the low-speed flows illustrated in Figure 18.18*a* and *b*. At the surface of a streamlined object such as the one in Figure 18.18*d*, the fluid is still stationary, but the flow speed increases rapidly over a thin boundary layer. Outside this boundary layer, the flow resembles that of a nonviscous fluid.

Now that we have some general feeling for fluid flow, let us look at flow through a pipe. In a pipe of fixed diameter, the streamlines are all parallel to the walls of the pipe. For an (ideal) nonviscous fluid flowing through such a pipe, the flow speed is the same everywhere and the pipe offers no resistance to the flow (**Figure 18.19*a***). For any viscous fluid at low flow speed, the flow speed is zero at the pipe walls and highest at the center (Figure 18.19*b*). At high flow speed, the speed is more constant across the diameter of the pipe, dropping off only in a boundary layer (Figure 18.19*c*). The higher the speed, the thinner the boundary layer.

Let us next consider flow through a constriction in a pipe (**Figure 18.20*a***). To simplify matters, we ignore any turbulence or boundary-layer effects. The first thing to note is that the streamlines must crowd together in the narrow part of the pipe. (A streamline cannot have an end because that would mean a fluid particle moving along that streamline would come to a stop.) Therefore the density of streamlines is greater in the narrow part than it is in the wide part.

Figure 18.19 Flow speed patterns through a pipe of fixed diameter.





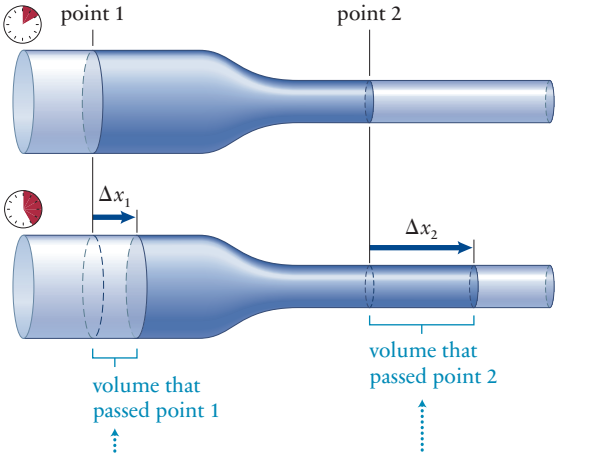


Figure 18.20 What happens when a fluid flows from a wider region of a pipe into a narrower region.

(*a*) When a pipe carrying a fluid narrows, the streamlines get closer together

(*b*) Where the pipe is narrower, the fluid must flow faster

If the flow is laminar, the mass of the fluid passing point 1 in a given time interval in the wide part must be equal to the mass of the fluid passing point 2 in the narrow part in that time interval (Figure 18.20*b*). (If that were not the case, mass would accumulate between those two points and the flow would not be laminar.) Consequently, in a given time interval, the displacement Δx_2 of a fluid particle moving through the narrow part is greater than the displacement Δx_1 of a fluid particle moving through the wide part. This means that the overall fluid flows faster in the narrow part of the pipe where the density of streamlines is greater than in the wide part.

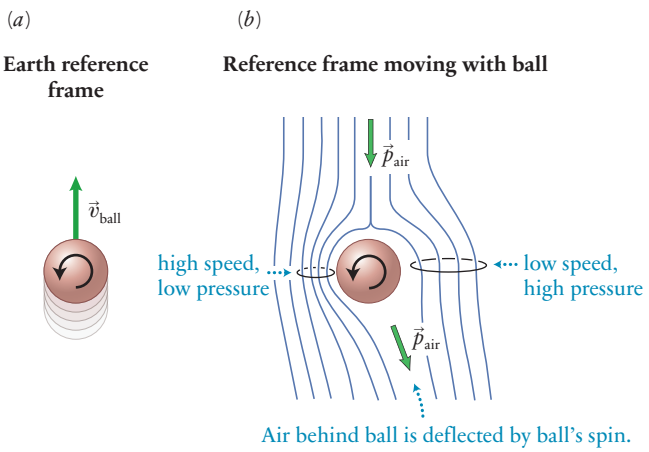
A flowing fluid speeds up when the region through which it flows narrows and slows down when the region through which it flows widens. The density of streamlines reflects the changes in flow speed: When streamlines in a laminar flow get closer together, the flow speed increases; when they get farther apart, the flow speed decreases.

This principle applies to every particle of a moving fluid. Thus each particle must accelerate as it moves

CONCEPTS

along a streamline from the wide part of the pipe to the narrow part. This means that the surrounding fluid must exert a force to the right on the particle while it is in the tapered region of the tube in Figure 18.20. Because the force exerted on fluid particles is a measure of the pressure in the fluid, the pressure is greater in the wide part of the pipe than in the narrow part.

When the flow speed in a laminar flow increases, the pressure in the fluid decreases.



This effect is sometimes called the *Bernoulli effect* after the Swiss physicist who first described the pressure difference quantitatively. The pressure difference occurs along the streamlines. Because there is no flow in the direction perpendicular to a streamline, the pressure must be the same across neighboring streamlines.

There are many examples of the Bernoulli effect. During a storm, fast winds blowing over the roof of a house cause the pressure above the roof to be lower than the pressure in the still air inside the house, creating an upward force on the roof. In extreme circumstances, this force can be great enough to lift the roof off the house. When a large truck speeds past a stationary car, the fast-moving air between the car and the truck has a lower pressure than the still air on the other side of the car, and consequently the car is pulled toward the truck.

Another familiar example is the curved, gravity-defying motion of a rapidly moving, spinning ball. **Figure 18.21***a* shows a top view of a curveball—a baseball thrown with a counterclockwise spin. Because of friction between the surface of the ball and the air, air is dragged around with the spinning ball as the ball moves through the air. Figure 18.21*b* shows the air movement viewed from a reference frame moving along with the ball. The motion of the air caused by the spinning of the ball adds to the flow of air past the ball, causing the air behind the ball to be deflected to the right and the air on the left of the ball to move faster than the air on the right. The deflection of the air means that the direction of the momentum of the air shifts rightward, and that change must be accompanied by an equal-magnitude leftward momentum change for the ball. Alternatively, according to the Bernoulli effect, the pressure in the air to the left of the ball is lower than the pressure to the right, causing a leftward force on the ball. Both of these effects make the ball veer to the left. Likewise a tennis ball that has "top spin" (meaning the top of the ball spins in the direction of the ball's translational motion) curves sharply downward.

The dimples on the surface of golf balls increase the friction between the air and the ball surface to enhance the effect of spin. A golf ball struck with a club is given a rapid backspin because of the slant of the club's face. The backspin forces the air behind the ball downward, causing the ball to experience a lift that carries it farther than it would travel without spin. The lift gained by the backspin more than compensates for the loss of range resulting from air drag.

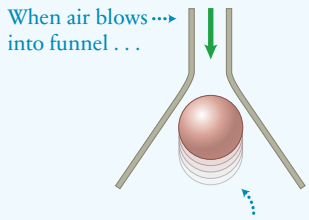


Figure 18.21 Motion of a spinning ball as seen (*a*) from the Earth reference frame and (*b*) from a reference frame moving along with the ball. Because the air is dragged along with the ball surface, the air moves faster to the left of the ball and more slowly to the right of the ball.

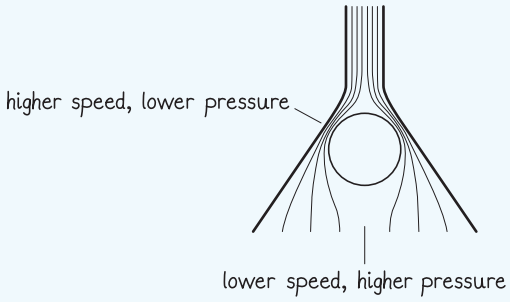
EXAMPLE 18.3 Magic pull

When air is blown downward into the narrow opening of a funnel (**Figure 18.22**), a lightweight ball initially positioned below the wide opening is pulled up into the funnel and held in place. Explain how the ball can be pulled upward even though the airflow and gravity are both directed downward.

Figure 18.22 Example 18.3.

❶ **GETTING STARTED** I know that if I were to blow against the ball, it would move away from me. So I reason that to pull the ball upward, there must be exerted on it an upward force that is greater than the combined effect of the downward gravitational and airflow forces. The ball is subject to an upward buoyant force, but I know this force is smaller than that of gravity alone because a ball—even a lightweight one—does not float in air. So there must be an additional force pulling the ball upward. Because this force is absent when no air flows past the ball, that flow must be causing the upward force.

❷ **DEVISE PLAN** To understand the effects of the flowing air, I should sketch the streamlines (I assume laminar flow). The density of the streamlines tells me how the speed of the flow varies, and from this information I can determine how



(Continued)

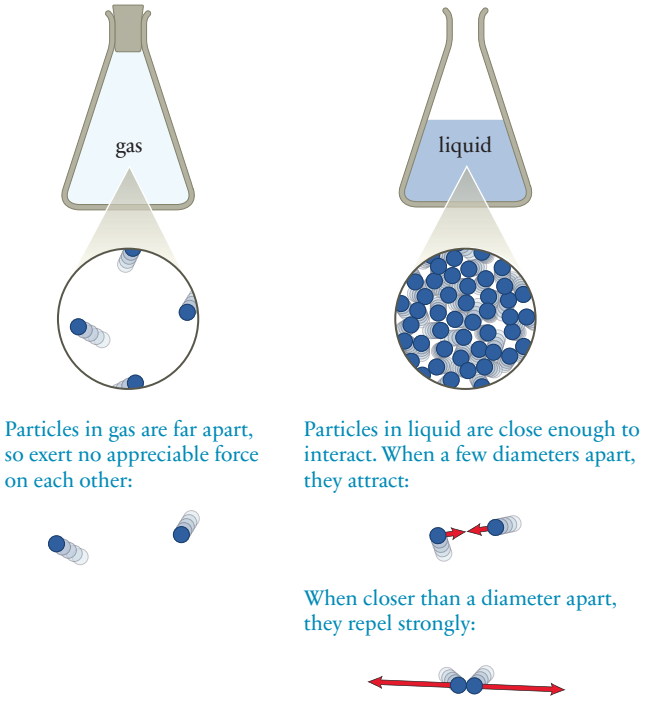
CONCEPTS

the air pressure varies around the ball, which in turn tells me in which direction the air exerts a force on the ball.

❸ **EXECUTE PLAN** **Figure 18.23** shows how the streamlines must bend around the ball. In order to pass around the ball, they must be squeezed together between the ball and the sides of the funnel. At the bottom of the funnel, the diameter of the funnel is very wide and so the streamlines are spaced far apart. This tells me that the flow speed is smaller below the ball than above it and consequently that the pressure is greater below the ball than above it. This pressure difference causes an upward force on the ball. If the pressure difference is great enough, this force can exceed the combined effect of the force of gravity and the downward force of the airflow on the ball. ✔

Figure 18.23

❹ **EVALUATE RESULT** My answer is consistent with the observation given in the problem statement, even though the ball's being pulled *upward* by a downward flow of air seems nothing short of magic! I assumed the flow to be laminar, which may not be entirely correct for an object like a ball (which is not streamlined). However, because air is a gas and because gases have very low viscosity, the assumption that the flow remains laminar is not unreasonable.



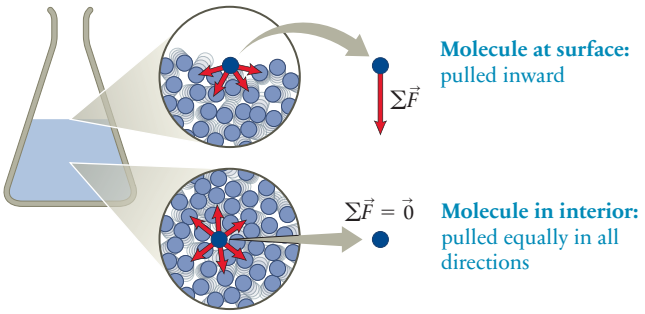
CONCEPTS

18.9 The cloth roof of a convertible car often bulges at high speed, even when the top fits tightly and no wind is getting caught under it. Explain what causes the bulging.

18.4 Surface effects

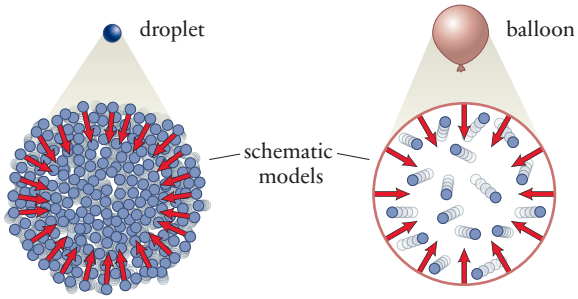
A distinguishing feature between liquids and gases is that liquids have a well-defined surface but gases do not. If you put a gas in an open container, the gas escapes. A liquid, however, remains in the container it is placed in, and small quantities of liquid placed on a solid surface form drops. In each case, the liquid has a well-defined surface that separates it from the surrounding air. On a small scale—that is, for small quantities of liquid and for small objects—this surface behaves like an elastic skin, pulling small volumes of liquid into drops and supporting small objects such as dust particles or water spiders.

Figure 18.24 Interaction between fluid particles in a gas when the particles are far apart and in a liquid when they are closer together.



We can understand the behavior of liquid surfaces by considering what happens at the molecular scale. When the particles in a fluid are far apart, they exert no appreciable force on one another (**Figure 18.24**). As they get closer together, however, the interaction between particles has both an attractive and a repulsive component. At a distance of a few particle diameters, particles exert attractive forces, called *cohesive forces*, on one another. When the separation distance becomes less than a particle diameter, however, the particles strongly resist being pushed closer together, resulting in very strong *repulsive forces* between particles. In a gas, the particles move at such great speed and their separation distances are so great that the cohesive forces are negligible. In other words, the gas particles essentially don't interact except when they collide and exert repulsive forces on one another.

Cohesive forces play an important role in liquids, however. The piston in Figure 18.5*a* stays in position because of the cohesive forces in the liquid, for instance. Likewise, if you press pure water with no air dissolved in it between two smooth plates, an enormously large force is required to separate the plates.



The cohesive forces between particles cause a liquid surface to act like a stretched elastic sheet that tends to minimize the surface area. To see why this happens, compare the forces exerted on a particle in the interior of a liquid with those exerted on a particle at the surface. The interior particle experiences attractive forces

Figure 18.25 The cohesive forces between molecules in a liquid cause a liquid surface to act like a stretched elastic sheet. Consequently, small volumes of liquid tend to adopt a spherical shape.

(*a*) Difference between vector sum of cohesive force on molecules at the surface and in the interior of a liquid

(*b*) Balloon as analogy for surface forces on liquid droplet

Inward pull on surface molecules tends to make droplet spherical.

Stretched balloon skin exerts analogous inward force on gas.

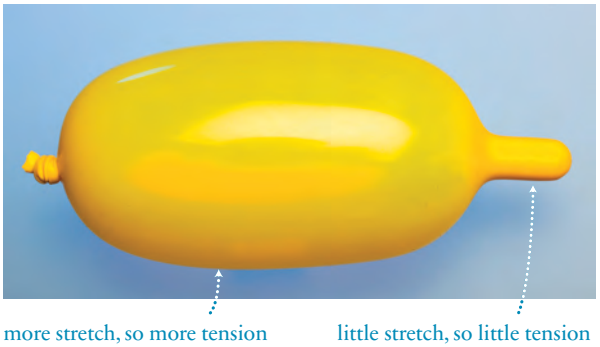
from neighbors in all directions, and the vector sum of these forces is zero. At the surface, however, there are no neighbors above the particle, and so the vector sum of the cohesive forces points into the liquid perpendicular to the surface. The surface particles cannot move into the liquid, however, because as they are pulled inward, they experience a strong repulsive outward force from neighbors.

Because of the inward pull on all surface particles, a small volume of liquid tends to arrange itself in the shape of a sphere (**Figure 18.25**). In a gas there is no attraction between neighboring particles, and therefore a collection of gas particles tends to fly apart, expanding into all available surrounding space. To keep gas particles together, you can put them inside a balloon. The stretched balloon pushes inward on the gas particles, exerting a force on them and keeping them together. The effect of the inward pull on the surface particles in a liquid is much like the force exerted by a balloon on the particles in a gas. The liquid surface thus acts like a membrane that is under tension and that pulls the liquid together in a spherical shape.

Figure 18.26 Astronaut Kevin Ford watches a water bubble float freely between him and the camera aboard the International Space Station. When no large gravitational force is involved, even a large volume of liquid coalesces into a spherical shape.

Just as an inflated balloon is said to be under tension, so do we say that a liquid surface has *surface tension*. In the absence of gravity, surface tension causes even large volumes of liquid to take on a spherical shape (**Figure 18.26**). In the presence of gravity, however, drops of liquid are not perfectly spherical, with larger drops flattening out more than small ones. The reason for the difference in how much large and small drops lose their spherical shape is that only particles on the drop surface are pulled into the spherical shape. The force of gravity, in contrast, pulls on all particles in a volume of liquid, not just those in the surface layer. To state it another way, surface tension is a surface effect but gravity is a volume effect. As the next exercise shows, the relative importance of these two effects changes with drop size.

CONCEPTS



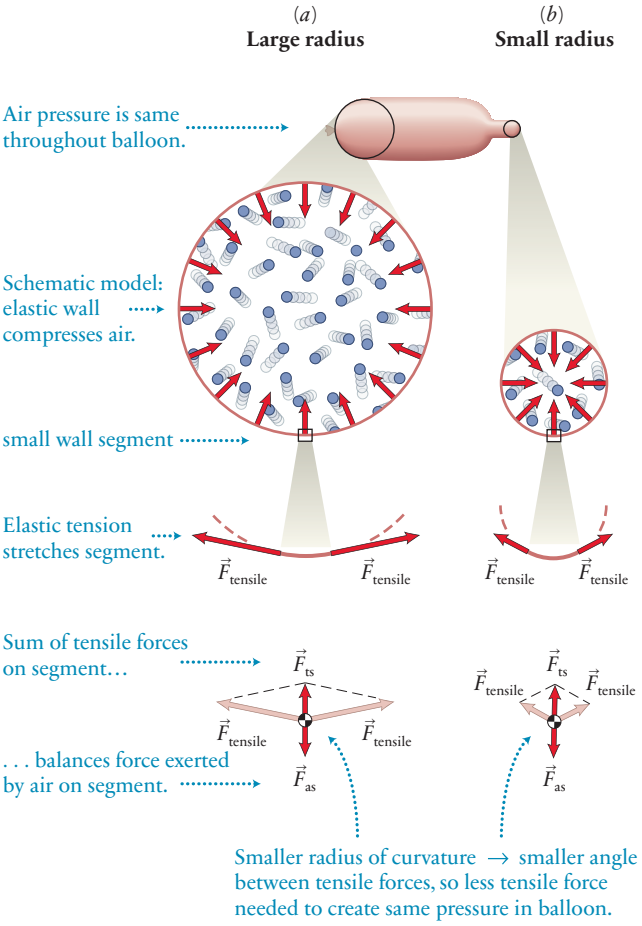
EXERCISE 18.4 Scaling a drop

Suppose surface tension increases in direct proportion to surface area (an oversimplification!). How does the ratio of surface tension to the force of gravity exerted on a drop change as the drop diameter increases tenfold?

SOLUTION The force of gravity is proportional to the mass of each drop, which is proportional to each drop's volume. The ratio of surface tension to the force of gravity on each drop is therefore proportional to the surface-area-to-volume ratio. For simplicity, I approximate the smaller drop as a sphere with diameter d. This means that I should compare the surface-area-to-volume ratio of this sphere with the surface-area-to-volume ratio of a sphere of diameter $10d$.

The surface area of a sphere of radius $R = \frac{1}{2}d$ is $4\pi R^2 = \pi d^2$, and its volume is $\frac{4}{3}\pi R^3 = \frac{4}{3}\pi(d/2)^3 = \frac{1}{6}\pi d^3$, and so the surface-area-to-volume ratio of a sphere is $(\pi d^2)/(\frac{1}{6}\pi d^3) = 6/d$. The surface-area-to-volume ratio thus decreases by a factor of 10 as the diameter of the drop increases by a factor of 10. ✔

Figure 18.27 A partially inflated balloon. The tension is greatest where the rubber is stretched the most.



The analogy between surface tension and the tension in the rubber of a balloon allows us to draw some important conclusions. Consider, for example, the air-filled balloon of **Figure 18.27**. The rubber in the uninflated end of the balloon is less stretched than the rubber in the inflated part, and so there is less tension in the uninflated rubber than in the inflated rubber. (You may have noticed that balloons are softest and most easily squeezed where they are least inflated.) To understand how the tension in a balloon relates to its shape and to the pressure in the air inside the balloon, answer the following checkpoint first.

18.10 How does the air pressure in the uninflated part of the balloon in Figure 18.27 compare with the air pressure in the inflated part?

Did the answer to Checkpoint 18.10 surprise you? How can one part of the balloon be soft and another part hard if the air pressure is the same everywhere inside the balloon? The reason has to do with *radius of curvature*, which is the radius of the circle that approximates a curve at the point under consideration. As **Figure 18.28** shows, the radius of curvature is different in the two parts. The air pressure must be the same in the two parts, as you learned in Checkpoint 18.10, and the inward force exerted by the rubber surface of the balloon on the air inside is caused by the tension in the rubber. As you can see by comparing the free-body diagrams for a small surface segment in Figure 18.28*a* and *b*, the smaller the radius of curvature, the smaller the tensile force needed to provide a given inward force. In the part of the balloon where the radius of curvature is smaller, the angle of the tensile forces is large and so smaller tensile forces add up to the same vector sum. Indeed when the radius is smaller, the rubber is stretched less and so the tensile force is smaller.

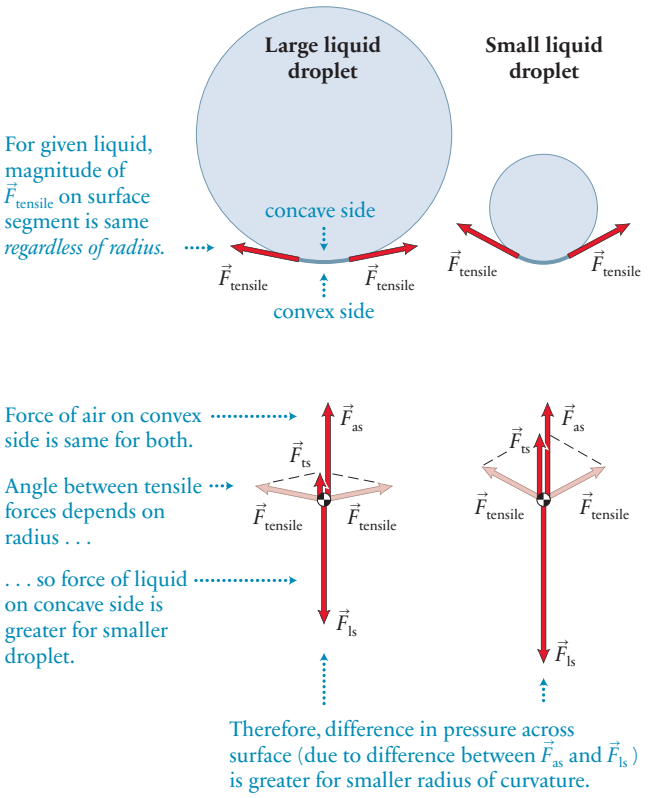
Figure 18.28 The reason why the balloon in Figure 18.27 has an uninflated end. Because the air pressure must be the same everywhere inside a balloon, areas with a small radius of curvature must have smaller-magnitude tensile forces than areas with a larger radius of curvature.

CONCEPTS

In an elastic membrane enclosing a gas, tension in the membrane increases with increasing radius of curvature, but the pressure is the same everywhere inside the volume enclosed by the membrane, as required by Pascal's principle.

The situation is different with liquids because a liquid surface is not exactly like a stretched rubber skin. In particular, surface tension in a liquid is determined entirely by the cohesive forces between the liquid particles and is constant regardless of the shape of the liquid surface. So the tensile forces exerted on a given segment of the infinitesimally thin surface layer separating liquid and gas are the same no matter what the radius of curvature of the surface is. As shown in **Figure 18.29**, these constant tensile forces exerted on the surface segment of a liquid droplet cause a greater inward force when the radius of curvature is small.

Figure 18.29 Because surface tension in a liquid is independent of the shape of the liquid surface, a small liquid sphere has a greater internal pressure than a larger liquid sphere.



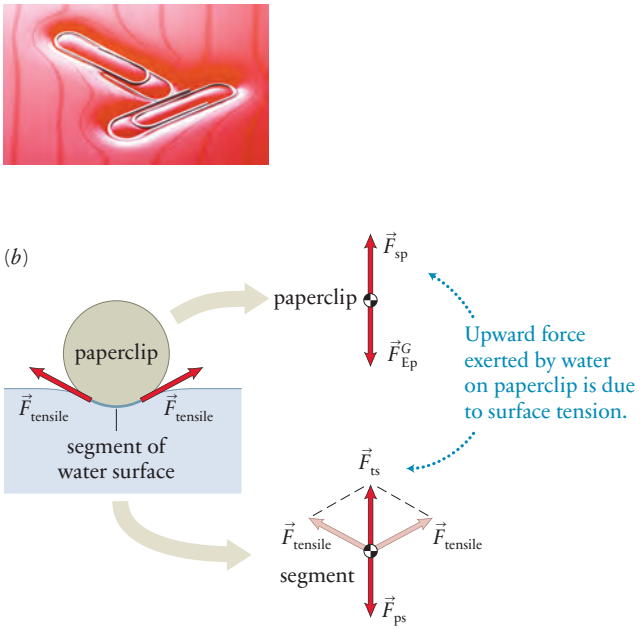


Figure 18.30 Surface tension enables paperclips to float on water.

Because the segment is at rest, this inward force on the segment must be balanced by the forces exerted by the liquid and air on either side of the surface layer. The outward force exerted by the liquid on the segment is therefore greater than the inward force exerted by the air on the segment. Because these forces result from the pressures in the fluids on either side of the surface, we can conclude that the pressure in the liquid on the concave side of the surface must be greater than the pressure in the air outside the droplet. We will refer to this difference as the *pressure difference across the surface:*

> **As the radius of curvature of a liquid surface decreases, the pressure difference across the surface increases, with the pressure being greatest on the concave side of the surface.**

This statement and the earlier boldfaced statement describing pressure in a membrane-enclosed gas are consequences of **Laplace's law,** which relates surface curvature to surface tension and to the pressure in a liquid.

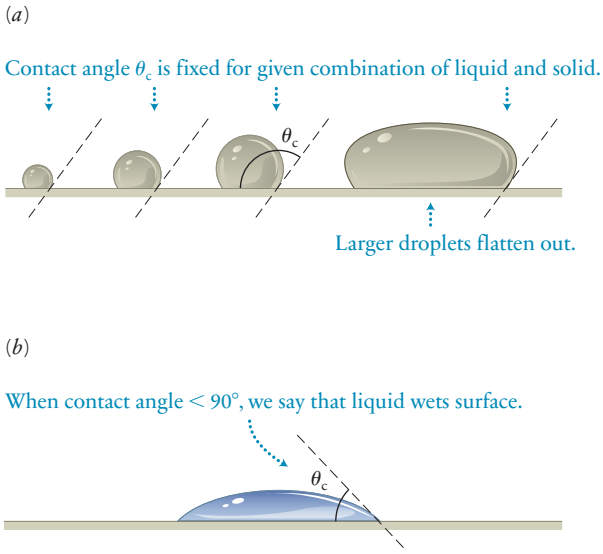
Surface tension makes it possible for small insects to walk on a water surface and for small objects to float on a liquid surface. For example, if you carefully place a steel paperclip on a water surface, it stays there even though a thicker steel cylinder would sink (**Figure 18.30*a***). There are two ways to explain this. The first is to invoke Laplace's law: The water surface beneath the paperclip is concave up and so the pressure above the surface is greater than the pressure just below it. The pressure just below the surface where the paperclip rests is atmospheric pressure, while the pressure above the surface where the paperclip rests is atmospheric pressure plus the pressure caused by the force exerted by the paperclip on the surface.

The second way to explain why the paperclip floats is illustrated in Figure 18.30*b*, which shows free-body diagrams for the segment of the surface just below the paperclip and for the paperclip. The tensile forces due to surface tension balance the downward force $\vec{F}_{\text{ns}}$ exerted by the paperclip on the surface segment. This downward force $\vec{F}_{\text{ns}}$ forms an interaction pair with the upward force $\vec{F}_{\text{sn}}$ exerted by the surface segment on the paperclip, which balances the downward force of gravity on the paperclip and makes the paperclip float.

18.11 (*a*) What is the difference between the pressure just below the water surface in a pool and the pressure in the air just above it? (*b*) Is the pressure inside a raindrop greater than, equal to, or smaller than the pressure in the surrounding air? (*c*) How does the pressure inside a small raindrop compare with the pressure inside a larger raindrop?

CONCEPTS

Figure 18.31 Small drops are nearly spherical; larger ones flatten out. For a given combination of liquid and solid surface, the contact angle is fixed and does not depend on the drop size or shape.



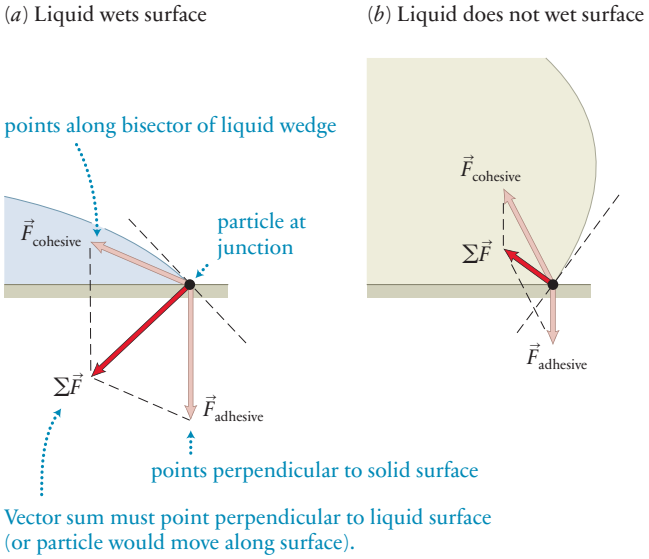


Figure 18.32 Free-body diagrams for a particle at the gas-liquid-solid junction for a liquid that (*a*) wets and (*b*) does not wet a horizontal surface.

A liquid surface that comes in contact with a solid surface forms an angle with the solid surface (**Figure 18.31**). This angle, called the *contact angle*, is the same for a given liquid-solid combination (Figure 18.31*a*).* The contact angle is defined as the angle between the solid surface and the tangent to the liquid surface at the point where liquid and solid meet; the contact angle is always measured in the liquid. If the contact angle is smaller than 90°, the liquid is said to *wet* the solid surface (Figure 18.31*b*). If the contact angle is greater than 90°, as in Figure 18.31*a*, the liquid does not wet the surface; it forms drops instead of spreading out and wetting the surface.

The contact angle is strongly influenced by how smooth and clean the solid surface is and by the presence of impurities in the liquid. For example, water beads up into drops on a paraffin wax surface, but adding a bit of soap to the water makes the drop spread out and wet the paraffin surface.

The contact angle for a liquid on a solid surface is due to the interplay between the cohesive forces between the particles in the liquid and the *adhesive forces*† between the liquid particles and the atoms in the solid. Consider, for example, a particle at the point where the surface meets the solid (**Figure 18.32**). This particle is subject to a cohesive force exerted by a wedge of liquid and an adhesive force exerted by the solid surface. Symmetry requires the cohesive force to be directed along the bisector of the wedge. Likewise, the adhesive force must be perpendicular to the solid surface. (If the adhesive force were not perpendicular to the solid surface, there would be a flow tangential to the surface in response to any tangential component of that force.) Ignoring the effects of gravity (which are very small on a single particle), we can say that the vector sum of the forces exerted on the particle is the sum of the cohesive force and the adhesive force. Because the liquid cannot sustain any shear force, the vector sum of the forces on any particle at its surface must always be perpendicular to the surface (see Section 18.1). Given the directions of these two forces and their vector sum, their relative magnitudes are fixed. For example, for a liquid that wets a solid with a contact angle of 60° or smaller, the adhesive force is always greater than the cohesive force (Figure 18.32*a*), while for a nonwetting combination, the cohesive force is always greater than the adhesive force (Figure 18.32*b*).

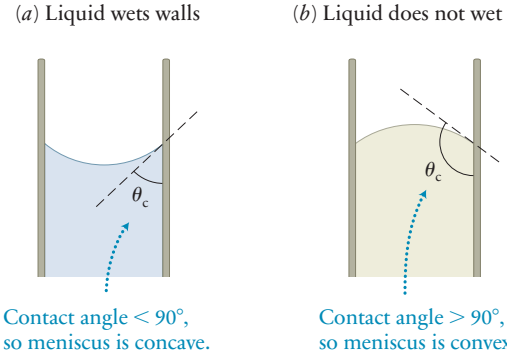
The contact angle also determines the shape of the edges of a liquid surface at any container walls (**Figure 18.33**). In a very narrow tube, called a *capillary* tube (after the Latin word for *hair*), the surface of a liquid is curved. This curved surface, called a **meniscus,** is concave when the liquid wets the walls of the capillary tube (Figure 18.33*a*) and convex when the liquid is nonwetting (Figure 18.33*b*). By looking closely at the edge of the surface of a liquid in a glass, you can determine whether or not the liquid wets the glass.

CONCEPTS

*The gas surrounding the liquid and solid also affects the contact angle. Because this effect is generally very small, we shall ignore it.

†Cohesive forces are exerted between like particles. Adhesive forces are exerted between unlike particles.

Figure 18.33 The concave or convex shape of the surface of a liquid in a capillary tube is determined by the contact angle.



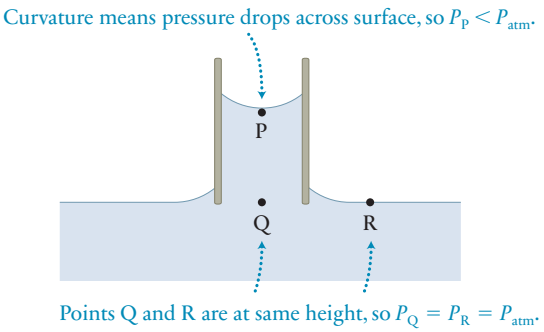


Figure 18.35 The pressure difference across the concave surface of a liquid that wets the walls of a capillary tube causes the liquid to rise in the tube, a phenomenon called *capillary rise*.

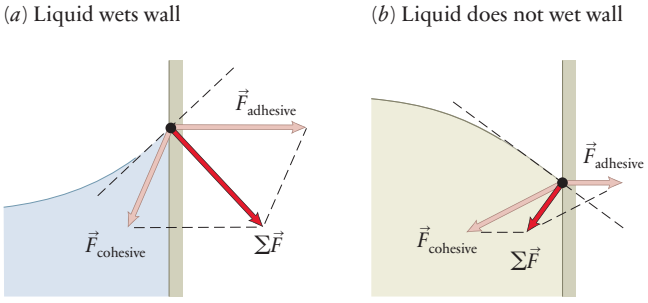
The free-body diagrams for a particle at the point where the liquid surface meets the glass are shown in **Figure 18.34** for a concave meniscus and a convex meniscus. Notice the similarity with the free-body diagrams in Figure 18.32.

The formation of a meniscus is responsible for the rise of liquid in a capillary tube, as **Figure 18.35** shows. Because the meniscus is concave, the pressure at point P in the liquid, just below the meniscus, must be smaller than the atmospheric pressure just above the meniscus. The pressure at Q, a point directly below P and at the same height as the surface of the liquid surrounding the capillary tube, must be the same as the pressure at R (otherwise the liquid would flow so as to eliminate any horizontal pressure difference). Because the surface at R is flat, there is no pressure difference across the surface, and so we know that the pressure at R (and therefore the pressure at Q) is equal to atmospheric pressure. The pressure difference between points P and Q causes an upward buoyant force to be exerted by the liquid in the tube between P and Q, causing a *capillary rise* until the downward force of gravity exerted on the liquid that has been raised into the tube balances the upward force due to the pressure difference. As illustrated in **Figure 18.36**, capillary rise is more pronounced in a narrow tube. The narrower the tube, the smaller the radius of curvature of the meniscus. As we know from Laplace's law, a smaller radius of curvature means a greater pressure difference across the surface and therefore a greater upward force on the liquid.

18.12 Explain why surface effects cannot support a large solid cylinder made of the same material as a needle.

Figure 18.34 Free-body diagrams for a particle at the gas-liquid-solid junction for a liquid that (*a*) wets and (*b*) does not wet a vertical surface.



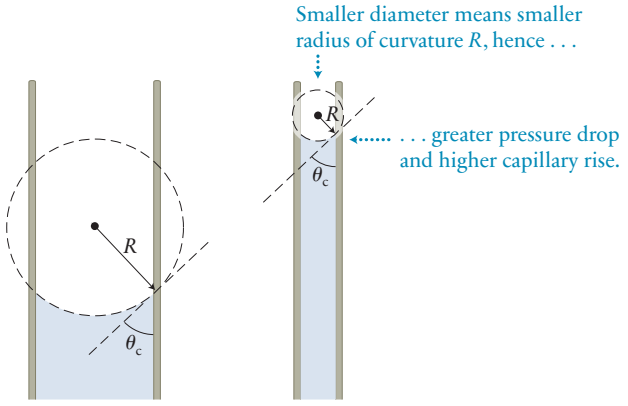


Figure 18.36 The narrower the tube, the greater the capillary rise.

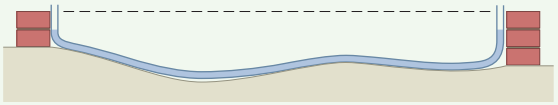
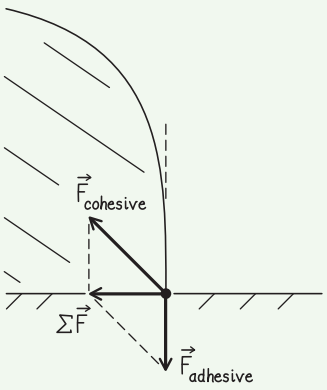


CONCEPTS

Self-quiz

1. Masons use a hose open at both ends and filled with water to ensure that the blocks they lay remain level (**Figure 18.37**). How does such a hose help them do this?

Figure 18.37



2. (*a*) Imagine a rock and a balloon of the same volume completely submerged in water. How do the buoyant forces exerted on them compare? (*b*) How do the buoyant forces compare when the balloon volume is half the rock volume? (*c*) Which object floats and which sinks in part *a* and in part *b*?
3. For a thrown ball to rise, what type of spin should the thrower place on it?
4. (*a*) Draw a free-body diagram analogous to Figure 18.32 for a gas-liquid-solid boundary at which the contact angle is 90°. Make your solid surface horizontal. (*b*) How do the magnitudes and directions of the adhesive and cohesive forces exerted on your particle compare? (*c*) How does the magnitude of the cohesive force between two liquid particles compare with the magnitude of the adhesive force between a liquid particle and an atom in the solid?
5. (*a*) Imagine a capillary tube placed in a nonwetting liquid (as opposed to the wetting-liquid situation of Figure 18.35). How does the pressure at a point P just below the now convex surface compare with atmospheric pressure? (*b*) How does the level in the tube compare with the level of the liquid outside the tube?

Answers

1. The air pressure at both water surfaces is atmospheric pressure. Therefore the height of the water surface at the left end of the hose must be the same as the height of the water surface at the right end, in order to balance the pressure throughout the water. If the masons align the two ends of the hose with the two ends of a row of blocks and no water bubbles out of either end of the hose, the two ends of the wall are at the same height, meaning the row is level.
2. (*a*) Because the rock and balloon occupy the same volume, they displace the same volume of water, and so the surrounding water exerts equal buoyant forces on them. (*b*) The smaller volume of the balloon displaces a smaller volume of water, and so the buoyant force exerted on the balloon is half the buoyant force exerted on the rock. (*c*) In either case, the balloon rises and the rock sinks. The buoyant force on a rock is always smaller than the force of gravity exerted on it. Likewise the buoyant force on a submerged balloon is always greater than the force of gravity exerted on it, regardless of the volume of the balloon.
3. The thrower needs to place a "backspin" on the ball, which is a spin in which the top of the ball moves toward the thrower. This direction of spin causes the speed of the air relative to the surface of the ball to be greater at the top of the ball than at the bottom. Consequently the air pressure is smaller at the top of the ball than at the bottom. As a result, the ball is subject to an upward force due to this pressure difference.
4. (*a*) See **Figure 18.38**. A contact angle of 90° means that the tangent line to the drop at the contact point is vertical. (*b*) The cohesive force makes an angle of 45° with the horizontal, and the adhesive force is directed vertically downward. The vector sum of the forces must be horizontal, perpendicular to the tangent to the drop at the contact point. The cohesive force is greater than the adhesive force because the vertical component of the cohesive force must cancel the vertically downward adhesive force. (*c*) They are equal. For a particle on the liquid-solid boundary, there are solid atoms below the boundary, liquid particles above the boundary, and liquid particles to the left and the right. The vector sum of the forces exerted on the liquid particle at the boundary is zero and so the magnitude of the cohesive forces between two liquid particles must be the same as the magnitude of the adhesive force between a liquid particle and an atom in the solid.

Figure 18.38

5. (*a*) Because the surface is convex, the pressure at P is greater than atmospheric pressure. (*b*) Because the pressure at R is still atmospheric pressure, the difference in pressure causes a downward force on the liquid in the tube and a resulting *capillary fall*.

18.5 Pressure and gravity

In the first part of this chapter we defined the ratio of the magnitude of the force $\vec{F}^{\perp}_{\text{fs}}$ exerted by a fluid on a surface and the area A of that surface as the **pressure** in a fluid:

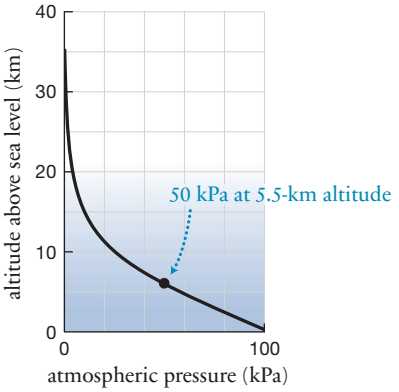
$$P \equiv \frac{F^{\perp}_{\text{fs}}}{A}. \tag{18.1}$$

Pressure is a scalar, and the SI unit of pressure is newtons per meter-squared, N/m^2. This derived unit is called the **pascal** (Pa), in honor of the French scientist Blaise Pascal:

$$1\ \text{Pa} \equiv 1\ \text{N/m}^2. \tag{18.2}$$

This definition means that a fluid in which the pressure is 1 Pa exerts a force of magnitude 1 N on a 1-m^2 area of the container that holds the fluid. Because a pressure of 1 Pa is very small, pressures are often given in kilopascals: 1 kPa = 1000 Pa. For example, the average pressure in the atmosphere at sea level is

$$P_{\text{atm}} = 101.3\ \text{kPa}. \tag{18.3}$$



This pressure is sometimes referred to as 1 atmosphere (1 atm). *Atmosphere* is not an SI unit, however, and so any pressure given in atmospheres must be converted to an SI unit (pascals or kilopascals) before you can do most calculations.

Inside a box that contains absolutely no atoms or molecules, the pressure is zero because nothing exerts a force on the walls of the box. The box is said to contain a *perfect vacuum*. In practice, a perfect vacuum does not exist because it is impossible to remove every particle from a volume of space. Even in deep outer space, the pressure, though very small, is nonzero. In practice, a *vacuum* is any space in which the pressure is less than about 1 Pa. In such a vacuum, $P = 0$ is a very good approximation.

There are several contributions to pressure in a fluid. One contribution is from the gravitational force exerted on the fluid. The pressure in the atmosphere at sea level, for example, is due to the gravitational force exerted by Earth on all the air surrounding the planet. Other contributions are from the motion of the fluid and, when the fluid is a liquid, from the curvature of the liquid surface. A fourth contribution is from the collisions that take place between the fluid particles, and between the fluid particles and the container walls—the pressure in an inflated balloon is an example of this fourth contribution. We'll discuss this contribution to the pressure in a gas in more detail in Chapter 19. In the remainder of this chapter, we concentrate on the gravitational, motion, and surface contributions to pressure.

Let us begin by looking at a familiar type of pressure, the *atmospheric pressure* that results from the air surrounding Earth. The atmosphere can be modeled as an "ocean" of air extending from the ground up. Because gases are compressible, the distribution of gas molecules in the air is not uniform. All the molecules are attracted to the ground by Earth's gravitational pull, which means that higher-up molecules press down on lower ones, compressing the air and making the mass density high near sea level and lower at altitudes above sea level. Because gases are compressible, the relationship between atmospheric pressure and altitude is complicated by the fact that the mass density of air varies with altitude. **Figure 18.39** shows how the average atmospheric pressure varies with altitude. If the mass density of air were constant, the curve would be a straight line with a negative slope. If the extremes were as in Figure 18.39—100 kPa at sea level and essentially zero at 30 km—the atmospheric pressure at the midpoint

Figure 18.39 Variation in atmospheric pressure with altitude above sea level.

QUANTITATIVE TOOLS

between these two altitudes, 15 km, would be half of its sea-level value. Instead we see a nonlinear relationship in Figure 18.39, with the pressure at 50 kPa, half the sea-level value, not at an altitude of 15 km but at a mere 5.5 km. This means that half of the atmosphere is below 5.5 km. At the cruising altitude of a commercial airplane (10 km), the atmospheric pressure is about one-quarter of what it is at sea level, meaning that 75% of the atmosphere is below the airplane. At an altitude of 100 km, the pressure in the atmosphere drops to about 1 Pa, close to vacuum.

Even though the changes in atmospheric pressure are considerable over large distances, they are usually negligible over small vertical distances because, even at its densest, at sea level, the mass density of air is so small. Near sea level, for example, the atmospheric pressure drops 12 Pa for every meter of altitude. The pressure difference between the air near your feet and the air near your head is therefore about 20 Pa, which is negligibly small relative to atmospheric pressure, 1×10^5 Pa.

EXAMPLE 18.5 Altimeter

Airplane cabins are pressurized to prevent passengers from developing altitude sickness during flight. Your altimeter watch, which uses pressure to determine altitude, indicates a cabin altitude of 2500 m even though the captain has just announced that the airplane is flying at an altitude of 10,000 m. If you ignore the motion of the airplane, what do you calculate to be the integral of the magnitude of the force exerted by the air on the fuselage of the airplane, which you estimate to be a cylinder of length 60 m and diameter 6.0 m?

❶ **GETTING STARTED** Pressure decreases with altitude as shown in Figure 18.39. Because the cabin is pressurized, the pressure inside the cabin is greater than it would be if it were allowed to equalize with the exterior atmospheric pressure at 10,000 m. That the altimeter indicates an altitude of 2500 m tells me that the cabin pressure is equal not to atmospheric pressure at sea level (about 100 kPa) but to a value somewhat lower than 100 kPa. (Because I can feel my ears "pop" as the airplane takes off and lands, I know that the cabin pressure must indeed change somewhat.)

❷ **DEVISE PLAN** The force exerted by the air on the fuselage is the vector sum of two forces: an outward force due to the pressure P_{in} inside the cabin and an inward force due to the pressure P_{out} outside the cabin. According to Eq. 18.1, the magnitude of each of these forces is PdA, where dA is the surface area of a segment of the fuselage. Because $P_{in} > P_{out}$, the air exerts on each fuselage segment an outward force of magnitude $(P_{in} - P_{out})dA$. Figure 18.39 gives me the values for P_{out} at 10,000 m and for what the cabin pressure P_{in} must be given that it corresponds to atmospheric pressure at 2500 m. Ignoring the tiny variation in air pressure over the height of the airplane, the values of P_{in} and P_{out} are identical over the entire fuselage, and so I just need to multiply the pressure difference by the surface area $A = \int dA$ of the entire fuselage to compute the integral of the magnitude of the forces exerted on the fuselage.

❸ **EXECUTE PLAN** From Figure 18.39, I see that $P_{out} = P_{10\,km} = 24$ kPa and $P_{in} = P_{2.5\,km} = 80$ kPa, so $P_{in} - P_{out} = 80$ kPa $-$ 24 kPa $= 56$ kPa. The surface area of the (assumed) cylindrical fuselage is equal to circumference times length plus the surface area of the two circular ends: $A = 2\pi R\ell + 2\pi R^2 = 2\pi(3.0\text{ m})(60\text{ m}) + 2\pi(3.0\text{ m})^2 = 1.2 \times 10^3\text{ m}^2$. The sum of the magnitudes of the forces exerted by the air on the fuselage is thus $(56\text{ kPa})(1000\text{ Pa}/1\text{ kPa})(1.2 \times 10^3\text{ m}^2) = 6.7 \times 10^7$ N. ✔

❹ **EVALUATE RESULT** This force magnitude is very large, corresponding to the force of gravity exerted on 6.8×10^6 kg, or 6800 metric tons! The fuselage does not rupture because the force is distributed over a very large area. For comparison, if the pressure inside the cabin were maintained at a pressure equal to the atmospheric pressure at sea level, the pressure difference across the fuselage would be $P_{in} - P_{out} = 101$ kPa $-$ 24 kPa $= 77$ kPa and the force would be some 40% greater.

18.13 Consider a book lying on a table at sea level with the front cover facing up. The book is 0.28 m tall, 0.22 m wide, and 50 mm thick; its mass is 3.0 kg. How does the force exerted by the atmosphere on the front cover compare with the force of gravity exerted on the book?

The answer to Checkpoint 18.13 is astonishing. With the book under so much pressure, how can anyone lift it? The reason you can is that the air is pushing on the book from all directions. Not only does it push down on the front cover, it also pushes up on the bottom cover. Because the surface areas of the top and bottom covers are the same and because the air

pressure below the book is virtually the same as that above the book, the magnitudes of the upward and downward forces exerted by the atmosphere on the book are the same, and so their vector sum is zero.

You may wonder how the atmosphere can exert an upward force on the bottom cover if the book is lying flat on a table. The reason is that there is always a tiny bit of air between the cover and the table surface, and the air pressure in this layer has to be the same as the air pressure everywhere else around the book (otherwise air would rush into or out of the space between table and cover to eliminate the pressure difference). If you were to remove the air from underneath the book—say, by putting the book on top of the opening of a chamber from which the air has been evacuated—it would be nearly impossible to lift the book off the table.

18.14 A dart that has a suction cup at one end sticks to a ceiling. Describe what force holds the dart against the ceiling.

In contrast to gases, liquids are nearly incompressible, which means that we can take the mass density in a liquid to be uniform. Therefore we can derive a simple expression to describe how the pressure in a liquid varies with height. Consider a cylindrical volume of liquid inside a large stationary body of identical liquid (**Figure 18.40***a*). The cylindrical volume has volume V and horizontal cross-sectional area A, and Figure 18.40*b* shows that three forces are exerted on it in the vertical direction: an upward force exerted by the column of liquid below the bottom of the cylindrical volume (point 1), a downward force exerted by the column of liquid above the top of the volume (point 2), and a downward force of gravity. Because our volume is at rest, the vector sum of the three forces must be zero, and so, with the positive y axis pointing upward, we can say for all the forces exerted on the cylindrical volume in the vertical direction,

$$\Sigma F_{cy} = F^{c}_{1cy} + F^{c}_{2cy} + F^{G}_{Ecy} = P_1A - P_2A - mg = 0, \qquad (18.4)$$

where m is the mass of the liquid in the cylindrical volume. Because the mass density ρ of the liquid is the same everywhere, we can write for the mass of the cylindrical volume $m = \rho V = \rho A(y_2 - y_1)$, and so

$$P_1A - P_2A - \rho A(y_2 - y_1)g = 0 \qquad (18.5)$$

or, dividing all terms by A and bringing terms with the same subscripts to the same side,

$$P_1 + \rho g y_1 = P_2 + \rho g y_2 \quad \text{(stationary liquid)}. \qquad (18.6)$$

Equation 18.6 tells us that the quantity $P + \rho gy$ is the same at the top and bottom of the cylindrical volume. Because the top and bottom are at arbitrary positions, the fact that $(P + \rho gy)_{top} = (P + \rho gy)_{bottom}$ means that the quantity $P + \rho gy$ is the same *everywhere* in the *entire* liquid. In other words, the pressure in a stationary liquid is the same at all points in any given horizontal plane through the liquid (that is, at some fixed value of y).

Rearranging Eq. 18.6 to bring all the terms containing y to one side ($P_1 = P_2 + \rho gy_2 - \rho gy_1$), we see that the pressure at all points in a horizontal plane 1 located a vertical distance $d = y_2 - y_1$ below another horizontal plane 2 is given by

$$P_1 = P_2 + \rho g d \quad \text{(stationary liquid 1 below 2)}. \qquad (18.7)$$

Figure 18.40 Model for describing how the pressure in a liquid varies with height.

(*a*) Imaginary cylindrical volume of liquid at rest inside larger volume of same liquid (*b*) Free-body diagram for cylinder

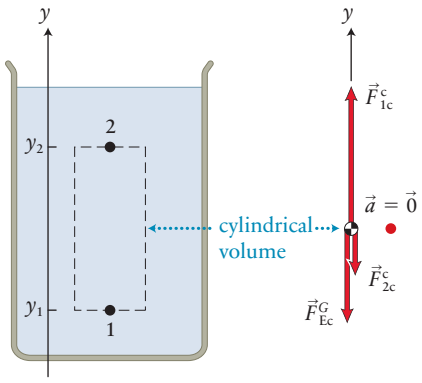


Figure 18.41 If the cylindrical volume is defined such that its top is at the liquid surface, the pressure at the top is equal to atmospheric pressure.

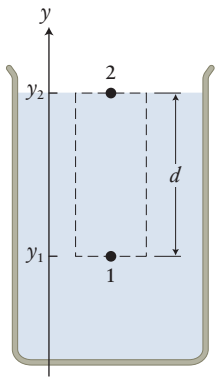

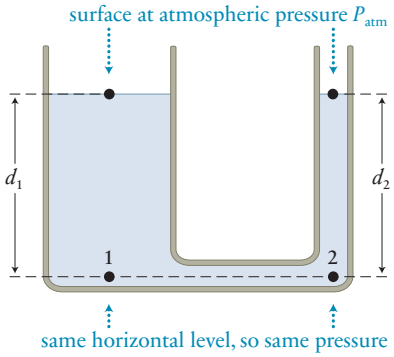

Figure 18.42 Liquid rises to the same level in connected tubes, regardless of their width or shape.

If we let point 2 be at the surface of the liquid (**Figure 18.41**), P_2 is the pressure at the surface, and Eq. 18.7 tells us that the pressure at a depth $d = y_2 - y_1$ below the surface is given by

$$P = P_{surface} + \rho g d \quad \text{(stationary liquid)}. \tag{18.8}$$

This expression shows that the pressure P in a stationary liquid increases with depth or, put differently, P decreases linearly with the height in the liquid, just as we concluded in Section 18.2.

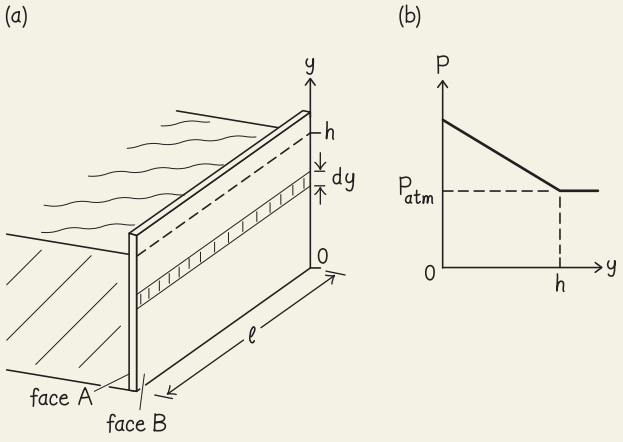
The term that contains g is the gravitational contribution to the pressure and is sometimes referred to as *hydrostatic pressure*.

Now consider two liquid-filled tubes, one wide and one narrow and both open at one end, connected as shown in **Figure 18.42**. In each tube, the pressure at the surface of the liquid is equal to atmospheric pressure. This means that the downward force $P_{atm}A_{wide}$ exerted by the atmosphere on the surface of the liquid in the wide tube is significantly greater than the downward force $P_{atm}A_{narrow}$ exerted by the atmosphere on the surface of the liquid in the narrow tube. How does this difference in force affect the levels of the water in each tube?

To answer this question, let's consider the pressures at points 1 and 2 in Figure 18.42. Because these points are in the same horizontal plane, the pressures must be equal, $P_1 = P_2$. Equation 18.8 tells us that these pressures are related to the (atmospheric) pressure at the surface by

$$P_1 = P_{atm} + \rho g d_1 \quad \text{and} \quad P_2 = P_{atm} + \rho g d_2. \tag{18.9}$$

Because $P_1 = P_2$, we must have $d_1 = d_2$: The liquid rises to the same height in both tubes, even though the forces exerted by the atmosphere on the surfaces of the liquid are different. The reason is that, despite the difference in these downward forces, the *pressure* at the bottom of each tube must be the same ($P_1 = P_2$). If the pressures were not the same, the pressure difference would cause the liquid to flow until the pressure difference is zero, which occurs only when $d_1 = d_2$. The equal height of the liquid surfaces in the two tubes means that these surfaces are in the same horizontal plane. So the pressures at two points in a horizontal plane are the same as long as the two points are connected by an uninterrupted path through the liquid.



EXAMPLE 18.6 Dam

A dam of horizontal length ℓ holds water of mass density ρ to a height h. What is the magnitude of the force exerted by the water on the dam?

❶ **GETTING STARTED** I begin with a sketch (**Figure 18.43*a***). The pressure in the water behind the dam is equal to atmospheric pressure at the water surface and increases linearly with depth as given by Eq. 18.8. If I choose my y axis pointing upward, with the origin at the bottom of the dam, the pressure varies with y as shown in Figure 18.43*b*. For convenience, I call the water side of the dam face A and the opposite side face B.

❷ **DEVISE PLAN** Because the pressure varies with y, the magnitude of the force $\vec{F}_{wd}$ also varies with y. I therefore divide the area of face A into thin horizontal strips each of width dy (Figure 18.43*a*). Because I know the pressure at a given value of y, I can calculate the force dF_{wd} exerted on the strip. To calculate the force exerted by the water on the whole dam, I integrate my expression over y from $y = 0$ at the bottom of the dam to $y = h$ at the water surface.

Figure 18.43

QUANTITATIVE TOOLS

3 EXECUTE PLAN Because a point in the water located at some arbitrary value of y is at a depth $d = h - y$ below the water surface and because $P_{\text{surface}} = P_{\text{atm}}$, I write Eq. 18.8 in the form

$$P(y) = P_{\text{atm}} + \rho g(h - y).$$

The area of each strip is $dA = \ell\, dy$, and so the magnitude of the force exerted by the water on each strip is $dF = P(y)dA = P(y)\ell\, dy$. The magnitude of the force exerted by the water on the entire dam is then

$$F_{\text{wd}} = \int dF_{\text{ws}} = \ell \int_0^h P(y)dy = \ell\,[P_{\text{atm}}y + \rho g h y - \tfrac{1}{2}\rho g y^2]_0^h$$
$$= \ell h\,(P_{\text{atm}} + \tfrac{1}{2}\rho g h). \checkmark$$

4 EVALUATE RESULT The product ℓh is the surface area of the dam, and so the term $\ell h P_{\text{atm}}$ is the magnitude of the force exerted by the atmosphere on the dam. Because the atmosphere exerts a force of the same magnitude on face B in the opposite direction, the first term in my answer drops out of the vector sum of the forces exerted by the water on face A of the dam and by the atmosphere on face B of the dam. The remaining term, $\ell h(\frac{1}{2}\rho g h)$, is the product of the area of the face of the dam and $\frac{1}{2}\rho g h$, which is the pressure increase halfway down in the water. Because the pressure increases linearly with depth, this term represents the average value of the pressure increase between surface and bottom, and so my answer makes sense.

Let us now turn to buoyancy. The volume of liquid in Figure 18.40 is held in place by the buoyant force $\vec{F}^{\text{b}}_{\text{lv}}$ exerted by the surrounding liquid. The vector sum of the forces exerted on the volume of liquid is thus

$$\Sigma\vec{F}_{\text{v}} = \vec{F}^{\text{b}}_{\text{lv}} + \vec{F}^{G}_{\text{Ev}} = \vec{0}. \tag{18.10}$$

Because the magnitude of the force of gravity on the volume of liquid is $\rho V g$, we obtain for the magnitude of the **buoyant force** exerted by the surrounding liquid on the volume of liquid

$$F^{\text{b}}_{\text{lv}} = \rho V g. \tag{18.11}$$

The direction of the buoyant force is always opposite the direction of the gravitational acceleration. Because this expression holds for any object in any fluid, we can write for the buoyant force on any object o in a fluid f:

$$F^{\text{b}}_{\text{fo}} = \rho_{\text{f}} V_{\text{disp}} g, \tag{18.12}$$

where we have added a subscript to V to remind us that this volume represents the *displaced volume* of fluid and a subscript on ρ to remind us that it is the mass density of the fluid.

The vector sum of the upward buoyant force and the downward gravitational force exerted on an object in a given fluid determines whether the object sinks or floats in that fluid. When they are equal in magnitude, $F^{\text{b}}_{\text{fo}} = F^{G}_{\text{Eo}}$ or $\rho_{\text{f}} V_{\text{disp}} g = mg = \rho_{\text{o,av}} V_{\text{o}} g$, where we have written the mass of the object as the product of its average mass density $\rho_{\text{o,av}}$ and volume V_{o}. For an object that is floating, the displaced volume is less than the volume of that object:

$$V_{\text{disp}} = \frac{\rho_{\text{o,av}}}{\rho_{\text{f}}} V_{\text{o}} \quad \text{or} \quad \frac{\rho_{\text{o,av}}}{\rho_{\text{f}}} < 1. \tag{18.13}$$

Therefore we have

$$\rho_{o,\text{av}} < \rho_{\text{f}} \quad \text{(object floats)}. \tag{18.14}$$

An object placed in a fluid floats whenever the average mass density of the object is smaller than the mass density of the fluid.

Conversely, an object sinks when the magnitude of the buoyant force is smaller than that of the gravitational force. Working through the same thought sequence that got us from forces to Eq. 18.14, we see that

$$\rho_{o,av} > \rho_f \quad \text{(object sinks)}. \tag{18.15}$$

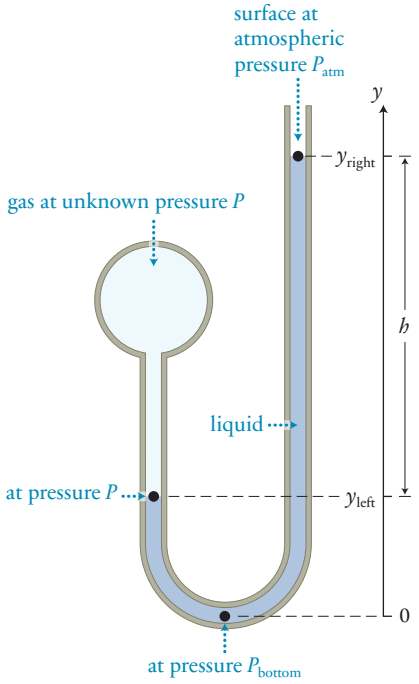
An object placed in a fluid sinks whenever the average mass density of the object exceeds the mass density of the fluid.

When the object's average mass density is equal to the mass density of the fluid, $\rho_{o,av} = \rho_f$, the object is said to have *neutral buoyancy*—it can "hang" motionless anywhere in the fluid.

Figure 18.44 Simple mechanical pressure gauge.

18.15 An object floats with 80% of its volume submerged in water. How does the average mass density of the object compare with that of water?

18.6 Working with pressure



The results in Section 18.5 allow us to understand a number of applications of pressure. Let's first consider measurements of pressure. A *pressure gauge* is used to measure pressures that are near or greater than atmospheric pressure; a *vacuum gauge* is used to measure pressures that are smaller than atmospheric pressure.

The most common pressure gauges have a flexible, sealed chamber that changes shape when the pressure inside or outside the chamber changes. The deformation of the chamber is measured electrically, optically, or mechanically. For example, in a simple mechanical pressure gauge (**Figure 18.44**), the chamber deformation is coupled via a gear to an indicating needle on a calibrated dial. The reading on a pressure gauge is the pressure in excess of atmospheric pressure. Thus when you use a pressure gauge to check the pressure in, say, a bicycle tire, the reading on the gauge, called *gauge pressure* P_{gauge}, is related to the actual pressure P in the tire by

$$P = P_{gauge} + P_{atm}. \tag{18.16}$$

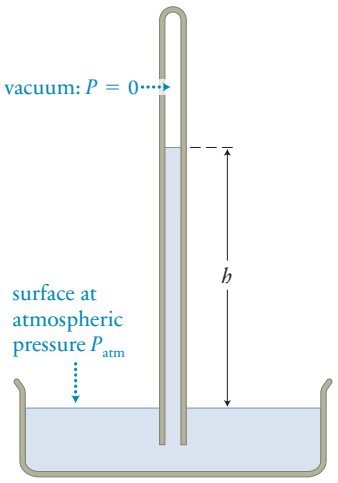
For example, when a tire pressure gauge reads 2.4 atm, the pressure inside the tire is 3.4 atm. If the pressure inside a container is smaller than atmospheric pressure, the pressure gauge reading is negative.

Figure 18.45 An open-tube manometer. The difference in the levels in the two legs of the manometer gives the pressure P inside the bulb.

The simplest pressure gauge is the open-tube *manometer* (**Figure 18.45**). A manometer is essentially a liquid-filled, U-shaped tube, one leg of which is connected to the container where the pressure P is to be measured and the other leg of which is open to the atmosphere. The pressure in the liquid at the bottom of the U is P_{bottom}, while that at the surface of the liquid in the right leg is atmospheric pressure. Applying Eq. 18.7 to these two points, we get $P_{bottom} = P_{atm} + \rho g y_{right}$. Applying the same procedure to the left leg, we have $P_{bottom} = P + \rho g y_{left}$, and so $P = P_{atm} + \rho g(y_{right} - y_{left})$ or, if we denote the difference in the heights of the liquid in the two legs by h, the pressure measured by the manometer is

$$P = P_{atm} + \rho g h. \tag{18.17}$$

Equation 18.17 shows that using a manometer to measure the pressure in some fluid-filled container requires knowing atmospheric pressure, which means we cannot use a manometer to measure atmospheric pressure. We can use another device, though, a *barometer*, illustrated in



QUANTITATIVE TOOLS

Figure 18.46. This device consists of a shallow reservoir; a long, thin tube closed at one end and open at the other; and a dense liquid, usually mercury. Some of the liquid sits in the reservoir. The tube is filled completely with the liquid, and its open end is covered temporarily. The tube is then inverted and its open end plunged into the liquid in the reservoir. As the temporary cover is removed, some of the liquid drains from the tube into the reservoir, leaving a vacuum above the liquid in the closed end of the tube. The level of the liquid in the tube remains above the level of the liquid in the reservoir so as to satisfy Eq. 18.7 when we define the liquid surface in the reservoir as point 1 and the liquid surface in the tube as point 2. When we let the reservoir liquid surface be at $y_1 = 0$, the left side of Eq. 18.6 becomes $P_{atm} + 0$. Because there is a vacuum above the tube liquid surface, the right side of Eq. 18.6 is $0 + \rho gh$, and so we have

$$P_{atm} = \rho gh. \tag{18.18}$$

If we know the mass density ρ of the liquid, we can determine atmospheric pressure by measuring the height h of the liquid in the tube.

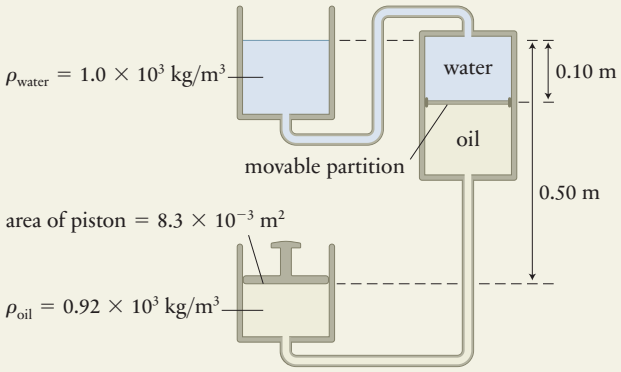


Figure 18.46 A barometer. The height of the column of liquid in the tube gives the atmospheric pressure.

EXAMPLE 18.7 Liquid support

In **Figure 18.47**, the top tank, which is open to the atmosphere, contains water ($\rho_{water} = 1.0 \times 10^3$ kg/m^3) and the bottom tank contains oil ($\rho_{oil} = 0.92 \times 10^3$ kg/m^3) covered by a piston. The tank on the right has a freely movable partition that keeps the oil and water separate. The partition is a vertical distance 0.10 m below the open surface of the water. If the piston in the bottom tank is 0.50 m below the open surface of the water and has a surface area of 8.3×10^{-3} m^2, what must the mass of the piston be to keep the system in mechanical equilibrium? For simplicity, ignore the mass of the partition.

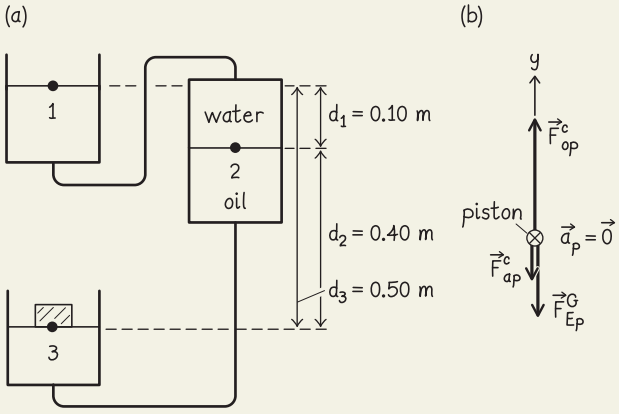

Figure 18.47 Example 18.7.

❶ **GETTING STARTED** I begin by making a sketch of the arrangement and identifying points of interest (**Figure 18.48***a*). Point 1 is at the water surface in the top tank, and the pressure here is atmospheric pressure. Point 2 is on the partition in the right tank separating the water from the oil. In mechanical equilibrium, the partition is not accelerating, and so, because I ignore the partition mass, the pressure must be the same on the two sides of the partition. Point 3 is at the position in the bottom tank where the oil and piston meet.

I also draw a free-body diagram for the piston, which also has zero acceleration in mechanical equilibrium

Figure 18.48

(Figure 18.48*b*). The piston is subject to an upward force $\vec{F}^c_{op}$ exerted by the oil, a downward force $\vec{F}^c_{ap}$ exerted by the air above the piston, and a downward gravitational force $\vec{F}^G_{Ep}$.

❷ **DEVISE PLAN** When the system is in mechanical equilibrium, the piston is stationary. Therefore the vector sum of the forces exerted on it must be zero. From my free-body diagram, I see that the magnitude of the upward force exerted by the oil on the piston is equal in magnitude to the sum of the downward gravitational force exerted on the piston and the downward force exerted by the air on the piston: $F^c_{op} = F^G_{Ep} + F^c_{ap} = m_p g + F^c_{ap}$.

The magnitudes F^c_{ap} and F^c_{op} are given by a rearranged form of Eq. 18.1: $F^c_{ap} = P_{air}A_{piston}$, and $F^c_{op} = P_3 A_{piston}$. The problem therefore reduces to determining the pressure P_3 at point 3, where the oil and piston meet. That point is 0.40 m below the partition in the tank on the right, where the pressure is P_2. Because points 2 and 3 are in a connected liquid (the oil), I can use Eq. 18.7 to relate P_2 and P_3. Points 1 and 2 are also in a connected liquid (the water), so I can use Eq. 18.7 to relate P_2 and $P_1 = P_{atm}$.

(Continued)

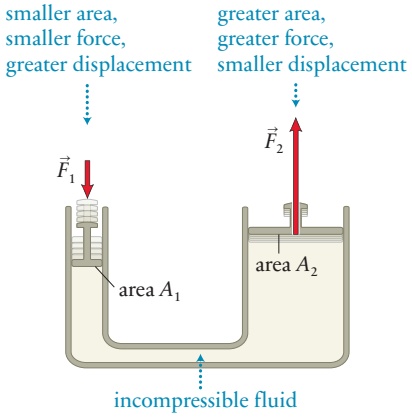
3 EXECUTE PLAN Because the vector sum of the forces exerted on the piston is zero, I have $F^c_{op} - F^c_{ap} - F^G_{Ep} = P_3 A_{piston} - P_{air} A_{piston} - m_{piston} g = 0$, or

$$m_{piston} = \frac{(P_3 - P_{air})A_{piston}}{g}. \qquad (1)$$

To obtain P_3, I first apply Eq. 18.7 to points 1 and 2, remembering that the lower point always goes on the left side of the equation: $P_2 = P_1 + \rho_{water} g d_1 = P_{air} + \rho_{water} g d_1$. Then I apply Eq. 18.7 to points 2 and 3: $P_3 = P_2 + \rho_{oil} g d_2 = P_{air} + \rho_{water} g d_1 + \rho_{oil} g d_2$. Substituting this expression into Eq. 1, I get

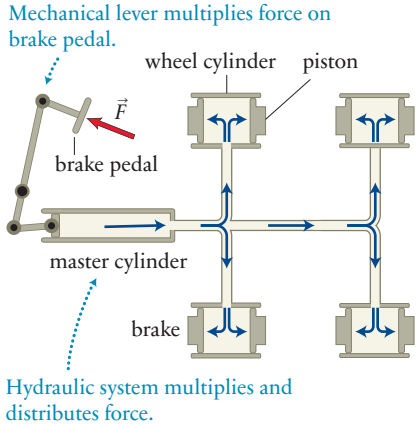
$$m_{piston} = \frac{(P_{air} + \rho_{water} g d_1 + \rho_{oil} g d_2 - P_{air})A_{piston}}{g}$$

$$= (\rho_{water} d_1 + \rho_{oil} d_2)A_{piston}$$



$$= [(1.0 \times 10^3 \text{ kg/m}^3)(0.10 \text{ m}) + (0.92 \times 10^3 \text{ kg/m}^3)(0.40 \text{ m})]$$

$$\times (8.3 \times 10^{-3} \text{ m}^2) = 3.9 \text{ kg}. \checkmark$$



4 EVALUATE RESULT The atmospheric pressure term drops out because it affects both the water surface and the piston. Points 1 and 3 are separated by 0.5 m. Because I know that the pressure difference due to 10 m of water is equal to atmospheric pressure at sea level, or about 100 kPa (see Checkpoint 18.4; these are handy numbers to remember), I know that 0.5 m of water should correspond to a pressure difference of about 5 kPa. The mass density of oil is a bit smaller than that of water, but I can ignore the difference. The surface area of the piston is about 10^{-2} m^2, and so the force giving rise to the 5-kPa pressure difference is about 50 N, which is equal to the gravitational force exerted on a mass of 5 kg, which is close to the answer I obtained.

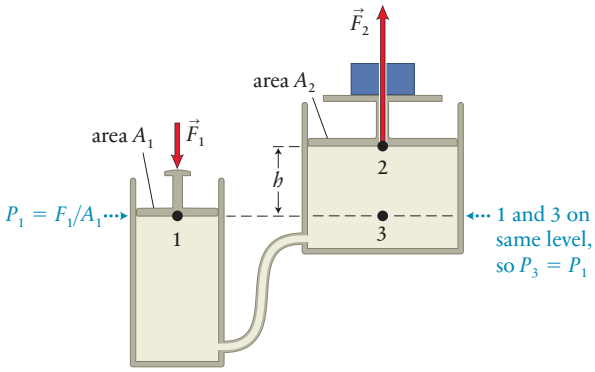
Figure 18.49 Hydraulic systems make it possible to lift heavy loads or exert large forces.

(*a*) Basic hydraulic system

(*b*) Schematic model of hydraulic brake system

18.16 Oil and water don't mix, and the mass density of oil is smaller than that of water. Suppose water is poured into a U-shaped tube that is open at both ends until the water surface is halfway up each leg of the tube, and then some oil is poured on top of the water in the right leg. Once the system comes to equilibrium, are the top of the oil column in the right leg and the top of the water column in the left leg at the same height? If not, which is higher?

The principles we have discussed in this section allow us to understand the working of *hydraulic systems*, which are used for lifting heavy loads or exerting large forces. The basic idea behind a hydraulic system is simple: A liquid, usually oil, is used to transmit a force applied at one point to another point. **Figure 18.49*a*** shows a schematic hydraulic system: two pistons fitted into two connected, oil-filled cylinders. Because the oil is incompressible, a force exerted on one piston increases the pressure everywhere in the oil, and so the force is transmitted to the other piston.



The tube that connects the two cylinders can be any length or shape, which means it can snake through tight spaces and can also fork, allowing an applied force to be distributed. In the brake system of a car, for example, the force your foot exerts on the brake pedal is transmitted to the piston in an oil-filled master cylinder. The pressure increase in the oil is transmitted through steel tubes to the four brakes in the wheels, where the oil exerts a force on the brake pads, pushing them against a disk attached to the wheel, which slows down the car (Figure 18.49*b*).

Another great advantage of hydraulic systems is that they permit us to "multiply" a force by varying the size of the pistons. In **Figure 18.50**, a force of magnitude F_1 is exerted on a small piston of area A_1, causing a gauge pressure $P_1 = F_1/A_1$ in the liquid at the small piston. Because $P_3 = P_2 + \rho g h$, the gauge pressure P_2 at the large piston is then

$$P_2 = P_3 - \rho g h = P_1 - \rho g h, \qquad (18.19)$$

QUANTITATIVE TOOLS

Figure 18.50 Hydraulic system used to "multiply" a force.

where h is the vertical distance between the pistons. When the liquid in a hydraulic system is oil, we can ignore the term ρgh because the mass density of oil is not very great and h is generally small, so that $P_1 \approx P_2$. The gauge pressure P_2 at point 2 causes the liquid to exert a force of magnitude F_2 on the piston. If the area of that piston is A_2, we have $P_2 = F_2/A_2$, so that

$$\frac{F_1}{A_1} = \frac{F_2}{A_2} \tag{18.20}$$

or

$$F_2 = \frac{A_2}{A_1} F_1. \tag{18.21}$$

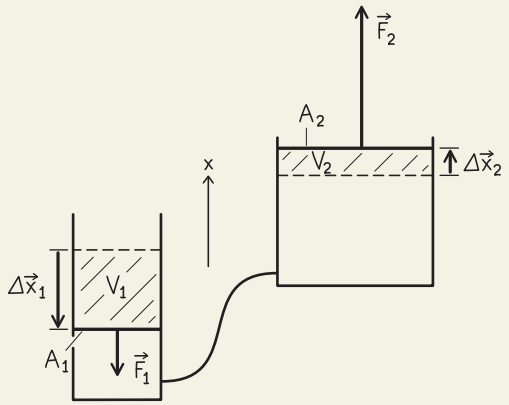
Because $A_2 > A_1$, we have $F_2 > F_1$. Therefore a small force applied to the small piston causes the liquid to exert a large force on the large piston (even though the *pressure* is the same at both points). The factor A_2/A_1 is what permits you to exert large forces on the brakes of a car even though the force your foot exerts on the brake pedal is relatively small.

PROCEDURE: Working with pressure in liquids at rest

The branch of physics that deals with pressure in a liquid at rest is called *hydrostatics*. The pressure in a liquid at rest is determined by the force of gravity and by what happens at the boundary of the liquid. To determine the pressure in such liquids:

1. Begin by making a sketch showing all the **boundaries** and identifying all the factors that affect pressure: pistons, gases at surfaces open to the atmosphere, and so on. Note the known vertical heights of liquid surfaces, the areas of these surfaces, the surface areas of pistons, and the liquid mass densities.
2. Determine the **pressure at each surface,** The pressure at a liquid surface open to the air is equal to atmospheric pressure P_{atm}. The pressure at a liquid surface bordering a vacuum is zero: $P = 0$. The pressure at a liquid surface open to a gas other than the atmosphere is equal to the pressure in the gas: $P = P_{\text{gas}}$. The pressure at a liquid surface that is in contact with a solid, such as a piston, is $P = F^{\text{c}}_{\text{sl}}/A$, where F^{c}_{sl} is the magnitude of the force exerted by the solid on the liquid and A is the area over which that force is exerted.
3. Use **horizontal planes,** The pressure is the same at all points on a horizontal plane in a connected liquid. The pressure difference between two horizontal planes 1 and 2 is given by $P_1 = P_2 + \rho gd$ (Eq. 18.7), where d is the vertical distance between the horizontal planes and 1 is below 2.

QUANTITATIVE TOOLS



EXAMPLE 18.8 Liquid work

Suppose a load is placed on the large piston in Figure 18.50 and we wish to raise that load by a certain distance. How does the work done on the small piston compare with the work required to raise the load? Ignore the masses of the pistons.

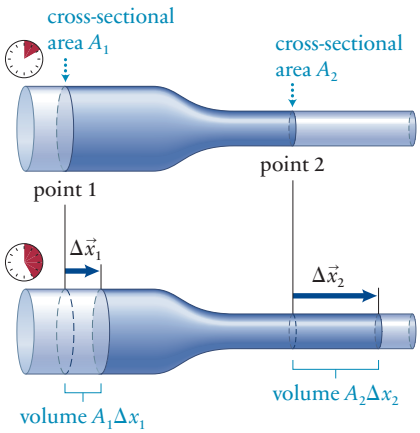
1 GETTING STARTED I begin by making a sketch (**Figure 18.51**). To keep my subscripts simple, I call the small piston 1 and the large piston 2. I denote the displacements of the two pistons by $\Delta\vec{x}_1$ and $\Delta\vec{x}_2$, and the forces exerted on them by $\vec{F}_1$ and $\vec{F}_2$.

2 DEVISE PLAN The magnitudes F_1 and F_2 are related by Eq. 18.21, $F_2 = (A_2/A_1)F_1$. Each force does an amount of work given by the scalar product of the force and the force displacement, which is equal to the displacement of the piston on which the force is exerted. Both forces do positive work because the direction of each force is the same as the direction of the force displacement. Because the liquid in the cylinders is incompressible, I know that the volume V_1 of liquid pushed out of the small cylinder must be equal to the volume V_2 of liquid pushed into the large cylinder: $V_1 = V_2$. This expression will help me relate the piston displacements to the piston surface areas.

Figure 18.51

3 EXECUTE PLAN Raising the load a distance $d = \Delta x_2$ requires work $W_2 = \vec{F}_2 \cdot \Delta\vec{x}_2 = F_2 d$. Using Eq. 18.21, I can write for the work done on the small piston

$$W_1 = \vec{F}_1 \cdot \Delta\vec{x}_1 = F_1 \Delta x_1 = F_2 \frac{A_1}{A_2} \Delta x_1. \qquad (1)$$



The volume of liquid pushed out of the small cylinder is $V_1 = A_1 \Delta x_1$, and that pushed into the large cylinder is $V_2 = A_2 \Delta x_2 = A_2 d$. Because these two volumes are equal, I have $A_1 \Delta x_1 = A_2 d$, or $\Delta x_1 = (A_2/A_1)d$. Substituting this expression into Eq. 1, I get $W_1 = F_2 d$, telling me that the same work is done on both pistons. ✔

4 EVALUATE RESULT My answer tells me that no energy is gained by using the hydraulic lift, which makes sense. The force exerted on the small piston is increased by the factor A_2/A_1 when it is transmitted to the large piston, but the displacement decreases by the inverse factor A_1/A_2, and so the work done is the same.

18.17 In the derivation of Eq. 18.21, we ignored the effect of atmospheric pressure on the two pistons. How is the result we obtained affected by atmospheric pressure?

18.7 Bernoulli's equation

Figure 18.52 A fluid flows through a tapered tube.

Next we turn our attention to fluids in motion. Consider the laminar flow of a nonviscous fluid through the tapered tube in **Figure 18.52**. In a time interval Δt, a thin "slice" of fluid in the wide part of the tube undergoes a displacement Δx_1. The volume of fluid that enters the tube at point 1 is thus $A_1|\Delta x_1|$, where A_1 is the cross-sectional area of the wide part of the tube. If the mass density of the fluid at point 1 is ρ_1, the amount of mass entering the tube at point 1 is $m_1 = \rho_1 A_1 |\Delta x_1|$. Likewise, if a thin slice of fluid in the narrow part of the tube has a displacement Δx_2, and the cross-sectional area of the narrow part is A_2, then the mass of the fluid emerging at point 2 is $\rho_2 A_2 |\Delta x_2|$. If the flow is laminar, the flow speed at any location doesn't change with time. This means that no mass can accumulate in the tube, and so the mass of the fluid emerging from the narrow part at point 2 during a time interval Δt must be the same as the mass entering at point 1:

$$\rho_1 A_1 |\Delta x_1| = \rho_2 A_2 |\Delta x_2| \quad \text{(laminar flow of nonviscous fluid)}. \qquad (18.22)$$

QUANTITATIVE TOOLS

If the flow speed of the fluid is v_1 at point 1 and v_2 at point 2, we have $|\Delta x_1| = v_1 \Delta t$ and $|\Delta x_2| = v_2 \Delta t$. Substituting these expressions into Eq. 18.22 and dividing both sides by Δt, we obtain

$$\rho_1 A_1 v_1 = \rho_2 A_2 v_2 \quad \text{(laminar flow of nonviscous fluid).} \tag{18.23}$$

Equation 18.23 is called the **continuity equation.** This equation quantitatively expresses the idea that the mass of the fluid emerging from the narrow part at point 2 during a time interval Δt is the same as the mass entering at point 1.

For an incompressible fluid, the mass density is the same in all parts of the tube and so

$$A_1 v_1 = A_2 v_2 \quad \text{(laminar flow of nonviscous, incompressible fluid).} \tag{18.24}$$

This equation expresses quantitatively what we concluded in Section 18.3: A fluid flows faster in a narrow part of a tube than in a wide part.

We can write Eq. 18.24 in another form by introducing a quantity Q, called the **volume flow rate,** the rate at which a volume of fluid crosses a section of a tube. If a volume V crosses a section in a time interval Δt, the volume flow rate is

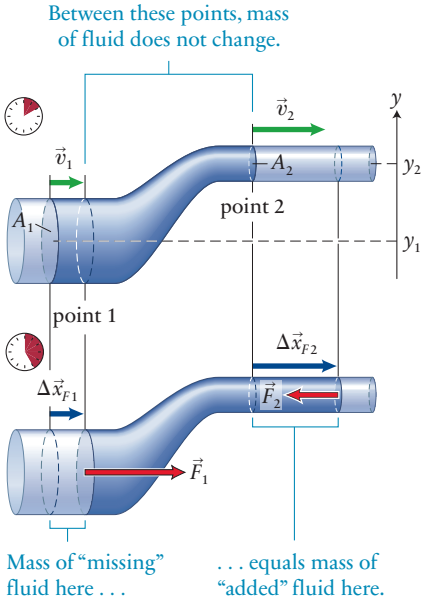
$$Q \equiv \frac{V}{\Delta t}. \tag{18.25}$$

The SI unit of volume flow rate is meters cubed per second (m^3/s). For a nonviscous fluid flowing at speed v through a pipe of cross-sectional area A, we have $V = A|\Delta x| = Av\Delta t$, and so the volume flow rate is

$$Q = Av. \tag{18.26}$$

Equation 18.24 thus tells us that the volume flow rate is the same at all locations in an incompressible fluid: $Q_1 = Q_2$.

We also concluded in Section 18.3 that in order for a fluid to accelerate in the region where a tube narrows, the pressure must be greater in the wide part. Let us therefore now relate pressure to flow speed. Consider the tapered tube in **Figure 18.53**. At point 1 the tube's cross-sectional area is A_1, the fluid's speed is v_1, the pressure is P_1, and the vertical height above some arbitrarily chosen origin is y_1. The corresponding quantities at point 2 are A_2, v_2, P_2, and y_2. Let us consider the system made up of Earth and the fluid initially between points 1 and 2. How does the energy of this system change?



To answer this question, let us apply the energy law (Eq. 9.1, $\Delta E = W$) to this system over a time interval Δt. As Figure 18.53 shows, during the time interval Δt the system has shifted to the right. The difference between the initial and final states of the system is a "missing" volume of fluid on the left and an "added" volume of fluid on the right. The continuity equation requires the masses of these two volumes to be the same: $m_1 = m_2 = m$. Because the mass of the fluid between points 1 and 2 doesn't change, the only forms of energy we need to consider are the kinetic and potential energies associated with m_1 and m_2. The change in kinetic energy is

$$\Delta K = \tfrac{1}{2} m_2 v_2^2 - \tfrac{1}{2} m_1 v_1^2 = \tfrac{1}{2} m (v_2^2 - v_1^2), \tag{18.27}$$

and the change in gravitational potential energy is

$$\Delta U^G = m_2 g y_2 - m_1 g y_1 = mg(y_2 - y_1). \tag{18.28}$$

Figure 18.53 A volume of fluid flows through a tapered tube that changes altitude.

Substituting Eqs. 18.27 and 18.28 into the left side of the energy law yields

$$\Delta E = \Delta K + \Delta U^G = \tfrac{1}{2}m(v_2^2 - v_1^2) + mg(y_2 - y_1). \qquad (18.29)$$

Our system is not closed because the fluid that is in contact with the left and right termini of the system exerts forces $\vec{F}_1$ and $\vec{F}_2$ on the system and the points of application of these forces undergo nonzero force displacements $\Delta\vec{x}_{F1}$ and $\Delta\vec{x}_{F2}$,* respectively. So let us now evaluate the work W done on the system. We take the time interval Δt to be small enough so that we can consider the forces to be constant. Because $\vec{F}_1$ and the force displacement of $\vec{F}_1$ are in the same direction, the work done on the system at point 1 is positive:

$$W_1 = F_{1x}\Delta x_{F1} = +P_1A_1v_1\Delta t. \qquad (18.30)$$

At point 2, negative work is done on the system because the force and force displacement point in opposite directions:

$$W_2 = F_{2x}\Delta x_{F2} = -P_2A_2v_2\Delta t, \qquad (18.31)$$

and so the work done on the system is

$$W = P_1A_1v_1\Delta t - P_2A_2v_2\Delta t. \qquad (18.32)$$

Using Eq. 18.24, we can write $A_1v_1\Delta t = A_2v_2\Delta t$. The quantity $A_1v_1\Delta t$ is the volume of the mass of fluid m that flows into (or out of) the section of tube we are considering. From the definition of mass density, we know that $V = m/\rho$, which means that

$$\frac{m}{\rho} = A_1v_1\Delta t. \qquad (18.33)$$

Substituting this expression into Eq. 18.32, we get

$$W = \frac{m}{\rho}(P_1 - P_2). \qquad (18.34)$$

Because the work done on the system must be equal to the change in the system's energy, we have, from Eqs. 18.29 and 18.34:

$$\tfrac{1}{2}m(v_2^2 - v_1^2) + mg(y_2 - y_1) = \frac{m}{\rho}(P_1 - P_2) \qquad (18.35)$$

or, dividing both sides by m, rearranging terms, and multiplying through by ρ,

$$P_1 + \rho g y_1 + \tfrac{1}{2}\rho v_1^2 = P_2 + \rho g y_2 + \tfrac{1}{2}\rho v_2^2 \quad \text{(laminar flow of incompressible, nonviscous fluid).} \qquad (18.36)$$

Together with the continuity equation (Eq. 18.23), Eq. 18.36, known as **Bernoulli's equation,** forms the foundation of the hydrodynamics of

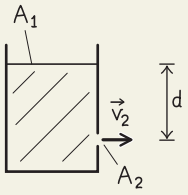
*The subscript F on the displacement means we are considering the displacement of the point of application of the force (see Section 9.1).

QUANTITATIVE TOOLS

incompressible fluids. Strictly speaking, Bernoulli's equation applies only to liquids because we used Eq. 18.24, which is valid only for incompressible fluids. However, for the flow of a gas at modest velocities (and for height differences $y_2 - y_1$ that are not too great), the pressure variations have little effect on the mass density and Bernoulli's equation is still a reasonable approximation.

Because the points 1 and 2 are arbitrary, Eq. 18.36 tells us that the quantity $P + \rho g y + \frac{1}{2}\rho v^2$ is the same at different locations in a flow stream. If the fluid is stationary, $v = 0$ everywhere, and Eq. 18.36 takes on the same form as Eq. 18.6. If points 1 and 2 are at the same height, then $y_1 = y_2$, and Eq. 18.36 becomes

$$P_1 + \tfrac{1}{2}\rho v_1^2 = P_2 + \tfrac{1}{2}\rho v_2^2 \quad \begin{array}{l}\text{(horizontal laminar flow}\\ \text{of incompressible,}\\ \text{nonviscous fluid).}\end{array} \qquad (18.37)$$



This equation confirms what we concluded in Section 18.3: The pressure P is greater where the flow speed v is smaller, and vice versa.

EXAMPLE 18.9 Leaky bucket

Water leaks out of a small hole in the side of a bucket. The hole is a distance d below the surface of the water, and the cross section of the hole is much smaller than the diameter of the bucket. At what speed does the water emerge from the hole?

❶ **GETTING STARTED** I begin by making a sketch of the bucket (**Figure 18.54**), defining my point 1 at the water surface and my point 2 at the hole. The bucket can be regarded as a tube open at both ends, with the top opening, cross-sectional area A_1, as one end and the hole, cross-sectional area A_2, as the other end.

Figure 18.54

❷ **DEVISE PLAN** Because $A_1 \gg A_2$, the continuity equation (Eq. 18.23, $\rho_1 A_1 v_1 = \rho_2 A_2 v_2$) tells me that the speed v_1 at which the surface of the water moves downward is much smaller than the speed v_2 at which the water emerges from the hole, $v_1 \ll v_2$. For all practical purposes, therefore, I can assume $v_1 \approx 0$. I also know that the pressure both at the water surface and at the hole is equal to atmospheric pressure. I can then use Bernoulli's equation (Eq. 18.36) to determine v_2.

❸ **EXECUTE PLAN** Because $P_1 = P_2 = P_{\text{atm}}$, Bernoulli's equation reduces to $\rho g y_1 + \frac{1}{2}\rho v_1^2 = \rho g y_2 + \frac{1}{2}\rho v_2^2$. Dividing through by $\frac{1}{2}\rho$, setting $v_1 = 0$, and bringing the terms containing y to the left side, I get $v_2^2 = 2g(y_1 - y_2) = 2gd$, and so $v_2 = \sqrt{2gd}$. ✔

❹ **EVALUATE RESULT** My answer is equal to the speed acquired over a vertical distance d by a freely falling object starting from rest. Because the Earth-object system is closed, $\Delta K + \Delta U^G = \frac{1}{2}mv^2 - mgd = 0$, and so $v^2 = 2gd$. My result makes sense: For each water drop that emerges from the hole, the water at the surface is reduced by an equal amount and the kinetic energy of the emerging drop must be equal to the decrease in potential energy.

18.18 Suppose that the diameter of the hole in Example 18.9 is 10.0 mm, the bucket diameter is 0.50 m, and the distance from the hole to the water surface is 0.30 m. At what speed does the water emerge from the hole?

18.8 Viscosity and surface tension

So far in our discussion of fluid flow we have ignored energy dissipation. As pointed out in Section 18.3, viscosity is a measure of a fluid's resistance to shear stress. Dissipation of energy occurs in both liquids and gases, and so both have a nonzero viscosity. Consider, for example, two flat plates

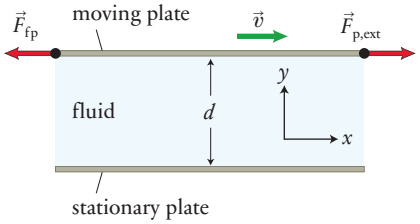


Figure 18.55 To measure viscosity, a fluid is placed between two parallel plates. The bottom plate is held fixed while the top plate is translated. The force required to keep the top plate moving at constant speed gives the viscosity of the fluid.

separated by a fluid (**Figure 18.55**). The lower plate is held fixed while the upper plate is translated in the plane of the plate. Because of friction between adjacent fluid layers, a force $\vec{F}_{p,ext}$ is required to move the upper plate at constant speed v. Experiments show that the magnitude of this force is proportional to the surface area A of the upper plate and to the speed v, and inversely proportional to the distance d between the plates. Because the force is directed in the direction opposite that of the velocity of the upper plate, we can write for a plate moving in the positive x direction:

$$F_{fpx} \equiv -\eta A \frac{v_x}{d}. \tag{18.38}$$

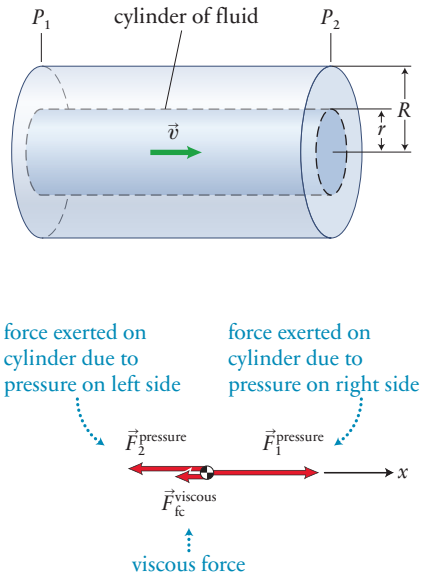
The proportionality constant η (Greek lowercase eta) is the **viscosity** of the fluid. The SI unit for viscosity is the pascal-second, with $1\ \text{Pa}\cdot\text{s} = 1\ \text{kg}/(\text{m}\cdot\text{s})$. The greater the viscosity of a fluid, the greater the force needed to move the plate at constant speed. Because the work done by the plate on the fluid ends up as thermal energy in the fluid, a greater viscosity means more energy dissipation in the fluid as fluid layers rub past one another.

The ratio v_x/d in Eq. 18.38 can also be written as dv_x/dy because both v_x/d and dv_x/dy express the change in the x component of the velocity divided by the distance over which the change occurs. The derivative dv_x/dy, called the *velocity gradient*, is a measure of the rate at which one fluid layer moves relative to an adjacent layer. The advantage of expressing Eq. 18.38 in terms of the velocity gradient is that the resulting equation can be applied more generally:

$$F_{fpx} = -\eta A \frac{dv_x}{dy}. \tag{18.39}$$

Because viscous forces are generally small, fluids are often used as lubricants to reduce friction between solids. **Table 18.1** lists some typical viscosities. The viscosity of gases is typically several orders of magnitude smaller than that of liquids. The viscosity of liquids typically decreases as temperature increases. Honey, for example, becomes more runny as it is heated. In contrast, gases typically get more viscous at higher temperatures.

Table 18.1 Viscosity of fluids



Fluid	Viscosity (Pa · s)	Temperature (°C)
Air	1.71×10^{-5}	0
	1.81×10^{-5}	20
	2.18×10^{-5}	100
Blood	3.0×10^{-3}	20
	2.0×10^{-3}	37
Castor oil	5.3	0
	0.986	20
	0.017	100
Water	1.79×10^{-3}	0
	1.00×10^{-3}	20
	0.282×10^{-3}	100

Many instances of fluid flow, such as the velocity distribution of water through pipes or the flow of blood through arteries, involve laminar flow through cylindrical tubes. Let us therefore consider the flow of a fluid through a horizontal cylindrical pipe of length ℓ and radius R. Because the boundary layer of the fluid sticks to the interior wall of the pipe, this layer is at rest. The layer of fluid adjacent to the boundary layer moves slowly in the direction of the flow, and adjacent layers move at increasing speeds, with the fluid at the center of the pipe having the maximum speed (see Figure 18.19*b*).

Consider a cylinder of fluid of radius r flowing in the positive x direction through a tube of radius $R > r$. The dashed outline in **Figure 18.56** shows such a cylinder of fluid. Because of friction between the fluid in the cylinder and the more slowly moving layer of fluid adjacent to the cylinder boundary, a viscous force $\vec{F}_{fc}^{\,viscous}$ is exerted on the cylinder in the negative x direction. To keep the cylinder moving at constant velocity through the tube, a force of equal magnitude must be exerted on it in the positive x direction. This force requires a pressure difference ΔP between the ends of the cylinder, and so we see that for a fluid with nonzero viscosity, pressure must decrease as the fluid moves along the tube. For motion at constant speed, we have

$$\Sigma \vec{F}_c = \vec{F}_{fc}^{\,pressure} + \vec{F}_{fc}^{\,viscous} = 0. \tag{18.40}$$

Figure 18.56 In mechanical equilibrium, the force due to the pressure on the two ends of the fluid in the cylinder defined by the dashed lines must balance the viscous force opposing the motion of the cylinder.

If the pressure at the left end of the cylinder is P_1, the fluid to the left of this end exerts a force of magnitude $F_1^{pressure} = P_1(\pi r^2)$ in the positive x direction, where πr^2 is the cross-sectional area of the cylinder. If the pressure at the right end of the cylinder is P_2, the fluid to the right of this end exerts a force of magnitude $F_2^{pressure} = P_2(\pi r^2)$ in the negative x direction. The vector sum of these two forces is $(P_1 - P_2)(\pi r^2)$. The viscous force $F^{viscous}$ on the cylinder is given by Eq. 18.39, with A equal to the surface area $2\pi r\ell$ of the cylinder of fluid and $dv_x/dy = -dv_x/dr$.* Substituting this information into Eq. 18.40, we get

$$(P_1 - P_2)(\pi r^2) + \eta(2\pi r\ell)\frac{dv_x}{dr} = 0 \tag{18.41}$$

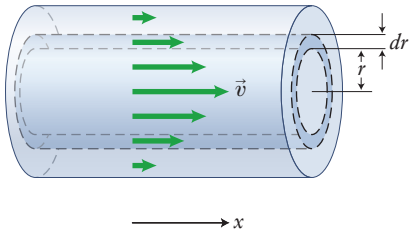
or, rearranging terms,

$$-dv_x = \frac{(P_1 - P_2)(\pi r^2)}{\eta(2\pi r\ell)}dr = \frac{(P_1 - P_2)}{2\eta\ell}rdr. \tag{18.42}$$

If we integrate the right side from r to R, the x component of velocity goes from v_x (the value at r) to 0 (the value at R, where the fluid is at rest because its boundary layer sticks to the tube wall):

$$-\int_{v_x}^{0} dv_x = \frac{P_1 - P_2}{2\eta\ell}\int_r^R rdr = \frac{P_1 - P_2}{2\eta\ell}\left[\tfrac{1}{2}r^2\right]_r^R \tag{18.43}$$

or



$$v_x = \frac{P_1 - P_2}{4\eta\ell}(R^2 - r^2) \quad \text{(laminar flow in cylindrical tube).} \tag{18.44}$$

*In Figure 18.19*b* v_x decreases with increasing r, and so dv_x/dr is negative. In Figure 18.55 v_x increases with increasing y, and so dv_x/dy is positive.

This equation shows that the velocity varies with the square of r, and so its curve has a parabolic shape (see Figure 18.19*b*) with a maximum at the center of the tube, where $r = 0$.

Because the fluid velocity varies with r, the volume flow rate is no longer simply Av. To calculate the volume flow rate, we consider a thin cylindrical shell of thickness dr (**Figure 18.57**). The shell has a cross-sectional area $dA = 2\pi r dr$ and contributes to the overall volume flow rate an amount

Figure 18.57 Each cylindrical shell (dashed lines) contributes an amount dQ to the volume flow rate through the tube.

$$dQ = v_x dA = v_x(2\pi r dr) = \frac{P_1 - P_2}{4\eta\ell}(R^2 - r^2)(2\pi r dr)$$

$$= \frac{\pi(P_1 - P_2)}{2\eta\ell}(R^2 r - r^3)dr, \qquad (18.45)$$

where we have substituted Eq. 18.44 for v_x. To obtain the volume flow rate Q through the tube, we must integrate this expression from $r = 0$ to $r = R$. Integrating the factor $(R^2 r - r^3)$ in Eq. 18.45 yields

$$\int_0^R (R^2 r - r^3)dr = \left[\tfrac{1}{2}R^2 r^2 - \tfrac{1}{4}r^4\right]_0^R = \tfrac{1}{2}R^4 - \tfrac{1}{4}R^4 = \tfrac{1}{4}R^4, \qquad (18.46)$$

and so the volume flow rate through a cylindrical tube is

$$Q = \frac{\pi R^4}{8\eta\ell}(P_1 - P_2) \quad \text{(laminar flow in cylindrical tube).} \qquad (18.47)$$

Equation 18.47, called **Poiseuille's law,** shows that a high viscosity leads to a low-volume flow rate, which is reasonable. The strong dependence on the tube radius R means that a small adjustment in radius can lead to a large increase in volume flow rate. For example, increasing R by just 20% increases the volume flow rate by a factor of $(1.2)^4 = 2.1$.

EXAMPLE 18.10 Blood flow

Blood flows through an artery that has a radius of 3.0 mm. What is the maximum flow speed if the volume flow rate through the artery is 2.0×10^{-6} m^3/s?

❶ **GETTING STARTED** I assume that the artery is cylindrical, which means I can use the results from this section.

❷ **DEVISE PLAN** I can obtain the maximum flow speed by setting $r = 0$ in Eq. 18.44. This equation contains the unknown factor $(P_1 - P_2)/(4\eta\ell)$. The expression for the volume flow rate, Eq. 18.47, however, contains the same factor, which gives me two equations with two unknowns—the maximum flow speed v and the factor $(P_1 - P_2)/(4\eta\ell)$—so I can solve for both unknowns.

❸ **EXECUTE PLAN** Setting $r = 0$ in Eq. 18.44 gives $v_{max} = (P_1 - P_2)R^2/(4\eta\ell)$. Next, I rewrite Eq. 18.47 in the form $(P_1 - P_2)/(4\eta\ell) = 2Q/(\pi R^4)$, which I substitute into my expression for v_{max}:

$$v_{max} = \frac{(P_1 - P_2)R^2}{4\eta\ell} = \frac{2Q}{\pi R^4}R^2 = \frac{2Q}{\pi R^2}$$

$$= \frac{2(2.0 \times 10^{-6}\ \text{m}^3/\text{s})}{\pi(3.0 \times 10^{-3}\ \text{m})^2} = 0.14\ \text{m/s}. \checkmark$$

❹ **EVALUATE RESULT** I can rewrite the equality $v_{max} = (2Q)/(\pi R^2)$ from my final equation in the form $Q = \frac{1}{2}\pi R^2 v_{max} = \frac{1}{2}Av_{max}$, where A is the cross-sectional area of the artery. This equation is very similar to Eq. 18.26, the definition of volume flow rate. Indeed, $\frac{1}{2}v_{max}$ is the average flow speed. The value I obtain also appears to be reasonable—a given volume of blood travels about 1 m in 7 s.

Having dealt with forces in the bulk of a fluid, let us now turn to forces at liquid surfaces. As we saw in Section 18.4, these forces cause surface tension at the surface and are responsible for the shape of drops of liquid and capillary rise.

QUANTITATIVE TOOLS

Figure 18.58 shows a device commonly used to measure surface tension, a length of metal bent into a U shape and attached to a loosely fitted wire to form a rectangular loop. The wire fits so loosely that it slides off when the loop is held with the U inverted. When the loop is dipped into a soap solution, however, the soap film that forms inside the loop holds the wire stationary, as Figure 18.58 shows. An upward force must be exerted on the wire to hold it in place by balancing the downward force of gravity. The only likely candidate for this upward force is the one exerted by the film, so that $F_{\text{fw}} = F^G_{\text{Ew}}$. Experiments show that F_{fw} remains constant as we move the wire up or down. Because the thickness of the film changes as the wire is moved, the observation that the force magnitude F_{fw} does not change means that the film thickness is unimportant. Therefore we must attribute the upward force exerted on the wire to the front and back surfaces of the film. Experimentally we also find that the magnitude of this force is proportional to the length ℓ of the wire. The constant of proportionality

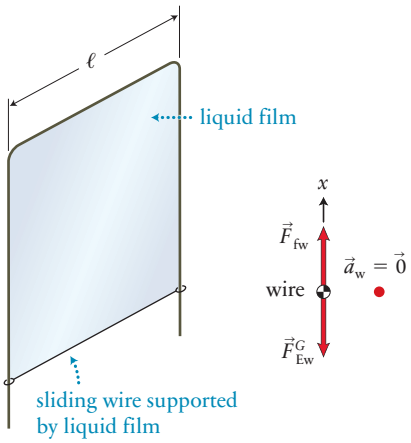
$$\gamma \equiv \frac{F_{\text{fw}}}{2\ell} \tag{18.48}$$

is called the **surface tension** of the liquid that makes up the film. The factor 2 in the denominator accounts for the two surfaces of the film.

The SI unit for surface tension is newtons per meter. **Table 18.2** gives the surface tension for a number of liquids in contact with air.

We can also understand surface tension in terms of the energy associated with the surface of a liquid. Moving the wire in Figure 18.58 causes a force displacement Δx_F, and so work $W = F_{\text{fw}x}\Delta x_F$ is done by the film on the wire. Because $\vec{F}_{\text{fw}}$ points in the positive x direction, we have $F_{\text{fw}x} = +2\ell\gamma$, and so $W = 2\ell\gamma\Delta x_F = -2\gamma\Delta A$, where ΔA is the change in the surface area A of the film. (When the wire moves, Δx_F and ΔA have opposite algebraic signs, so $\ell\Delta x_F = -\Delta A$.) As we move the wire down, we increase the surface area A of the film, and so $\Delta A > 0$ and the work done by the film on the wire is negative. Consequently the work done by the wire on the film is positive (the energy of the film increases). Where does the energy associated with this work go? As we increase the surface area, more liquid particles

Figure 18.58 The force exerted by a liquid film on a wire is due to surface tension in the film.



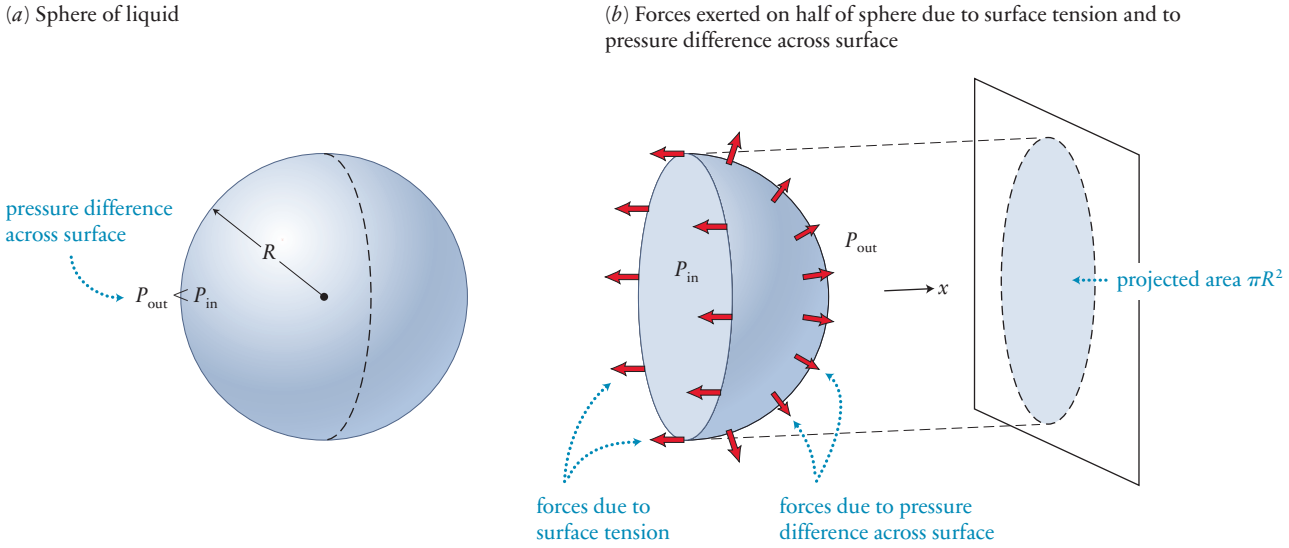


Table 18.2 Surface tensions of liquids in contact with air

Liquid	Surface tension (N/m)	Temperature (°C)
alcohol	2.23×10^{-2}	20
copper	1.100	1130
glycerin	6.31×10^{-2}	20
gold	1.000	1070
mercury	0.465	20
neon*	5.15×10^{-3}	−247
olive oil	3.20×10^{-2}	20
oxygen*	1.57×10^{-2}	−193
silver	0.800	970
water	7.57×10^{-2}	0
	7.28×10^{-2}	20
	5.89×10^{-2}	100

*Values given for liquid in contact with vapor.

Figure 18.59 Model for deriving the relationship between surface tension and pressure difference across a curved liquid surface. The surface tension forces are all directed perpendicular to the circular cross section, and the pressure-difference forces are all directed outward.

must be brought to the surface. For each particle brought to the surface, we reduce the number of bonds between particles (see Figure 18.25), and so the energy associated with the work we do in moving the wire downward goes into breaking bonds between neighboring particles in order to bring them to the surface. So, another way of understanding surface tension is to see it as the energy required to increase the surface area of a liquid. The greater the surface tension of a liquid, the more energy required to increase the surface area of a sample of the liquid by a certain amount.

As we saw in Section 18.4, surface tension is responsible for the pressure difference across a curved liquid surface. To derive the relationship between surface tension and pressure difference, consider the spherical body of liquid in **Figure 18.59*a***. The radius of the sphere is R, and the liquid has a surface tension γ. The pressure inside the liquid is P_{in}, and the pressure outside is P_{out}. Let's consider the forces exerted on one hemisphere, as illustrated in Figure 18.59*b*. Because the hemisphere remains at rest, the vector sum of the outward force due to the pressure difference across the surface and the inward force due to the surface tension must be zero:

$$\Sigma F_{\text{hemi } x} = F_x^{\text{pressure}} + F_x^{\text{surf tension}} = 0. \tag{18.49}$$

The force due to the pressure difference is perpendicular to the hemisphere surface. The components of the forces that are exerted on each segment of the surface but are not in the x direction cancel, and the x components of all these forces sum to the pressure difference $P_{in} - P_{out}$ times πR^2, which is the area of the circle projected on the screen in Figure 18.59*b*. The force due to the surface tension is exerted along the perimeter of the hemisphere, which has length $\ell = 2\pi R$. Therefore the magnitude of the force due to surface tension is $F_x^{\text{surf tension}} = 2\pi R\gamma$ (from Eq. 18.48, $\gamma = F/2\ell$; using this equation would give us $F = 2\ell\gamma = 2(2\pi R)\gamma = 4\pi R\gamma$, but we have to drop the factor 2 from Eq. 18.48 because here we are working with only one surface). Substituting these forces into Eq. 18.49 gives

$$(P_{in} - P_{out})\pi R^2 - 2\pi R\gamma = 0 \tag{18.50}$$

QUANTITATIVE TOOLS

or, rearranging terms,

$$P_{\text{in}} - P_{\text{out}} = \frac{2\gamma}{R} \quad \text{(spherical surface)}. \tag{18.51}$$

Equation 18.51 is a quantitative form of **Laplace's law** for a spherical surface.

For a cylindrical surface, it can be shown that Eq. 18.51 takes the form

$$P_{\text{in}} - P_{\text{out}} = \frac{\gamma}{R} \quad \text{(cylindrical surface)}. \tag{18.52}$$

EXAMPLE 18.11 Transmural pressure

The pressure difference across the wall of a blood vessel is called *transmural pressure*. Suppose an aorta of radius 11 mm has a transmural pressure of 12 kPa and a capillary of radius 4.0 μm has a transmural pressure of 5.0 kPa. Which blood vessel requires a greater tensile stress (tensile force per unit length) in its wall?

❶ **GETTING STARTED** I consider the aorta and the capillary to be elastic cylindrical tubes. Because the wall of a blood vessel keeps the blood confined within the tube, the tension in the wall plays the role of the surface tension γ of an unconfined liquid.

❷ **DEVISE PLAN** To determine γ for each vessel, I can use Eq. 18.52, which relates the pressure difference across the wall to the radius of the cylinder.

❸ **EXECUTE PLAN** I first rewrite Eq. 18.52 in the form $\gamma = (P_{\text{in}} - P_{\text{out}})R$. For the aorta,

$$\gamma = (12\ \text{kPa})\left(\frac{1000\ \text{Pa}}{1\ \text{kPa}}\right)(11\ \text{mm})\left(\frac{1\ \text{m}}{1000\ \text{mm}}\right)$$

$$= 1.3 \times 10^2\ \text{N/m}.$$

(You should be able to confirm that the units in this expression are indeed newtons per meter.) For the capillary,

$$\gamma = (5.0\ \text{kPa})\left(\frac{1000\ \text{Pa}}{1\ \text{kPa}}\right)(4.0\ \mu\text{m})\left(\frac{1\ \text{m}}{10^6\ \mu\text{m}}\right)$$

$$= 0.020\ \text{N/m}.$$

The tensile force per unit length in the aorta is much greater than that in the capillary. ✔

❹ **EVALUATE RESULT** The pressure differences across the aorta and capillary are of the same order of magnitude, and so less tension is required when the radius is small. This is the same situation as in Figure 18.27: The pressure difference is the same everywhere on the balloon surface, but the tension is less where the radius of curvature is smaller.

18.19 What is Laplace's law, Eq. 18.51, for a soap bubble?

Chapter Summary

Pressure due to a fluid (Sections 18.1, 18.5, 18.6)

Concepts A **fluid** is a substance that has no fixed shape and the ability to flow. A *nonviscous* fluid is one that has no resistance to deformation by shear stress.

Pascal's principle states that a pressure change applied to an enclosed liquid is transmitted undiminished to every part of the liquid and to the walls of the container.

Quantitative Tools If a fluid exerts a force $\vec{F}^{\,c}_{fs}$ perpendicular to a surface of area A, the **pressure** P on this area is a scalar defined by

$$P \equiv \frac{F^{c}_{fs}}{A}. \tag{18.1}$$

The SI unit of pressure is the **pascal** (Pa):

$$1\ \text{Pa} \equiv 1\ \text{N/m}^2. \tag{18.2}$$

The atmospheric pressure at sea level is 1.01325×10^5 Pa.

The pressure P at a depth d below the surface of a liquid at rest is independent of the shape of the container and is

$$P = P_{\text{surface}} + \rho g d, \tag{18.8}$$

where P_{surface} is the pressure at the surface of the liquid, g is the acceleration due to gravity, and ρ is the mass density of the liquid.

When pressure is measured, the actual pressure P is the sum of *gauge pressure* (pressure in excess of atmospheric pressure) and atmospheric pressure:

$$P = P_{\text{gauge}} + P_{\text{atm}}. \tag{18.16}$$

Buoyancy (Sections 18.2, 18.5)

Concepts If an object is fully or partially submerged in a fluid, the fluid exerts an upward **buoyant force** on the object. **Archimedes' principle** states that the buoyant force is equal in magnitude to the force of gravity exerted on the fluid displaced by the object. The volume of the displaced fluid is equal to the volume of the submerged part of the object.

Quantitative Tools The **buoyant force** $\vec{F}^{\,b}_{fo}$ that a fluid of mass density ρ_f exerts on an object that displaces a volume V_{disp} of fluid has magnitude

$$F^{b}_{fo} = \rho_f V_{\text{disp}} g. \tag{18.12}$$

Laminar flow of nonviscous fluids (Sections 18.3, 18.7)

Concepts In **laminar flow,** the velocity of the fluid at any given location is constant. Chaotically changing flow is called **turbulent flow.**

The mass density of an incompressible fluid is the same at all locations in the fluid.

Quantitative Tools The **continuity equation** for laminar flow of a nonviscous fluid through a tube is

$$\rho_1 A_1 v_1 = \rho_2 A_2 v_2, \tag{18.23}$$

where ρ, A, and v are the fluid mass density, tube cross-sectional area, and fluid speed, respectively, at any given location.

The **volume flow rate** Q (m^3/s) of a volume V of the fluid flowing past a given location in the tube in a time interval Δt is

$$Q \equiv \frac{V}{\Delta t}. \tag{18.25}$$

The volume flow rate can also be expressed as

$$Q = Av, \tag{18.26}$$

where A is the cross-sectional area of the tube and v is the fluid speed.

Bernoulli's equation describing laminar flow in an incompressible, nonviscous fluid is

$$P_1 + \rho g y_1 + \tfrac{1}{2}\rho v_1^2 = P_2 + \rho g y_2 + \tfrac{1}{2}\rho v_2^2, \tag{18.36}$$

where y is the vertical distance above an arbitrarily chosen reference location.

Viscosity and surface tension (Sections 18.4, 18.8)

Concepts **Viscosity** is a scalar measure of a fluid's resistance to shear deformation.

Surface tension is a scalar that gives the magnitude of the force per unit length exerted by a liquid surface on the perimeter of the surface.

Quantitative Tools The **viscosity** η (Pa · s) of a fluid confined between a lower fixed plate and an upper plate that is free to move is defined by

$$F_{\text{fp}x} \equiv -\eta A \frac{v_x}{d}, \tag{18.38}$$

where $F_{\text{fp}x}$ is the x component of the force $\vec{F}_{\text{fp}}$ exerted by the fluid on the upper plate when it moves in the plane of the plate with speed v_x, A is the plate surface area, and d is the vertical distance between the plates. More generally, we can write

$$F_{\text{fp}x} = -\eta A \frac{dv_x}{dy}, \tag{18.39}$$

where dv_x/dy is the rate at which one infinitesimally thin fluid layer moves past an adjacent layer.

Poiseuille's law: If P_1 and P_2 are the pressures at opposite faces of a cylindrical tube of radius R and length ℓ, the flow rate through the tube is

$$Q = \frac{\pi R^4}{8\eta\ell}(P_1 - P_2). \tag{18.47}$$

If a liquid exerts a force $\vec{F}_{\text{fw}}$ on a length ℓ of wire, the **surface tension** γ (N/m) of the liquid is

$$\gamma \equiv \frac{F_{\text{fw}}}{2\ell}. \tag{18.48}$$

Laplace's law states that the pressure difference $P_{\text{in}} - P_{\text{out}}$ across a curved liquid surface of radius of curvature R is

$$P_{\text{in}} - P_{\text{out}} = \begin{cases} \dfrac{2\gamma}{R} \text{ (spherical surface)} & (18.51) \\ \dfrac{\gamma}{R} \text{ (cylindrical surface).} & (18.52) \end{cases}$$

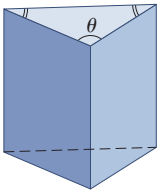
Dots indicate difficulty level of problems: • = *easy,* •• = *intermediate,* ••• = *hard;* CR = *context-rich problem.*

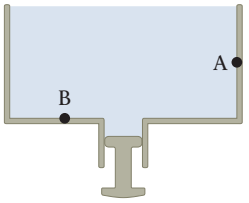
Unless told otherwise, use 1000 kg/m^3 for the mass density of water.

18.1 Forces in a fluid



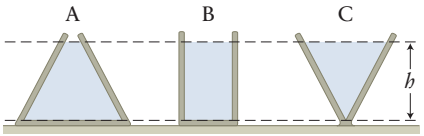
1. The liquid-filled cylinder in Figure P18.1 is clamped in place and has a piston on either end. The piston on the right is cylindrical and has a radius of 30.0 mm. The piston on the left is also cylindrical and has a radius of 10.0 mm. If the right cylinder is pushed leftward with a force of 30.0 N, what force must be exerted on the left cylinder to keep it from moving? •

Figure P18.1



2. On Earth, a cylindrical container of water open to the atmosphere experiences atmospheric pressure at the top surface and a greater pressure at the bottom of the container. How do these pressures change when the container is being carried on the orbiting International Space Station? •
3. A box has six faces with three distinct areas $A < B < C$. Assume that A and B represent the four vertical surfaces, and the two horizontal surfaces have area C. When the box is submerged, rank the faces in order of (*a*) increasing water pressure and (*b*) increasing force exerted by the water. ••
4. You are designing a wedge-shaped container as illustrated in Figure P18.4. You must choose a value for the angle θ, which then determines the other two equal angles in this isosceles wedge. (*a*) When the container is filled with a fluid, what must the value of θ be if F/A, the ratio of the magnitude of the force exerted by the fluid on a side to the area of that side, is the same for all three sides? (*b*) What must θ be in order to have the magnitude of the force exerted by the fluid be the same on all three sides? ••

Figure P18.4



5. The open fixed container in Figure P18.5 is filled with a liquid and fitted with a piston at the bottom. Give the direction (if any) of the following: (*a*) the force $\vec{F}^{\,c}_{\ell w}$ exerted by the liquid on the wall at location A, (*b*) the pressure P in the liquid at A, (*c*) the force $\vec{F}^{\,c}_{w\ell}$ exerted by the wall on the liquid at location B, (*d*) the force $\vec{F}^{\,c}_{\ell p}$ exerted by the liquid on the piston if the piston is pushed, and (*e*) the force $\vec{F}^{\,c}_{\ell p}$ exerted by the liquid on the piston if the piston is pulled. (*f*) Which answers would change if the container were filled with a gas rather than a liquid? ••

Figure P18.5

6. You and your snowboard, with a combined mass of 70 kg, ride a half-pipe that has a radius of 5.0 m. As you pass the bottom, you create a pressure of 27 kN/m^2 on the half-pipe while moving at 8.2 m/s. If your snowboard is 1.3 m long, what is the average width of the part of your snowboard that is in contact with the half-pipe? ••
7. For the floor in any room, the *floor loading* is the maximum safe *average* pressure on the floor (the gravitational force exerted by Earth on all objects resting on the floor divided by the floor area), and the floor's *point loading* is the maximum safe *actual* pressure (the gravitational force exerted by Earth on all objects resting on the floor divided by the floor area covered by those objects). A particular room has a floor loading of 3 kN/m^2 and a point loading of 60 kN/m^2. What fraction of the floor area can be subjected to the point loading without exceeding the floor loading? ••
8. Three jars each have volume V and height h, but they have different shapes as shown in Figure P18.8. Water is to be added to each jar and the pressure is to be measured right at the bottom of each jar. Rank the jars in order of increasing pressure if the volume of water is (*a*) V and (*b*) $V/2$. ••

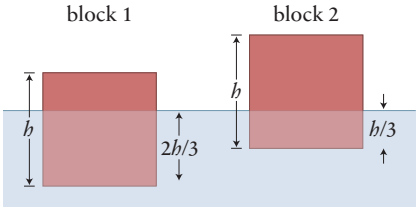
Figure P18.8

9. In a galaxy far, far away, a planet composed of an incompressible liquid of uniform mass density ρ has mass m_{planet} and radius R. Determine the pressure midway between the surface and the center of the planet. •••

18.2 Buoyancy

10. A cube measuring 100 mm on a side floats upright in water with 70.0 mm submerged. What is the mass of the cube? •
11. A scuba diving weight has a mass of 5.0 kg and is made from a material that has a mass density of 2000 kg/m^3. How much force is required to lift it from the bottom of a shallow pool? •
12. You have three bricks made of lead, stone, and plastic. The bricks have identical dimensions. When completely submerged (*a*) which brick feels the greatest buoyant force, and (*b*) which is most likely to float when released? •
13. A ship constructed of 2.50×10^6 kg of steel is roughly shaped like a box of length 50.0 m, width 20.0 m, and height 20.0 m. (*a*) What is the mass density of the ship? (*b*) Does the ship float? (*c*) If it floats, what is the maximum cargo mass it can carry without sinking? ••
14. A wooden block of height h is pushed from the air into a bucket of water that has a depth equal to $2h$. Make a graph showing how the buoyant force exerted on the block changes as its bottom moves from the surface to the bottom of the bucket. You do not need to specify the size of the buoyant force, only how it changes with depth. ••

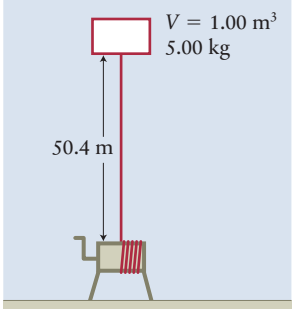
15. Glass A contains 250 g of water, and an identical glass B contains 220 g of water with a 30-g cube of ice floating in it. How do the water levels in the two glasses compare? ••



16. A rowboat floating in a small swimming pool has a large concrete block in it. If the block is thrown overboard into the pool, does the water level in the pool rise, fall, or stay the same? ••

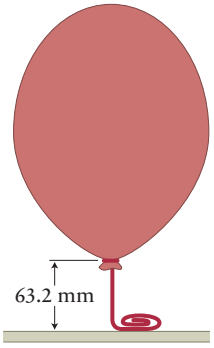
17. You have constructed a raft that is 2.00 m long, 2.00 m wide, and 0.100 m thick. If the mass of the raft is 40.0 kg and your mass is 55.0 kg, how many 65.0-kg friends can cross a river with you during one trip? ••

18. A spherical balloon filled with helium gas must lift a 1.50-kg scientific payload off the ground, and the mass of the empty balloon is 0.500 kg. (*a*) What is the minimum diameter of the balloon? (*b*) A helium shortage forces the scientists to consider using nitrogen gas in the balloon. What minimum balloon diameter is needed if nitrogen gas is used? The mass densities are 1.286 kg/m^3 for air, 0.179 kg/m^3 for helium gas, and 1.251 kg/m^3 for nitrogen gas. ••



19. Two same-sized blocks of wood float in a tank as shown in Figure P18.19. Block 1 has two-thirds of its volume submerged, and block 2 has one-third of its volume submerged. Determine the ratio ρ_1/ρ_2 of the mass densities of the blocks. ••

Figure P18.19

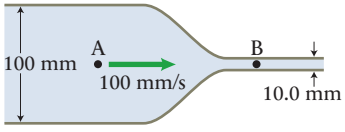


20. A 5.00-kg air-filled, sealed, rigid float tank that has a volume of 1.00 m^3 is pulled 50.4 m down to the seafloor in order to assist in lifting a sunken object. A diver standing on the seafloor cranks a winch to pull the tank down (Figure P18.20). (*a*) How much work is required to pull the tank down? (Ignore the mass of the air in the tank and the mass of the winch rope. Assume that the water mass density does not change with depth.) (*b*) What is the average power required if it takes 10 min to winch down the tank? ••

Figure P18.20

21. You want to determine the lifting force of a helium balloon. When you tie a long cord to the balloon and then release the balloon, it floats up until it supports a 63.2-mm length of cord and then it remains stationary, as shown in Figure P18.21. A 1.00-m length of the cord has a mass of 0.0160 kg, and the mass of the uninflated balloon is 2300 mg. What is the volume of the inflated balloon? The mass densities are 1.286 kg/m^3 for air and 0.179 kg/m^3 for helium. ••

Figure P18.21



22. A cylindrical water tank that has a diameter of 2.50 m contains water to a depth of 3.75 m. A 40.0-kg object placed in the water floats with 75% of its volume submerged. By how much does the addition of the object increase the pressure in the water at the bottom of the tank? •••

23. An uninflated balloon of mass 6.00×10^{-3} kg has a volume of 6.90×10^{-2} m^3 when fully inflated with a mixture of helium and hydrogen gas. You tie a long, heavy cord to the balloon and allow the balloon to float above a table. The length of cord lifted off the table is 283 mm, and the linear mass density of the cord is 0.260 kg/m. (*a*) What is the mass density of the gas mixture in the balloon? (*b*) What is the ratio of helium to hydrogen in the mixture? The mass densities are 1.286 kg/m^3 for air, 0.179 kg/m^3 for helium gas, and 0.090 kg/m^3 for hydrogen gas. •••

18.3 Fluid flow

24. The pipe in Figure P18.24 shrinks from a diameter of 100 mm in the wide section to a diameter of 10.0 mm in the narrow section. If the water's speed is 100 mm/s at location A, what is its speed at location B? •

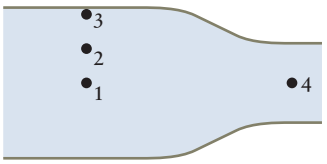


Figure P18.24

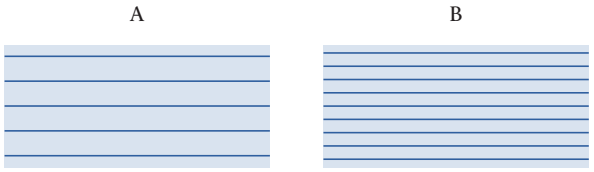
25. In an air duct running along the outside of a building, air flowing through the duct has a mass density of 1.20 kg/m^3 and is moving at 5.38 m/s. The duct passes through a wall into an air-conditioned room. If the mass density of the air in the duct rises to 1.24 kg/m^3 once the air reaches the air-conditioned region, what is the air's new speed? (Ignore the small dimensional change of the duct material in the colder room.) •

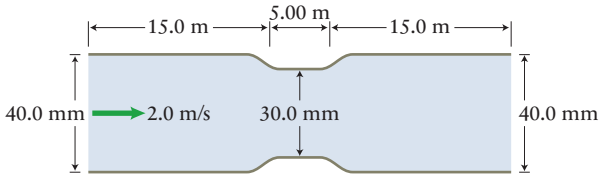


26. A viscous liquid is flowing through the pipe in Figure P18.26. If the flow is laminar, rank the speed of the liquid at points 1–4 in order of increasing speed. •

Figure P18.26

27. Figure P18.27 shows streamlines of water flowing in two regions A and B of the same pipe (neither of the two regions shown spans the entire diameter of the pipe). Between these two regions no other pipes are connected to this one. Compare the speed, pressure, and pipe diameter in the two regions A and B. ••

Figure P18.27



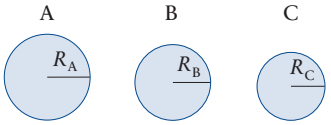
28. The water in a river flows gently in a continuous, straight channel of uniform width. Over a certain distance downstream, the water's speed decreases. What is most likely happening? State your reasons. ••

29. You are traveling in a car when the driver lights a cigarette. Why is it that when you open a window slightly the smoky air blows out of the car? Why doesn't air from the outside flow in through the opening instead? ••

30. The capped end of a pipe in your basement springs a leak. The pipe has a diameter of 50.0 mm and is attached to a joist so that it is 2.00 m above the basement floor. The water squirts out horizontally through a hole that has a diameter of 3.00 mm and hits the floor 6.00 m from the leak. What is the speed of the water inside the pipe as it moves toward the leak? Ignore air resistance. ••

31. A garden hose 30.0 m long and 40.0 mm in diameter attached to a faucet carries water that enters the hose at 2.00 m/s. The hose was previously cut at its center and has been repaired by splicing a length of hose that is 5.00 m long and 30.0 mm in diameter into the break (Figure P18.31). (*a*) What is the water speed in the small middle section of the repaired hose? (*b*) How long does the water take to flow the length of the repaired hose? ••

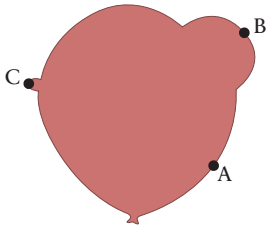
Figure P18.31



32. Consider a nonviscous fluid undergoing laminar flow in an open, horizontal channel. The Bernoulli effect says that where the flow speed is greater, the pressure is smaller, but the pressure at the surface, in contact with the surrounding air, is atmospheric pressure everywhere. How is that possible? •••

18.4 Surface effects

33. A drop of liquid is placed on a surface. A particle of the liquid at the contact point is subject to a cohesive force of 4.00 N directed 52.0° above the surface. If the contact angle is 104°, what is the magnitude of the adhesive force between the particle and the surface? •



34. Three water droplets are shown in Figure P18.34. All three are in the same room with the same atmospheric pressure. In which of the three droplets is the pressure greatest and why? •

Figure P18.34

35. A partially inflated and irregularly shaped balloon is shown in Figure P18.35. Rank the points on the balloon's surface in order of (*a*) increasing tension in the membrane and (*b*) increasing pressure on the inside. •

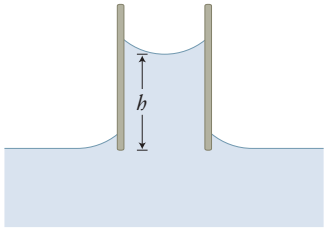
Figure P18.35

36. Suppose a certain liquid in contact with a surface has cohesive and adhesive forces such that its behavior is exactly between wetting and not wetting a surface. How do the magnitudes of the adhesive and cohesive forces compare? ••

37. A glass capillary tube has a diameter of 2.00 mm and contains a small amount of liquid that forms a concave spherical meniscus. A particle of the liquid located where the liquid surface meets the tube wall is subject to a cohesive force of 4.00 N at an angle of 35.0° to the wall and an adhesive force of 1.00 N. What is the radius of curvature of the meniscus? ••

38. Dishwashing liquid dissolved in water forms an aqueous solution containing bubbles (the "suds") that are soap-film spheres filled with air. How does the pressure difference across the surface of one of these bubbles in the solution compare with the pressure difference across the surface of a bubble of the same size that escapes from the solution and floats in the air? ••

39. What is the relationship between the radius of a capillary tube R_{tube} and the radius of curvature R_{men} of the spherical meniscus a liquid forms in the tube, in terms of the contact angle θ_c? Answer for both a wetting liquid and a nonwetting liquid. (Hint: See Figure 18.36.) ••



40. Liquid A forms a concave meniscus of radius R in a capillary tube in which its capillary rise is h_A. Liquid B has twice the surface tension and twice the mass density of liquid A and forms a concave meniscus of radius $R/2$ in an identical capillary tube. How does the capillary rise h_B of liquid B compare with h_A? ••

41. Figure 18.32 shows a drop of a wetting liquid and a drop of a nonwetting liquid sitting on a horizontal solid surface and surrounded by air. Show that, for both drops, the relationship between the contact angle and the magnitudes of the cohesive and adhesive forces exerted on a particle of liquid at the gas-liquid-solid junction is $2\sin(\theta_c/2) = F_{\text{cohesive}}/F_{\text{adhesive}}$. Assume that the surface is smooth and clean, the liquid contains no impurities, and the contact angle is not influenced by the gas. •••

42. You have three capillary tubes that are made of paraffin wax and have diameters of 1.00 mm, 2.00 mm, and 3.00 mm. (*a*) Is the meniscus that water forms in each tube convex or concave? (*b*) How might you change the water so that the answer to part *a* changes? (*c*) Because any liquid surface in a capillary tube curves either concavely or convexly, the peak or trough of the meniscus is vertically higher or lower than the location where the liquid surface meets the tube wall. Which of the three capillary tubes has the greatest vertical separation distance between the liquid-wall contact point and the meniscus peak or trough? •••

43. Figure P18.43 shows the capillary rise h for the liquid in a capillary tube sitting in a dish of liquid. Suppose you insert an identical capillary tube into the liquid but push this tube deep enough into the liquid to make the top of the tube be a distance $h/2$ above the surface of the liquid in the dish. How far do you expect the liquid to rise in this tube? •••

Figure P18.43

18.5 Pressure and gravity

44. A certain class of submarines can dive to 730 m below sea level. What is the pressure at this depth? •

45. The thresher shark has large eyes, about 0.10 m in diameter. Calculate the force exerted on a thresher shark's eye by the hydrostatic pressure in ocean water at a depth of 400 m. (Assume the water's mass density at this depth is 1000 kg/m^3.) •

46. Timbers used in building construction can withstand a pressure of 1.4×10^7 Pa before being crushed. If the mass density of wood is $\rho = 960$ kg/m^3, calculate the height h a pile of timbers would have to be in order for the ones at the bottom to be crushed. Assume that all the timbers have the same size and shape and that they are piled one on top of the other. ••

47. A cylindrical space capsule lands in the ocean. This capsule is 2.34 m long, 1.10 m in diameter, and weighted at one end so that it floats with its long central axis vertical and 0.820 m of its length above the water surface. The mass density of sea water is 1025 kg/m^3. (*a*) What is the magnitude of the buoyant force exerted on the capsule? (*b*) Suppose the capsule springs a leak and sinks. What is the magnitude of the buoyant force exerted on it once it sinks? (*c*) Why does the capsule sink if the magnitude of the buoyant force is greater after it has sunk than when it was floating? ••

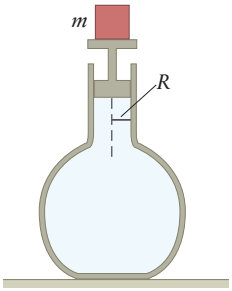
48. A certain diving bell for use in the ocean has a square window measuring 0.250 m on each side. The inside of the bell is pressurized and maintained at a pressure of 2.00 atm. How deep can this bell be lowered before the vector sum of forces exerted by the seawater on the window exceeds 195 kN? The mass density of seawater is 1025 kg/m^3. ••

49. Pascal demonstrated his principle by causing a wooden barrel full of water to burst when a small amount of additional water was poured into a long, thin tube extending vertically upward from the top of the barrel. Explain why this worked and estimate the magnitude of the force that burst the barrel's top (diameter 0.42 m) and the length of the tube (diameter 6.0×10^{-3} m) if 3.39×10^{-4} m^3 of water (less than 12 fluid ounces) was added. ••

50. When a garden hose with an output diameter of 20 mm is directed straight upward, the stream of water rises to a height of 0.15 m. You then use your thumb to partially cover the output opening so that its diameter is reduced to 10 mm. How high does the water rise now? Ignore drag and assume that the smaller opening you create with your thumb is circular. ••

51. (*a*) For the garden hose of Problem 50, calculate how high the water would rise if you constricted the opening to make its diameter 1.0 mm rather than 10 mm. (*b*) Based on your experience, would you expect to see such a height from the stream? If not, what physical effects do you think are responsible? ••

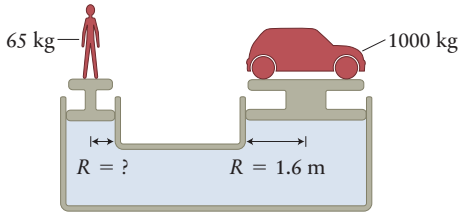
52. (*a*) Consider a fluid whose mass density ρ varies with height y above sea level. Use Eq. 18.6, $P_1 + \rho g y_1 = P_2 + \rho g y_2$, to obtain an expression that shows how dP, the change in pressure along a column of the fluid of infinitesimal height dy, varies with y. (*b*) Using the simplification that the mass density of air at any given height y above sea level is proportional to atmospheric pressure at that height, integrate the differential equation you found in part *a* to obtain an expression that shows how atmospheric pressure varies with height y above sea level. •••



53. A river valley is in the shape of a V. A dam is built in this valley, so it also has a V shape, of height h and width w at the top and essentially zero at the bottom. Write an expression for the magnitude of the force that the water exerts against this dam. •••

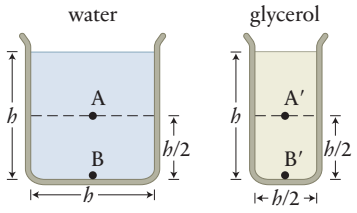
18.6 Working with pressure

54. If the outside air pressure changes from 1.0 atm to 1.1 atm, by how much does mercury in a barometer rise? The mass density of mercury is 13,534 kg/m^3. •



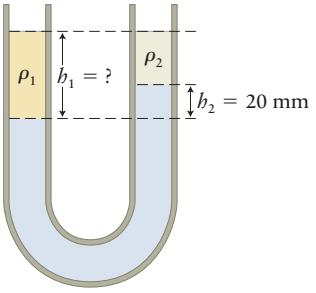
55. A small block of mass m sits atop a piston that seals a volume of air in a flask in which the radius of the neck is R (Figure P18.55). Obtain an equation for the pressure in the bottle as a function of atmospheric pressure. •

Figure P18.55



56. The two pistons in the hydraulic system shown in Figure P18.56 are coupled through a reservoir of water. The pistons are at the same height above ground. The piston on the right has a radius of 1.6 m, and the mass of the car sitting on the piston is 1000 kg. You are standing on the left piston, and neither you nor the car is moving. If your mass is 65 kg, what is the radius of the left piston? •

Figure P18.56



57. The container on the left in Figure P18.57 is a cube of side length h. The dimensions of the container on the right are height h, width $h/2$, and length $h/2$. Points A and A′ are at height $h/2$, and points B and B′ are at the bottoms of the containers. Calculate the ratio of gauge pressures $(P_A/P_B)/(P_{A'}/P_{B'})$ if the left container is filled with water and the right container is filled with glycerol. The mass density of glycerol is 1261 kg/m^3. ••

Figure P18.57

58. After pouring some water into the U-tube of Figure P18.58, you pour a volume V_1 of oil of mass density $\rho_1 = 800$ kg/m^3 into the left side of the tube and a volume V_2 of oil of mass density $\rho_2 = 700$ kg/m^3 into the right side. Once the two oils have been added, the levels on the left and right sides are the same, and the water level on the right side is a height $h_2 = 20$ mm higher than the water level on the left side. What is the height h_1 of the oil on the left side? ••

Figure P18.58

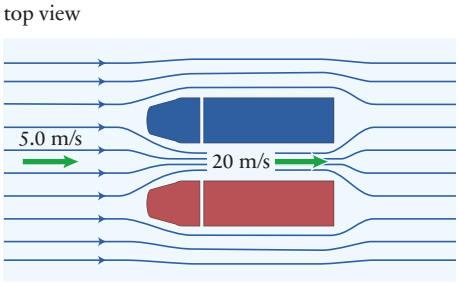
59. Initially, both legs of a mercury manometer are open to the atmosphere, and the mercury height in the left leg is 40.0 mm. You inflate a balloon until it has a surface area of 0.300 m^2 and affix its open end to the opening of the manometer's right leg. When you do this, the mercury level in the left leg changes to 65 mm. What is the magnitude of the inward force exerted by the balloon's elasticity on the air in the balloon? The mass density of mercury is 13.5×10^3 kg/m^3. ••

60. Suppose you increase the gauge pressure in the tires of your car by 10%. (*a*) How does the area of the tires in contact with a level road change? (*b*) If the gauge pressure in the tires is 2.0 atm before you increase it, by what percentage does the actual tire pressure change? ••

61. In a service station's hydraulic lift, the diameter of the large piston is 200 mm and the diameter of the small piston is 30 mm. Force is exerted on the small piston by an air compressor. (*a*) How much gauge pressure must the compressor supply to lift a 1500-kg car? (*b*) If the car must be raised 1.8 m off the floor, through what distance must the small piston travel? ••

62. A hydrogen-filled balloon is used to lift a 125-kg stone off the ground. The basket holding the stone has a mass of 15.0 kg. What must the minimum radius R of the balloon be in order to lift the stone off the ground? Use 1.29 kg/m^3 for the mass density of air, and ignore the mass of the hydrogen and the mass of the balloon. ••

63. In a large vat that is initially empty, a solid aluminum cylinder hangs by an ideal spring. The cylinder is 52.5 mm long and 30.0 mm in diameter, and the spring is stretched 42.0 mm. The vat is then filled with a liquid, submerging the cylinder and causing it to rise 11.8 mm. What is the mass density of the liquid? The mass density of aluminum is 2700 kg/m^3. ••



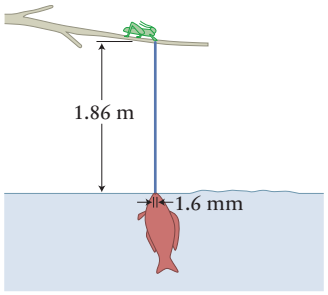
64. A 15.0-kg block measures 0.750 m top to bottom, and each horizontal face has an area of 0.0125 m^2. The block hangs, with its long central axis vertical, from a wire that can support a maximum tension of 135 N. The block is initially submerged in water, but then the water level is gradually lowered. What is the greatest distance the surface of the water can be below the top of the block without breaking the wire? ••

65. At an atmospheric pressure of 1.00 atm, the height of the liquid in the tube of a mercury barometer is 760 mm *only if* you ignore capillary rise in the tube. Obtain an expression that shows how h, the number of millimeters the mercury height differs from 760 mm, depends on the diameter d of the tube, and then calculate the value of h for $d = 7.0$ mm. The contact angle for mercury on this glass tube is 137°, and its mass density is 13.5×10^3 kg/m^3. •••
66. A small, smooth cube made of wood that has a mass density of 850 kg/m^3 is dropped from rest 5.00 m above the surface of a lake. Determine (*a*) the maximum depth the cube reaches and (*b*) the time interval the wood is under water before it returns to the surface. Assume that viscous drag is negligible so that the only force the water exerts on the cube is the buoyant force. •••
67. A right circular cone that has altitude h and a base of radius R is submerged in a liquid of mass density ρ. The cone's vertex points directly downward, so that the circular top face of the cone is horizontal. The volume of a right circular cone is $\pi R^2 h/3$. (*a*) By direct integration of the pressure over the surface of the cone, calculate the magnitude of the upward force exerted by the liquid on the cone. (*b*) Show that your answer in part *a* is consistent with Archimedes' principle. •••

18.7 Bernoulli's equation

68. Water from a faucet can fill a 4.00-L bucket in 1 min. If the diameter of the water pipe feeding the faucet is 12.5 mm, what is the speed of the water in the pipe? •
69. The water behind a dam built across one end of a large lake is 25.2 m deep. If the dam springs a leak 1.40 m above the lakebed, at what speed does water exit the hole? •
70. Two tractor trailers, each 16 m long and 4.0 m tall, are parked next to each other as shown in Figure P18.70. A light wind that is blowing at 5.0 m/s in the parking lot but at 20 m/s between the trailers causes the air pressure between them to drop. What is the magnitude of the force exerted by the air on each trailer? (Use 1.0 kg/m^3 for the air mass density.) •

Figure P18.70



71. Water leaks out of a small hole in the side of a bucket. The hole is a distance d below the surface of the water, and the diameter of the hole is much smaller than the diameter of the bucket. Example 18.9 derived an expression for the speed v_2 at which water exits the hole by assuming that $v_1 \approx 0$ for the speed at which the water surface moves downward. Derive an expression for v_2 when v_1 cannot be ignored. ••
72. You carry a fire hose up a ladder to a height of 10.0 m above ground level and aim the nozzle at a burning roof that is 9.00 m high. You hold the hose horizontally and notice that the water strikes the roof at a horizontal distance of 7.0 m from where it exits the nozzle. The hose is connected to a large pressurized chamber in the fire truck 0.500 m above ground level. What is the pressure in the chamber? Ignore air resistance. ••
73. In an aorta that has a radius of 11 mm and a transmural pressure (pressure difference across the aorta wall) of 12 kPa, blood is moving in laminar flow at 350 mm/s. What percentage of the cross-sectional area of this aorta must be blocked in order for the transmural pressure in the blocked part to fall to zero? Assume that the blood has a mass density of 1060 kg/m^3 and is nonviscous, incompressible, and undergoing laminar flow at a speed of 350 mm/s in the unobstructed part. Ignore any pressure variation with height. ••
74. Does the laminar flow of a viscous fluid exhibit the Bernoulli effect? Does Bernoulli's equation (Eq. 18.36) apply to such a liquid? ••
75. A cylindrical tube that is 2.20 m long and has a radius of 150 mm is filled with water. It is oriented with its long central axis vertical, and it is open to the air at the upper end. A hole 80.0 mm in radius is drilled in the bottom, and the water is allowed to drain out. When the water level is half the height of the tube, (*a*) what is the speed of the water exiting though the hole, (*b*) at what rate (in meters cubed per second) is the water leaving the tube, and (*c*) how fast is the top of the water column falling? ••
76. Use integration to obtain an expression for the time interval needed for the water surface in the bucket in Problem 71 (or Example 18.9) to drain down to the level of the hole. You can't ignore v_1 anymore, but you can use either the expression for v_2 obtained in Problem 71 or an approximate expression for v_2 that is valid during most of the time interval in which the water is draining. •••

18.8 Viscosity and surface tension

77. A hollow stirrer that has a diameter of 1.0 mm is inserted into a cup of water at 20 °C. The surface tension of water at that temperature is $\gamma = 7.28 \times 10^{-2}$ N/m. What is the mass of the water supported by the surface tension in the stirrer? •
78. You insert a pipette of diameter 0.700 mm into a liquid that is at 20.0 °C and has a mass density of 1261 kg/m^3. If the liquid rises 29.0 mm up the pipette due to surface tension, what is the surface tension of the liquid? •
79. The volume flow rate of water at 20.0 °C through a cylindrical pipe is 2.00×10^{-4} m^3/s. What is the volume flow rate of castor oil moving through this pipe under the same conditions? At 20.0 °C, $\eta_{\text{castor oil}} = 0.986$ Pa · s. •
80. In a low-flow showerhead that contains 18 nozzle holes, the volume flow rate of the water is 4.00 L/min and the water speed is 4.30 m/s. What is the diameter of each hole? ••

81. In the device for measuring surface tension shown in Figure 18.58, the length of the movable wire is ℓ. When the film holding the wire in place is water at 20 °C, you must do 1.46 μJ of work on the wire to move it a distance Δx downward. If the film were instead mercury at the same temperature, how much work would be required to move the wire a distance $\Delta x/2$? The surface tensions at 20 °C are 7.28×10^{-2} N/m for water and 0.465 N/m for mercury. ••
82. A horizontal pipeline is 500 mm in diameter and carries oil at a rate of 150 kg/s. This oil has a mass density of 850 kg/m^3 and a viscosity of 0.224 Pa·s at the temperature of the pipeline. If the pressure in the oil is 3.75 atm at the front end, how long can the pipeline be so that the pressure at the far end is no less than 2.50 atm? ••
83. Water from a faucet fills a bathtub with 100 L of water in 5.00 min. That water travels through a cylindrical pipe that has a diameter of 12.5 mm. What is the maximum speed of the water? ••
84. The archerfish can form a tube by curling its tongue against a groove in the top of its mouth and then snapping shut its gills. The fish can then spit a stream of water at its prey (Figure P18.84). One archerfish was observed shooting a stream of water to a height of 1.86 m, and his tongue tube was measured to be 1.60 mm in diameter. What is the minimum volume flow rate of the spit water? ••

Figure P18.84

85. Two horizontal cylindrical pipes are connected together, and a viscous liquid undergoes laminar flow through them. The first pipe has radius R_1 and length ℓ_1, and the second has radius R_2 and length $2\ell_1$. If the pressure where the pipes connect is midway between the pressures at the other ends of the pipes, how does R_2 compare with R_1? ••
86. A liquid of viscosity 0.456 Pa·s and mass density 882 kg/m^3 flows through a pipe at a volume flow rate of 2.00 m^3/s. You need to increase this rate to 8.50 m^3/s by adding to the liquid a substance that will change its viscosity but not appreciably affect its mass density. (*a*) If nothing else (including the pressure difference) changes, what new viscosity value do you need in order to achieve the desired volume flow rate? What is the *mass* flow rate, in kilograms per second, (*b*) before you change the viscosity and (*c*) after you make the change? ••
87. Drops of an oil that has a mass density of 700 kg/m^3 are released from a broken undersea oil pipe that is 1000 m below the ocean surface. (*a*) If the drops have an average diameter of 100 μm, how long do they take to rise to the surface? Hint: The drops quickly reach terminal speed and experience a viscous drag force of magnitude $F^{\text{d}}_{\text{wo}} = (0.0200 \text{ Pa} \cdot \text{s})Rv$, where R is the radius of the drops and v is their speed. (*b*) After a chemical dispersant is applied to the oil to reduce the average drop diameter to 2.0 μm, how long do the drops take to rise to the surface? Use 1000 kg/m^3 for the mass density of ocean water. •••
88. Consider the cylindrical outer surface of the column of liquid in a tube of length ℓ and radius R. Imagine slicing this surface into two half cylinders along the long central axis of the pipe. Show, by integration, that Eq. 18.52 is valid—that is, (*a*) that the magnitude of the force due to the pressure difference $P_{\text{in}} - P_{\text{out}}$ across the right semi-cylindrical surface (balanced by the force due to the surface tension due to the left half) is equal to the pressure difference $(P_{\text{in}} - P_{\text{out}})$ times $2\ell R$, and (*b*) that the direction of this force is perpendicular to the pipe length and bisects the semi-cylindrical surface. •••

Additional Problems

89. A liquid moves through a pipe of diameter d at volume flow rate Q_1. When the pipe diameter is reduced to $d/4$ while the pressure is held constant, what is the new volume flow rate Q_2 in terms of Q_1? •
90. A blood vessel has a diameter of 3.20 mm because it is partially clogged by cholesterol. You want to remove enough cholesterol to double the volume flow rate of the blood through the vessel without changing its speed. What should be the new vessel diameter? Assume the blood is nonviscous and the flow is laminar. •
91. Europa, a satellite of Jupiter, appears to have a liquid ocean of water below an ice layer on its surface. The acceleration due to gravity at the surface is 1.3 m/s^2, and there is no atmosphere. You are designing a probe to descend into Europa's ocean, and it must withstand the pressure 125 m deep in that ocean. When you are testing the probe here on Earth, how deep in Earth's ocean should you lower the probe to have it experience the same pressure it will experience when it is 125 m down in Europa's ocean? The mass density of seawater is 1025 kg/m^3, and assume the water in Europa's ocean has a mass density of 1000 kg/m^3. •
92. Estimate how much the air surrounding your body affects the scale reading when you stand on a spring scale. ••
93. In an automobile braking system, the brake pedal pushes on one end of a column of liquid (the *brake fluid*) in a rigid tube. At the other end of the tube, the liquid presses on a piston attached to a brake shoe that pushes against the brake drum and slows the car's wheels by friction. In one such system, the diameter of the tube at which the brake pedal pushes is 12.0 mm, the diameter of the piston at the brake drum is 44.0 mm, and the mass density of the liquid is 850 kg/m^3. The coefficient of static friction between the brake shoe and the brake drum is 0.880, the coefficient of kinetic friction between them is 0.650, and the piston and brake shoe push perpendicular to the brake drum. When you push on the brake pedal with a force of 125 N, what are (*a*) the magnitude of the normal contact force exerted by the brake shoe on the drum and (*b*) the magnitude of the frictional contact force exerted by the brake shoe on the drum? ••

94. A thick layer of oil of mass density 800 kg/m^3 floats atop (but does not mix with) water in a deep container. You gently place a sphere of uniform mass density in the container so that it floats with 65.0% of its volume in the water and the remaining 35.0% in the oil. What is the mass density of the material of which the sphere is made? ●●

95. In bubble tea with pearls, a popular drink from Taiwan, balls of tapioca are put into cold tea mixed with sugar and milk. Some of the balls fall to the bottom of the cup, others rise to the surface, and a few hang motionless in the liquid. (*a*) If the tea mixture has a mass density of 1350 kg/m^3, what is the approximate mass of a ball that neither rises nor falls and just fits into a straw that has a diameter of 10 mm? (*b*) Do you expect the ball to continue to hang motionless if the temperature of the mixture changes? ●●

96. A cubical box measures 1.50 m on each side and has a mass of 3000 kg. Its walls are made of a dense but very thin metal, and the box is placed upright in a lake. (*a*) Once equilibrium is achieved, how far below the lake surface is the bottom of the box? (*b*) If you slowly add water to the box, how deep can the water level in the box be before the box sinks? Assume that the box always remains level. ●●

97. On a planet the same size as Earth, ocean water has a mass density of 1000 kg/m^3. A space probe measures the atmospheric pressure at the surface of this planet to be 2.40×10^5 Pa. At a depth of 150 m in the ocean, the probe reports a pressure of 14.4×10^5 Pa. What is the mass of the planet? ●●

98. A fire hose shoots water from ground level at an angle of 60.0° above the horizontal, with negligible air resistance. The initial speed of the water is such that the water strikes a building horizontally at a height of 25.0 m above the ground. The diameter of the cylindrical hose is 0.120 m at the location where the water exits. What are (*a*) the volume flow rate of water leaving the hose and (*b*) the mass flow rate of that water in kilograms per second? ●●

99. A spherical measuring device of radius 250 mm and mass density 1500 kg/m^3 is suspended under water by two wires. Wire A pulls horizontally to the left on the sphere, and wire B pulls upward and to the right at an angle of 50.0° above the horizontal. Calculate the tension in each wire. ●●

100. A long *evacuated* tube has a cross-sectional area of 1.50×10^{-3} m^2 and is permanently sealed at one end but can be opened at the other. When the tube is opened while oriented vertically with its open end just below the surface of the liquid in a large open beaker, the liquid rises to a height of 1.28 m in the tube. If the air pressure in the room is 1.00 atm, what is the mass density of the liquid? ●●

101. A large iceberg in the shape of a cube has a mass density of 917 kg/m^3 and floats upright in seawater that has a mass density of 1024 kg/m^3. (*a*) If the sides of the cube measure 75.0 m, what is the iceberg's frequency of oscillation? Hint: First show that the motion is simple harmonic. (*b*) What would be the frequency of a cube-shaped iceberg that was twice as massive? Solve this part by proportional reasoning. ●●

102. A cylindrical log of length ℓ and radius R floats horizontally half submerged in a liquid of mass density ρ. (*a*) By direct integration of the pressure over the surface of the log, calculate the vector sum of the upward forces exerted on the log by the liquid. (*b*) Show that your answer in part *a* is consistent with Archimedes' principle. ●●●

103. Working on a team designing a new cargo ship, you have been charged with investigating what dimensions enable a steel ship to carry as much cargo as possible. Certainly the larger the ship, the more cargo it can carry, but you are given a fixed amount of steel with which to work. Assume the ship can be modeled as a box of any dimensions. You realize at once that you cannot use the design with the smallest mass density. ●●● CR

104. Watching a parent and child balancing on a seesaw, you begin to wonder what effect the buoyant force exerted by the surrounding air might have on the distance each of them must be from the pivot to achieve balance. ●●● CR

105. You have been given the task of determining, for a redwood tree 100 m tall, the mechanisms that allow the tree to grow to such a height and the mechanisms that prevent it from growing any taller. Using your knowledge of fluid dynamics, you determine that capillary rise causes water to rise a height h through a tree's xylem (the hollow tubelike cells in trees that carry water), and for a xylem radius r, this height is approximately given by $h = (0.137\ \text{J/m}^2)/(\rho_{\text{water}} g r)$. Using a microscope, you observe that the xylem has a diameter of about 5 μm. You are convinced that a mechanism other than capillary rise is needed to enable the water to rise to the top leaves. ●●● CR

The conservation laws allow us to analyze a broad range of phenomena, yet they cannot explain the *irreversibility* of time. Cars are damaged in a collision, a cube of ice melts when placed in a drink, and a drop of ink diffuses throughout a glass of water. These phenomena are *irreversible*, meaning they happen in one direction only. Always, no exceptions.

Yet there's nothing in the conservation laws that prohibits cars damaged in a collision to spontaneously move apart "undamaged," that prohibits an ice cube from forming in a glass of water, or that prohibits a collection of diffused ink molecules from coming together into a single drop. So why do phenomena such as these never happen? What is it that causes the irreversible flow of time toward the future?

As we shall see in this chapter, the underlying reason has to do with the randomness of the interactions at the atomic level. To help us quantify the tendency of systems to evolve in one direction only over time, I introduce a quantity, *entropy*, whose change is strongly connected to our sense of irreversibility.

19.1 States

Have you ever seen a motionless pendulum suddenly start swinging of its own accord? No; when no forces are applied, pendulums slow down and eventually come to rest. To understand why a swinging pendulum always slows down and never speeds up, let us consider a pendulum swinging back and forth inside a container. As the pendulum swings, kinetic energy gets converted to gravitational potential energy, which then gets converted to kinetic energy, which then . . . . If no energy is dissipated, the sum of these two energies remains constant and the pendulum keeps swinging forever.

Over time, however, the swings get smaller because with each swing a small part of the coherent mechanical energy of the pendulum is converted to incoherent thermal energy (see Section 7.3). This conversion is due to friction in the pendulum suspension and to collisions with the air molecules surrounding the pendulum. When the pendulum has come to rest, all of its mechanical energy has been dissipated. This energy is not gone—it still exists but now in the form of incoherent thermal energy associated with the motion of the molecules in the air surrounding the pendulum. So the universal tendency for the mechanical energy to dissipate appears to be related to the incoherent nature of the motion of atoms and molecules at the atomic scale.

Not one of the conservation laws we have studied forbids the conversion of that thermal energy back to mechanical energy. The pendulum could start swinging again if the air molecules would supply the kinetic energy. To understand why this transfer of energy from air molecules to pendulum is never observed, we need to look at molecular motion on the atomic scale. Let's begin by getting some feel for how much energy the pendulum and the air molecules have.

EXERCISE 19.1 Pendulum energy

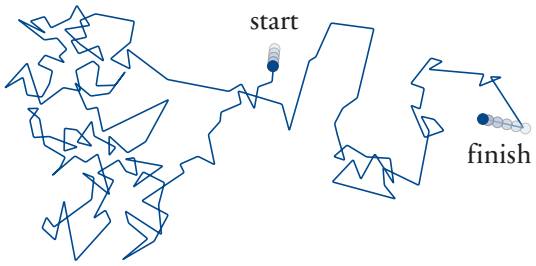
Consider a 0.10-kg pendulum swinging at a maximum speed of 0.80 m/s inside a box that contains 1.0×10^{23} nitrogen molecules. The mass of a nitrogen molecule is 4.7×10^{-26} kg, and at room temperature a typical nitrogen molecule moves at 500 m/s. What are (*a*) the mechanical energy of the pendulum, (*b*) the average kinetic energy of one nitrogen molecule, and (*c*) the sum of the average kinetic energies of all the nitrogen molecules?

SOLUTION (*a*) The mechanical energy of the pendulum is equal to its maximum kinetic energy: $\frac{1}{2}mv^2 = \frac{1}{2}(0.10\text{ kg}) \times (0.80\text{ m/s})^2 = 3.2 \times 10^{-2}$ J. ✔

(*b*) The average kinetic energy of a nitrogen molecule is $\frac{1}{2}(4.7 \times 10^{-26}\text{ kg})(500\text{ m/s})^2 = 5.9 \times 10^{-21}$ J. Comparing this value with the result I obtained in part *a*, I see that the mechanical energy of the pendulum is more than 18 orders of magnitude (a billion billion times) greater than the average kinetic energy of the individual nitrogen molecules. ✔

(*c*) The sum of the average kinetic energies of all the nitrogen molecules is $(1.0 \times 10^{23})(5.9 \times 10^{-21}\text{ J}) = 5.9 \times 10^{2}$ J. Note that this thermal energy (the kinetic energy associated with the incoherent motion of all the nitrogen molecules) is more than four orders of magnitude greater than the mechanical energy of the pendulum. ✔

19.1 The nitrogen molecules in Exercise 19.1 move considerably faster than the pendulum and continuously bombard the pendulum from all sides. (*a*) Why does this bombardment slow the pendulum down? (*b*) When the pendulum is at rest, why don't we see the effects of this continuous bombardment?



The inertia of a pendulum at rest is so much greater than that of the surrounding air molecules that the effect of collisions between air molecules and the pendulum is hardly noticeable. To see the effect of such collisions, we would have to greatly reduce the inertia of the pendulum. In 1827 the Scottish botanist Robert Brown was the first to observe the effect of this random molecular bombardment. Using a microscope to observe grains of pollen suspended in water, Brown noticed that the grains bounced around, following a zigzag path like the one shown in Figure 19.1 on the next page.

This random motion, called *Brownian motion*, is due to the random bombardment of the grains by the surrounding water molecules. Because the grains are small, the bombardment is not always equal on all sides, causing the grains to zigzag. The small random movements are what makes up Brownian motion.

19.2 How would Brownian motion change if the mass of the grain in Figure 19.1 were increased?

CONCEPTS

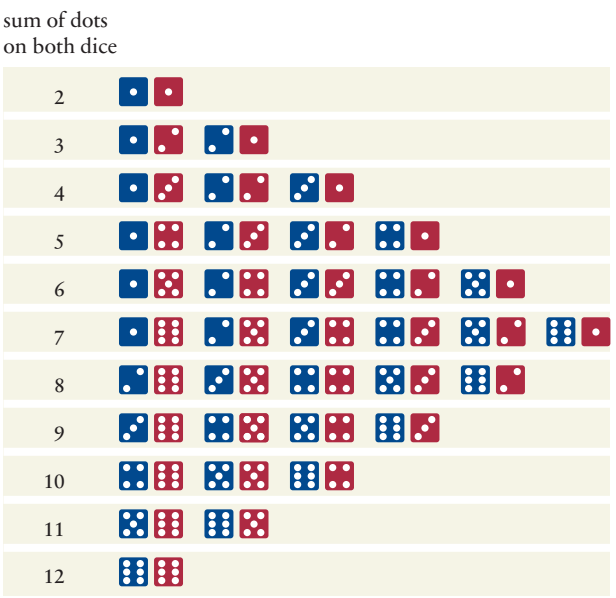
Figure 19.1 A grain of pollen suspended in water undergoes a random zigzag motion due to collisions with surrounding water molecules.

An important conclusion we can draw from the observation of Brownian motion in pollen grains suspended in water is that the bombardment is incoherent. As a result of this lack of coherence, the displacement of each grain over a long time interval is nearly zero and the grain never gains or loses any kinetic energy. If the grain were constantly kicked in the same direction, it would keep accelerating in that direction and gain kinetic energy. The same is true for a pendulum suspended in the air and hanging at rest: If it were constantly hit from one direction, it *would* start swinging.

Because it is impossible to treat the details of the incoherent atomic motion quantitatively, we need to use a very different approach to connect the atomic world of atoms and molecules to the *macroscopic* world we have described so far (*macroscopic* means "large relative to the size of a molecule"). In particular, we need to use probability theory to determine the likelihood of certain events taking place. As we shall see, the odds strongly favor slowing down a pendulum over speeding it up. To begin, let's review the essentials of probability theory using the throwing of two dice as an example.

CONCEPTS

EXERCISE 19.2 Throwing dice



When you throw two dice, one red and one blue, many times, what is the fraction of throws for which the dots on the two dice add to 4?

SOLUTION There are 36 combinations for the pair of dice (**Figure 19.2**), three of which add to 4. On every throw, each of the 36 combinations is equally likely to occur. If you throw the dice many times, the fraction of throws that add to 4 approaches the ratio $3/36 = 1/12$. ✔

19.3 What sum of dots are you most likely to throw with two dice?

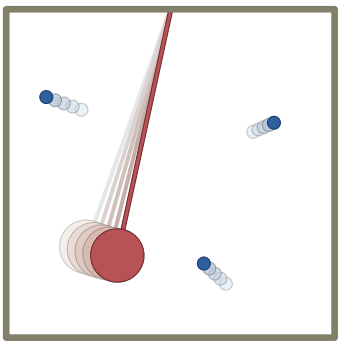
The **probability** that a certain event will occur is the fraction of times that event occurs in a large number of repetitions. Exercise 19.2 tells you that the probability of throwing a 4 is $1/12$. If you throw two dice 12 times, you won't necessarily throw a 4 exactly once. The more times you throw the dice, however, the closer the fraction of times you throw a 4 will be to $1/12$.

Figure 19.2 The 36 possible combinations for two dice.

If we consider the two dice as a system, there are several ways we can describe the state of this system. We can characterize it by the sum of the dots shown on the two dice after any given throw, or we can give a more detailed description by specifying the number of dots showing on each die. For systems with very large numbers of particles, we often care only about large-scale properties, not the detailed specifications of each particle. When we describe a system in terms of its large-scale properties, we are describing the system's **macrostate.** When we give a detailed specification of all the particles that make up the system, we are describing the system's **basic state.*** For a volume of gas, for example, the macrostate is described by large-scale properties that can be readily measured, such as temperature, pressure, and volume. The basic state is described by specifying the position and velocity of each individual gas particle.

Before describing a gas, let us return to the simpler system of two dice. The macrostate of the system after any throw is given by the sum thrown; the basic state is given by the number of dots shown on each die. As you can see in Figure 19.2, there are 36 basic states for the system and 11 macrostates. Because any basic state is equally likely to occur, the probability of any one basic state occurring is $1/36$. To calculate the probability of, say, the

*Often the term *microstate* is used instead of *basic state*. Because *microstate* and *macrostate* sound alike and are often hard to tell apart in spoken language, we'll use the term *basic state*.



macrostate 9, we divide the number of basic states associated with this macrostate by the number of basic states associated with all the macrostates. Four out of the 36 basic states correspond to the macrostate 9. Therefore the probability of throwing a 9 is $(1/36)(4) = 4/36$. Because there are more basic states for the macrostate 7 than there are for the macrostate 9, you are more likely to throw, on average, a 7 than a 9.

19.4 Suppose you are tossing four coins and decide to define the system's macrostate after any throw as the number of heads thrown. How many (*a*) macrostates and (*b*) basic states are there for this system? (*c*) What is the probability of tossing three heads? (*d*) What is the most likely macrostate after any toss?

Let us now see how all this applies to a swinging pendulum. Consider one swinging inside a box containing three gas particles (**Figure 19.3**). The particles are *distinguishable*—that is, we can tell them apart—and they collide randomly, but elastically, with one another, with the walls of the box, and with the pendulum. According to *quantum mechanics*, the energy of confined systems can only change by very small, indivisible, discrete units called *quanta* (singular: *quantum*), and many experiments confirm this discrete nature of energy units. The collisions in the box thus transfer energy units between the colliding objects.

To get a feel for how energy units are redistributed as the particles collide with the pendulum, we ignore any dissipation of energy in the pendulum's suspension and we assume that there are six identical (and therefore

Figure 19.3 As a pendulum in a box swings, it collides with three particles. The pendulum slows down as its energy is redistributed into the particles.

indistinguishable) energy units to be distributed among the pendulum and the three particles. (We'll drop the restriction that the energy units are indistinguishable later.) We further assume that the collisions distribute the energy units randomly throughout the system: that is, the redistribution jumbles up both the speeds of the particles and the directions in which they move. This assumption is justified not only by the observation of Brownian motion but also by the fact that the assumption leads to a behavior that accurately describes our observations.

Let us investigate how the six energy units can be distributed among the pendulum and the three gas particles. If we describe the system's macrostate by the number of energy units in the pendulum, there are seven macrostates. **Figure 19.4** shows how, for each of these seven macrostates, the energy units can be distributed over the pendulum and the three particles. Note that as the

Figure 19.4 The ways in which six energy units can be distributed among the pendulum and three particles of Figure 19.3. Distribution of six energy units among pendulum and three particles; each solid-colored box corresponds to one of the six units of energy. The number of basic states associated with all macrostates is 84. As the number of energy units in the pendulum decreases (left), the fraction of basic states associated with that macrostate increases (right).

Number of energy units in pendulum	Number of energy units in particles	Number of basic states	Fraction of basic states
6	0 — 1	1	$\frac{1}{84}$
5	1 — 3	3	$\frac{3}{84}$
4	2 — 3 — 3	6	$\frac{6}{84}$
3	3 — 3 — 6 — 1	10	$\frac{10}{84}$
2	4 — 3 — 6 — 3 — 3	15	$\frac{15}{84}$
1	5 — 3 — 6 — 6 — 3 — 3	21	$\frac{21}{84}$
0	6 — 3 — 6 — 6 — 3 — 3 — 6 — 1	28	$\frac{28}{84}$

three basic states having one energy unit in one particle

amount of energy in the particles increases, the number of basic states associated with that macrostate increases.

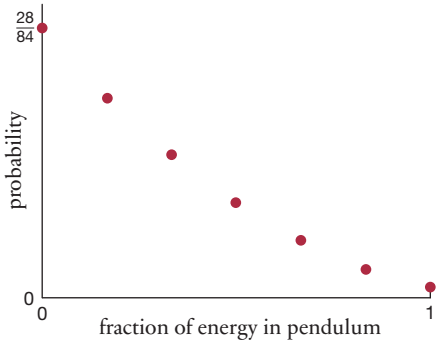
19.5 What are the six ways in which you can distribute three energy units over three particles such that one of the particles has two energy units?

Because collisions completely randomize the energy distribution, each basic state is equally likely to occur, and we can use statistics to determine the probability of any given macrostate. The probability of any one basic state is 1/84 (because there are 84 equally likely basic states). The probability of any macrostate is the number of basic states associated with that macrostate divided by the number of basic states associated with all macrostates, which is the number given in the last column of Figure 19.4. **Figure 19.5** shows how this probability depends on the fraction of energy in the pendulum.

19.6 What is the probability of finding (*a*) all of the energy in the pendulum and (*b*) either zero or one unit of energy in the pendulum?

We "digitized" the energy by arbitrarily dividing it into six units. However, collisions could redistribute smaller units of energy, and so the mechanical energy of the pendulum could change by smaller amounts. **Figure 19.6** shows how the probability of finding a certain fraction of energy in the pendulum relative to that of finding zero energy in it changes as we divide the energy into smaller units. Note by comparing Figures 19.5 and 19.6 that the division into finer units has little effect on the relative probabilities. In other words, the picture we obtain by dividing the energy into very coarse energy units is a remarkably good approximation of the much more realistic fine division predicted by quantum mechanics.

Figure 19.5 As the fraction of energy in the pendulum increases, the probability of that corresponding macrostate decreases.



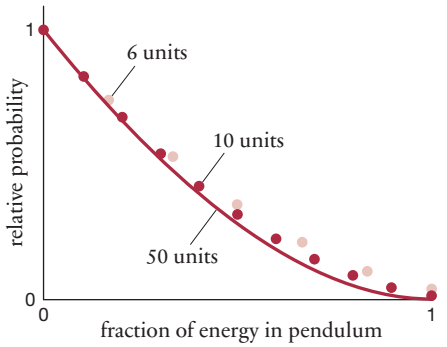


Figure 19.6 As the energy is divided into more units, the probability of finding a certain fraction of the system's energy in the pendulum relative to that of finding zero energy in it approaches the solid red line.

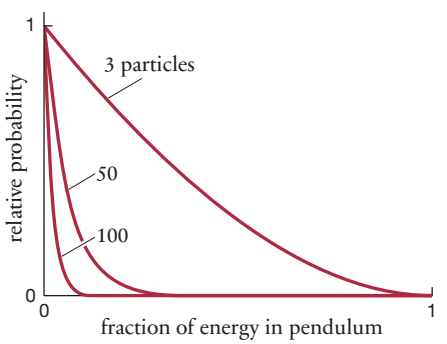


What happens if we increase the number of particles? **Figure 19.7** shows that as the number of particles increases, the spike in the relative probability near the origin sharpens and the relative probability of all 50 energy units in the pendulum drops precipitously: With 3 particles, it is on the order of 10^{-4}; with 50 particles, it is on the order of 10^{-29}; with 100 particles, it drops to 10^{-40}.

Even with a very large number of particles, however, the relative probability of the pendulum containing all the energy is nonzero. So, if we release a pendulum in a box that contains many particles and the mechanical energy of the pendulum is gradually transferred to the particles, there is a very small but nonzero probability of the pendulum gaining all its energy back again.

We can get a feeling for how long it would take for this to happen by multiplying the average time interval between collisions by the number of basic states for the system. This gives us the length of time it would take on average to cycle randomly through all the basic states. This time interval is called the *recurrence time* of the system.

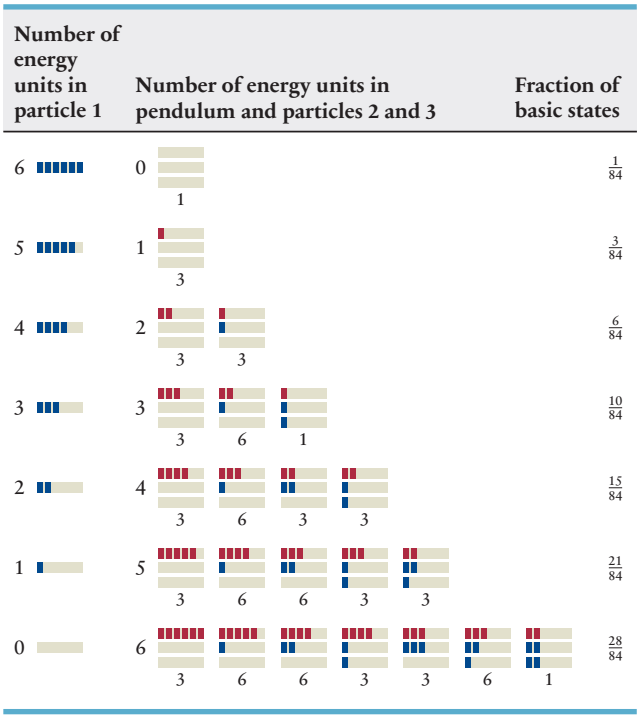
In a box of volume 1 m^3 containing 3 air molecules at room temperature, the average time interval between

Figure 19.7 As the number of particles increases from 3 to 100, the probability of finding a certain fraction of the system's 50 energy units in the pendulum relative to that of finding zero energy in it decreases significantly.

CONCEPTS

collisions is approximately 10^{15} s. So the recurrence time is approximately $(84)(10^{15}\text{ s}) = 10^{17}$ s. If there are 10^{20} particles, the average time interval between collisions is approximately 10^{-19} s. For a large number of particles, the number of basic states is equal to the number of particles raised to the number of energy units: $(10^{20})^6 = 10^{120}$ (Section 19.6). Thus the recurrence time is approximately $(10^{120})(10^{-19}\text{ s}) = 10^{101}$ s. The age of the universe is only about 10^{18} s, so don't hold your breath waiting for the pendulum to recover all its energy!

19.7 (*a*) Averaged over a long time interval, for what fraction of the time interval does the pendulum in Figure 19.3 have more than 50% of the energy of the system? (*b*) Does this fraction increase, decrease, or stay the same as we increase the number of particles?



19.2 Equipartition of energy

In our description of a pendulum swinging among gas particles, we saw that as the number of particles increases, the probability of nonzero energy in the pendulum goes to zero (Figure 19.7). Suppose now that we have a gas of four particles instead of a pendulum and three particles. The bars for the energy units in the pendulum in Figure 19.4 then represent the energy of the fourth particle, and we see that the probability is highest for that particle to have little or no energy. We can use the same argument for each of the four particles: Each particle tends to have the smallest amount of energy possible. Because the thermal energy E_{th} associated with the incoherent motion of the particles is fixed, the system tends to distribute this energy equally over all the particles, with each particle having, on average, an amount of energy E_{th}/N, where N is the number of particles. If at any instant one of the particles has a greater fraction of the thermal energy E_{th}, this energy is rapidly redistributed over the rest of the system.

Each particle is like the pendulum. Therefore if we exchange the role of the pendulum with the role of one of the particles in Figure 19.4, we obtain the macrostates and basic states shown in **Figure 19.8**. Again, the odds are highest for that particle to have little or no energy, and as we saw in Figure 19.7, these odds become even more pronounced for large numbers of particles. Each particle tends to minimize its energy.

The situation is the same for the pendulum and the three particles. On average, each part of this system has an equal share $E/4$ of the system's energy E. If we replace either the pendulum or one of the particles with an oscillating spring, with a heavier particle, or with some other object, we can go through the same arguments and in each case we see that:

Figure 19.8 If we interchange the pendulum with one of the particles in Figure 19.4, we obtain an identical configuration of macrostates and basic states.

As long as the interactions between different parts of a system randomize the distribution of energy, each part of the system tends to have an equal share of the system's energy.

This equal distribution of energy among the parts of a system is called **equipartition of energy**. In Section 20.1 we shall define more precisely what "part of the system" means. For now, consider each indivisible element of the system—a particle, a pendulum, an oscillating spring, whatever—as a "container" for energy.

CONCEPTS

EXAMPLE 19.3 Pendulum dissipation

Consider again the 0.10-kg pendulum of Exercise 19.1. The pendulum starts out swinging at a maximum speed of 0.80 m/s and stops swinging in 5.0 min. It is in a box that contains 1.0×10^{23} nitrogen molecules, each having a mass of 4.7×10^{-26} kg and moving at 500 m/s. The pendulum collides, on average, 1.0×10^{22} times per second with the nitrogen molecules. (*a*) In one collision what amount of mechanical energy is transferred on average to a nitrogen molecule, and what is the ratio of this transferred energy to the average kinetic energy of the nitrogen molecule? (*b*) By what fraction has the average kinetic energy of a nitrogen molecule increased when the pendulum stops swinging? (*c*) If the final mechanical energy of the pendulum is equal to the average kinetic energy of a nitrogen molecule, what is the pendulum's average final speed?

(Continued)

1 GETTING STARTED The collisions gradually transfer all the pendulum's initial kinetic energy to the nitrogen molecules. For simplicity, I assume that each collision transfers the same amount of energy.

2 DEVISE PLAN The number of collisions that occur during the 5.0 min it takes the pendulum to stop swinging is $(3.0 \times 10^2\ \text{s})(1.0 \times 10^{22}\ \text{collisions/s}) = 3.0 \times 10^{24}$ collisions. Dividing the initial kinetic energy of the pendulum (3.2×10^{-2} J; Exercise 19.1*a*) by this number gives me the average energy transferred in each collision. I can then compare this energy with the average kinetic energy of a nitrogen molecule calculated in Exercise 19.1*b* (5.9×10^{-21} J).

When the pendulum stops, all its mechanical energy has been transferred to the molecules. In Exercise 19.1, I determined the initial mechanical energy of the pendulum (3.2×10^{-2} J) and the sum of the average kinetic energies of all the nitrogen molecules (5.9×10^2 J). The ratio of these quantities gives me the fractional increase in the kinetic energy of each molecule.

The final average kinetic energy of the pendulum is half of its final mechanical energy: $\frac{1}{2}m_{\text{pend}}(v^2_{\text{pend,f}})_{\text{av}} = \frac{1}{2}E_{\text{pend,f}}$. To calculate the pendulum's average final speed, I set $E_{\text{pend,f}}$ equal to the final average kinetic energy of a nitrogen molecule from Exercise 19.1*b*.

3 EXECUTE PLAN (*a*) The average amount of mechanical energy transferred from pendulum to molecule in each collision is $(3.2 \times 10^{-2}\ \text{J})/(3.0 \times 10^{24}\ \text{collisions}) = 1.1 \times 10^{-26}$ J/collision. From Exercise 19.1*b*, the average kinetic energy of each molecule is 5.9×10^{-21} J. So the ratio of the energy transferred per collision to the average molecular kinetic energy is $(1.1 \times 10^{-26}\ \text{J})/(5.9 \times 10^{-21}\ \text{J}) = 1.9 \times 10^{-6}$. ✔

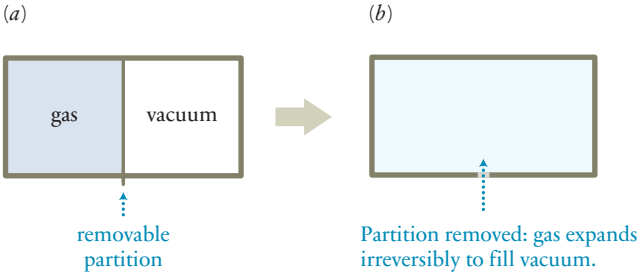
(*b*) The fractional increase in the average kinetic energy of each nitrogen molecule is the initial kinetic energy of the pendulum (which all ends up in the molecules) divided by the combined kinetic energy of the molecules from Exercise 19.1: $(3.2 \times 10^{-2}\ \text{J})/(5.9 \times 10^2\ \text{J}) = 5.4 \times 10^{-5}$. ✔

(*c*) Because the final mechanical energy of the pendulum is equal to the average kinetic energy of a nitrogen molecule, I have $\frac{1}{2}m_{\text{pend}}(v^2_{\text{pend,f}})_{\text{av}} = \frac{1}{2}(5.9 \times 10^{-21}\ \text{J})$, or $(0.10\ \text{kg})(v^2_{\text{pend,f}})_{\text{av}} = 5.9 \times 10^{21}$ J. Therefore the final average speed of the pendulum is $(v_{\text{pend,f}})_{\text{av}} = [(5.9 \times 10^{-21}\ \text{J})/(0.10\ \text{kg})]^{1/2} = 2.4 \times 10^{-10}$ m/s. ✔

4 EVALUATE RESULT Part *a* tells me that each collision transfers only a very small fraction of the pendulum's energy. This makes sense because it takes many collisions for the pendulum to come to rest. The small value I obtained in part *b* for the fractional increase in the molecules' energy makes sense because I know from experience that the air temperature (a quantity related to the kinetic energy of the molecules in the air) in the region around a swinging pendulum does not increase appreciably as the pendulum moves. Finally, my answer to part *c* shows that, for all practical purposes, the final average speed of the pendulum indeed is zero, as I had assumed in part *a*.

As Example 19.3 illustrates, the pendulum begins with much more mechanical energy than each individual gas molecule. Each collision between the pendulum and a nitrogen molecule can increase or decrease the energy of the pendulum. On average, however, these energy exchanges gradually decrease the energy of the pendulum until all nitrogen molecules and the pendulum have roughly the same energy. The pendulum's excess energy has been dissipated over all the molecules, raising their average energy by a minuscule amount.

19.8 Suppose a container holds a gas made up of two kinds of particles 1 and 2, with $m_2 = 2m_1$. Assume the particles interact via elastic collisions. (*a*) How do the average kinetic energies of the two kinds of particles compare? (*b*) How do their average speeds compare?



19.3 Equipartition of space

Collisions not only randomize the energy distribution in a gas, they also randomize spatial distributions. Consider, for example, a container divided into two compartments by a removable partition (**Figure 19.9**). In the left compartment is a gas, and the right compartment is empty. If we remove the partition, the gas diffuses to fill the entire volume. Likewise, if we put one type of gas on one side and another type of gas on the other side and then remove the partition, the two gases diffuse and mix. After some length of time has passed, both types of particles are evenly distributed throughout the container.

Both the diffusion of a single gas and the mixing of two different gases are irreversible processes. In Figure 19.9, for example, once the particles have expanded into the right side of the container, they do not spontaneously contract again into the left side.

Like dissipation of energy, this irreversible diffusion is due to the incoherent motion of particles at the atomic level. Collisions between the particles jumble up both

Figure 19.9 (*a*) A container has gas in one half and vacuum in the other, divided by a partition. (*b*) When the partition is removed, the gas expands irreversibly into the vacuum. After the expansion is complete, there is an equal likelihood of finding a gas particle anywhere in the container.

CONCEPTS

the speeds of the particles and the directions in which they move. Consequently the likelihood at any instant of finding a particle at any given position in the container is the same as at any other position or instant—there is no "preferred" position for the particles.

19.9 Suppose there are initially two indistinguishable particles in the left compartment of the container in Figure 19.9*a*. After the partition is removed, what is the probability at any given instant of finding one particle in each half of the container?

Checkpoint 19.9 suggests that we can use the statistical approach of Section 19.2 to determine the most likely locations of particles in a container. Consider, for example, a box that contains six indistinguishable particles. In order to count basic states, we need to "digitize" space just as we digitized energy in Section 19.2. So let's divide the container into four equal compartments as shown in Figure 19.10 (there are no real partitions).

The basic state of this system is determined by specifying how many particles are in each of the four compartments. There are many ways to characterize the system. Let's arbitrarily define the macrostate of the system to be the number of particles in the upper left compartment. (An alternative macrostate would be the number of particles in the lower right compartment, say, or the number in the lower half.) In Figure 19.10, all six particles are in the upper left compartment. The basic state is thus specified by the set of numbers (6, 0, 0, 0), representing the number of particles in each compartment, and the macrostate by the number 6 (for the number of particles in the upper left compartment). To determine the probability of having this distribution rather than any other, we need to determine the number of basic states and then the probability of each macrostate.

EXERCISE 19.4 Spatial macrostates and basic states

In Figure 19.10, how many basic states correspond to the macrostate in which (*a*) all six particles are in the top left compartment and (*b*) five particles are in the upper left compartment?

SOLUTION (*a*) One basic state because there is only one way to put all six particles in the upper left compartment (Figure 19.11*a*). ✔

(*b*) When five particles are in the upper left compartment, the last particle can be placed in any of the three other compartments. These three basic states are shown in Figure 19.11*b*. ✔

As you may have noticed, the problem of determining the distribution of six particles in four equal compartments of a container is identical to the energy distribution problem of Section 19.2, where we distributed six indistinguishable units of energy among four distinguishable "energy containers." Here we are distributing six indistinguishable "units of matter" among four distinguishable "spatial containers." The correspondence between the two problems is summarized in Table 19.1.

Figure 19.10

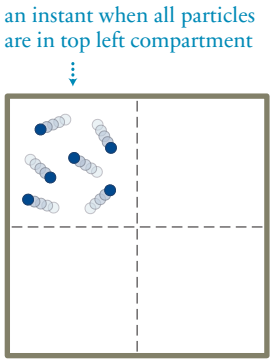


Figure 19.11

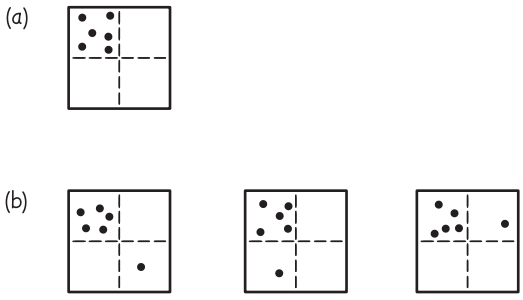

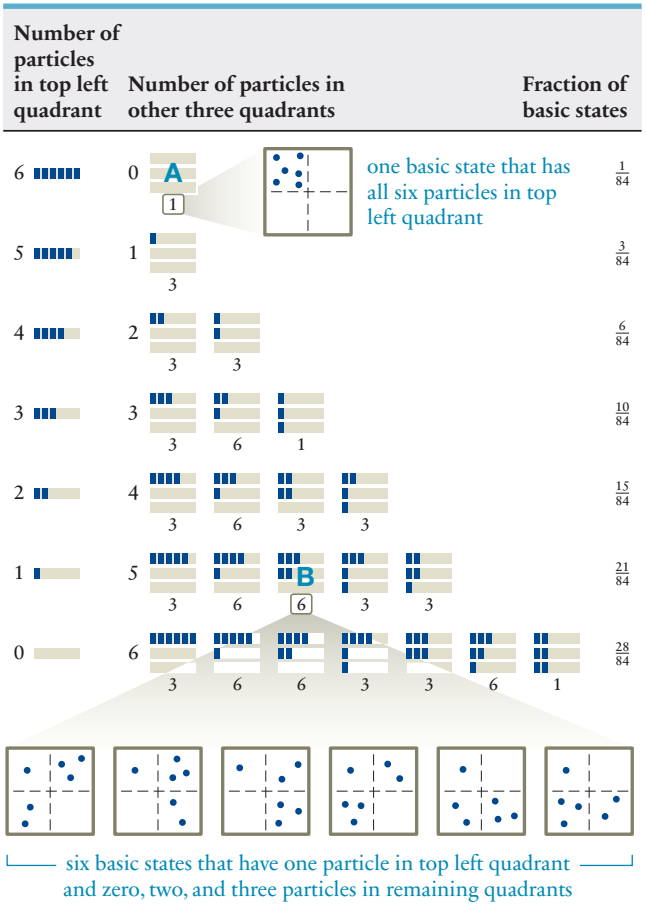

Table 19.1 Two problems, one idea

	Section 19.2	Section 19.3
phenomenon	distribution of energy	distribution of particles

macrostate defined by	energy units in pendulum	particles in top left compartment
basic state defined by	energy units in pendulum and each particle	particles in each compartment

CONCEPTS

Figure 19.12 Distribution of six particles in four equal compartments of a box.

Using the mapping from Table 19.1, we can adapt Figure 19.4 to our current discussion, as shown in Figure 19.12. The bar in the leftmost column, which represented the energy in the pendulum in Figure 19.4, now represents the number of particles in the top left compartment of the box. All the bars arranged in groups of three represent the number of particles in each of the other three compartments. The distribution labeled A thus represents the only basic state that corresponds to having all six particles in the top left compartment: The other three compartments are empty. The distribution labeled B represents six of the 21 basic states associated with the macrostate in which one particle is in the top left compartment. These basic states have three particles in any one of the other three compartments, two particles in another, and zero particles in the last remaining compartment.

19.10 (*a*) What is the probability of finding all six particles of Figure 19.10 in one compartment? (*b*) Of finding five particles in one compartment?

EXAMPLE 19.5 Particles in box

Use the data in Figure 19.12 to determine the average number of particles in the top left compartment of the four-compartment box shown there.

❶ **GETTING STARTED** The rightmost column in Figure 19.12 gives the fraction of basic states associated with each of the seven macrostates. This fraction represents the probability of finding the indicated number of particles in the top left compartment. For example, the probability of finding three particles there is $\frac{10}{84}$. In other words, if I observe the system for a long time interval, I'll see three particles in the top left compartment $\frac{10}{84}$th of the time.

❷ **DEVISE PLAN** To calculate the average number of particles in the top left compartment, I should take the sum over all macrostates of the product of the number of particles in that compartment (leftmost column in Figure 19.12) and the probability of finding that macrostate (rightmost column).

❸ **EXECUTE PLAN** Summing the products of the values in the leftmost and rightmost columns gives $6(\frac{1}{84}) + 5(\frac{3}{84}) + 4(\frac{6}{84}) + 3(\frac{10}{84}) + 2(\frac{15}{84}) + 1(\frac{21}{84}) + 0(\frac{28}{84}) = 1.5$. So, averaged over time, there are 1.5 particles in the top left compartment. ✔

❹ **EVALUATE RESULT** My answer makes sense because there are six particles in the box to be divided over four compartments: $6/4 = 1.5$.

Example 19.5 shows that even though the most probable macrostate has no particles in the upper left compartment, the average number of particles in that compartment is nonzero. Let us generalize our result by dividing the box into a large number M of equal compartments and increasing the number of particles N. On average each compartment tends to have its "share" N/M of the particles, yielding a uniform distribution of all the particles over space.

This tendency to distribute particles uniformly over space is called **equipartition of space** in analogy to the concept of equipartition of energy we encountered in Section 19.2. The diffusion of ink in water or smoke in air and the uniform distribution of gas particles in a container are all manifestations of this equipartitioning of space.

19.11 Suppose the partition in Figure 19.9 is designed to slide freely to the left and right. It is positioned in the center so that the container is divided into two equal compartments and clamped in place. Then $2N$ particles of a gas are added to the left compartment and N particles are added to the right compartment. When the clamp on the partition is removed, does the partition move to the right, move to the left, or stay where it is?

CONCEPTS

19.4 Evolution toward the most probable macrostate

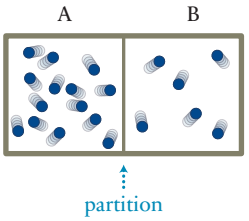
In Sections 19.2 and 19.3, we assumed that the distribution of energy and the spatial distribution of particles are entirely random, like the throw of dice. However, there is an important difference between the throwing of dice and, say, the slowing down of a pendulum.

Each time you throw two dice, the combination you get is completely independent of the combinations you threw before. After throwing a sum of 7, for example, you can throw 12, 2, another 7, or any other sum. The dissipation of the energy in a swinging pendulum, on the other hand, takes many collisions. Because a single collision redistributes only a very small portion of the system's energy, the way the energy is distributed after any given collision is only slightly different from the way it was distributed just before the collision. In other words, the energy distribution in each post-collision macrostate is not independent of the energy distribution in the pre-collision macrostate.

19.12 In the system shown in Figures 19.3 and 19.4, suppose each collision transfers exactly one unit of energy from one colliding object to the other. (*a*) If the system is in the macrostate that has six energy units in the pendulum, which basic state(s) can the system be in after one collision? (*b*) If the system is in the macrostate that has five energy units in the pendulum, which *macrostates* can the system be in after one collision? (*c*) How many basic states do the macrostates in part *b* correspond to?

Checkpoint 19.12 shows that only neighboring macrostates are accessible to the system after each collision. So, if we start with all the energy in the pendulum, the system can only gradually evolve to the most probable macrostate (the one with all the energy in the gas particles). It takes a minimum of six collisions to reach the most probable macrostate. The number is likely to be much greater because, as you saw in doing the checkpoint, collisions can take place between two particles, leaving the energy in the pendulum unchanged, or a collision may *add* energy to the pendulum.

19.13 Suppose the system in Figure 19.4 is in the macrostate in which two energy units are in the pendulum and one collision takes place. (*a*) What are the accessible macrostates? (*b*) What is the probability for each of these macrostates?



Note that the probability of reducing the energy in the pendulum is always higher than that of increasing the energy, and so the system gradually evolves to macrostates of increasing probability. Once the system is in the most probable macrostate, collisions continue to shuffle energy units around, but the system remains near this most probable macrostate. The system is therefore at equilibrium, and the most probable macrostate is the **equilibrium state.** If the pendulum and particles do temporarily occupy a macrostate that is less probable than the equilibrium state, then any subsequent collisions tend to move the system back toward equilibrium.

As we have seen, the probability of all the energy moving from the particles to the pendulum is vanishingly small, even for a gas of just 100 particles. This one-way flow of energy from pendulum to gas particles is the essence of *irreversibility* (see Section 5.3). Irreversibility is strongly connected to our sense of time. The direction of time is clear because everything around us is evolving irreversibly toward equilibrium. Now you can see that the underlying reason for irreversibility is statistics: Any system that is in a low-probability macrostate tends to evolve toward the macrostate that has the maximum number of basic states. Once the system has reached that equilibrium state, its probability of spontaneously returning to a macrostate that has a small number of basic states is vanishingly small.

To get a better sense of this evolution toward equilibrium, let's examine the particles in the closed box of **Figure 19.13**. The box contains 20 particles and is divided into compartments A and B. The partition prevents the particles from traveling from one compartment to the other but still allows particles from the two compartments to exchange energy with one another via collisions with the partition.

The energy of the system is constant—no energy can leak out because the system is closed. Suppose A contains 14 particles, B contains six particles, and the box contains ten units of energy. **Table 19.2** on the next page shows how these ten units can be distributed among the 20 particles. Let's define the macrostate by the energy units in compartment A. The number of basic states associated with each compartment is represented by the symbol Ω (the Greek capital omega) plus a subscript identifying the compartment. For example, there is only one basic state for compartment

Figure 19.13 Box containing 20 particles (14 on the left, 6 on the right) and 10 units of energy. The particles in the two compartments can exchange energy with one another through collisions with the partition.

CONCEPTS

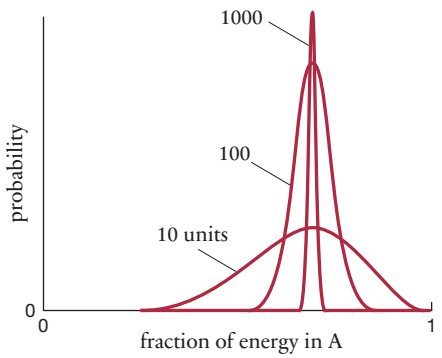
Total		1,961,256	8008	$\Omega_{tot} = 2.00 \times 10^7$	

A ($\Omega_A = 1$) for macrostate $E_A = 0$. With nine energy units in A ($E_A = 9$) and the other one in B, there are 497,420 basic states for A ($\Omega_A = 497{,}420$) and six basic states for B ($\Omega_B = 6$).

19.14 How many ways are there to distribute two indistinguishable energy units among six distinguishable particles?



CONCEPTS

Note in Table 19.2 that as the number of energy units in each compartment of the box increases, the number of basic states in that compartment increases rapidly. Because the number of energy units in the box is constant, the number of basic states in one compartment decreases as the number of basic states in the other compartment increases. What then is the most probable macrostate for the box as a whole?

To answer this question, consider the macrostate $E_A = 1$ in Table 19.2. There are 14 ways to distribute this 1 energy unit in A (it can go into any one of the 14 particles of A), so there are 14 basic states associated with compartment A for $E_A = 1$. One energy unit in A leaves nine energy units to be distributed in B, and as you can see from the table, there are 2002 ways to distribute these nine units over the six particles in B. For each of the 14 basic states associated with compartment A, there are 2002 basic states associated with compartment B. The number of basic states associated with the macrostate $E_A = 1$ is thus $14 \times 2002 = 28{,}028$. More generally, for a given macrostate, the number Ω of basic states available to the system is obtained by multiplying Ω_A by Ω_B: $\Omega = \Omega_A\Omega_B$.

The probability of each macrostate is obtained by dividing Ω, the number of basic states associated with that macrostate, by Ω_{tot}, the number of basic states associated with all macrostates (2.00×10^7; see Table 19.2). The table shows you that this probability is greatest for the macrostate $E_A = 7$, as you would expect. Given that there are 14 particles in A and six in B, on average each particle has half an energy unit, and so the $E_A = 7$ macrostate corresponds to an equipartitioning of the energy. The curve labeled 10 units in **Figure 19.14** shows this probability as a function of the fraction of energy contained in A.

Figure 19.14 Probability of finding a given fraction of the system's energy in compartment A of the box in Figure 19.13. As the number of energy units increases from 10 to 1000, the probability distribution becomes narrower but remains centered about the mean energy.

EXAMPLE 19.6 Probability of macrostates

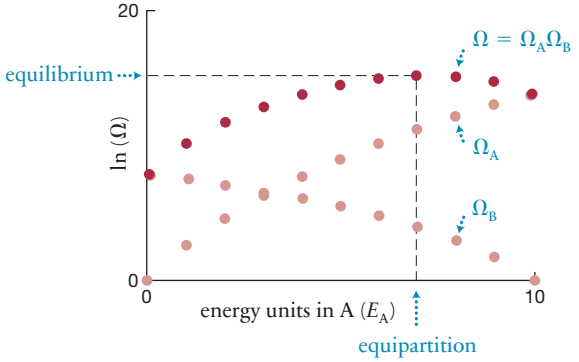
In Figure 19.13, after a very large number of particle-partition collisions have occurred, what is the probability of finding the system in (*a*) the macrostate $E_A = 1$ and (*b*) the macrostate $E_A = 7$?

1 GETTING STARTED Because all basic states are equally likely, the probability of finding the system in macrostate E_A is equal to the fraction Ω/Ω_{tot}, where Ω is the number of basic states of the system associated with the macrostate E_A and Ω_{tot} is the number of basic states associated with all macrostates (2.00×10^7; Table 19.2).

2 DEVISE PLAN To calculate the probability of a given macrostate E_A, I divide the value of Ω for that macrostate given in Table 19.2 by $\Omega_{tot} = 2.00 \times 10^7$.

3 EXECUTE PLAN (*a*) For $E_A = 1$, Table 19.2 tells me that $\Omega = 2.80 \times 10^4$. The probability of macrostate $E_A = 1$ is thus $(2.80 \times 10^4)/(2.00 \times 10^7) = 1.40 \times 10^{-3}$. ✔

(*b*) For macrostate $E_A = 7$, $\Omega = 4.34 \times 10^6$. So the probability of this macrostate occurring is $(4.34 \times 10^6)/(2.00 \times 10^7) = 2.17 \times 10^{-1}$. ✔



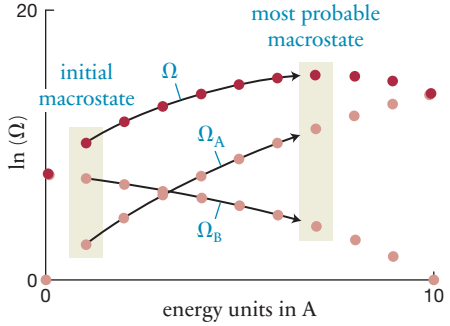
4 EVALUATE RESULT My result shows that the macrostate $E_A = 7$ is more than 150 times more probable than the macrostate $E_A = 1$. This makes sense because, as we saw earlier, the macrostate $E_A = 7$ is the equilibrium state for which there is an equipartition of energy.

If we increase the number of energy units in the box of Figure 19.13 to 100 or 1000, the number of basic states grows exponentially, and if we plot the probability of each macrostate as a function of the fraction of energy in A, we obtain the two curves labeled 100 and 1000 in Figure 19.14. Just as we saw in Figure 19.7, the most probable macrostate doesn't change, but the probability peaks much more narrowly around this state. In other words, the most probable macrostate—the equilibrium state—is now even more likely than any other macrostate.

Note that the number of basic states is very large, even with just ten energy units and 20 particles. In a box of volume 1 m^3 containing air at atmospheric pressure and room temperature, there are on the order of 10^{25} particles and 10^{20} energy units per particle, and so the number of basic states becomes unimaginably large—on the order of ten raised to the power 10^{21}! Because the number of basic states is so large, it is more convenient to work with the natural logarithm of that number. As you can see from the rightmost column in Table 19.2, the natural logarithm of the number of basic states is indeed much more manageable.

Figure 19.15 shows how the natural logarithms of Ω_A, Ω_B, and Ω vary with the number of energy units in compartment A in Figure 19.13. As you can see, the natural logarithm of the number of basic states changes much less rapidly than the number of basic states. Note that as E_A increases, the number of basic states Ω_A increases. As

Figure 19.15 Natural logarithm of the number of basic states for compartment A, for compartment B, and for the two compartments in Figure 19.13 combined. The number of basic states is maximal when the energy is equipartitioned (seven energy units in A).



E_A increases, however, E_B decreases and so Ω_B decreases. The number of basic states Ω is maximum when $E_A = 7$ and $E_B = 3$, representing an equipartition of energy. The most probable macrostate (equilibrium) is achieved when there is equipartition of energy.

19.15 What is the average energy per particle in compartments A and B in Figure 19.13 (*a*) when there is one energy unit in A and (*b*) when the system is at equilibrium?

As you can see from Table 19.2, with $E_A = 1$ the number of basic states for the system (2.80×10^4) is more than 100 times smaller than it is at equilibrium ($E_A = 7$, $\Omega = 4.34 \times 10^6$). Collisions between the particles and the partition redistribute the energy among the particles, and over time the system evolves toward the most probable macrostate—the one for which each particle has its "fair share" of the system's energy (10/20 = 0.5 unit), just as you found in Checkpoint 19.15*b*. As the system evolves toward equilibrium from the $E_A = 1$ macrostate (**Figure 19.16**), the number of basic states in B *decreases*; that is, B

Figure 19.16 If the system evolves toward equilibrium from an initial macrostate with 1 energy unit in A, the number of basic states increases in A and decreases in B. The decrease for B is smaller than the increase for A and so the number of basic states still increases.

CONCEPTS

moves toward a macrostate of *lower* probability. However, the rate at which Ω_A increases is greater than the rate at which Ω_B decreases, and so Ω still increases.

EXAMPLE 19.7 Equilibrium

Suppose the system depicted in Figure 19.13 evolves toward equilibrium from the macrostate $E_A = 4$, $E_B = 6$. Determine the changes in (*a*) the number of energy units and (*b*) the number of basic states for compartment A, for compartment B, and for the system.

1 GETTING STARTED From Table 19.2 I see that the equilibrium macrostate (the one that has the greatest number of basic states associated with it) has $E_A = 7$ and $E_B = 3$. This is the macrostate toward which the system evolves.

2 DEVISE PLAN The change in the number of energy units in A is $\Delta E_A = E_{A,f} - E_{A,i}$. The change in the number of energy units in B is $\Delta E_B = E_{B,f} - E_{B,i}$. The change for this system is the sum of these two values. To determine the changes in the number of basic states, I obtain the number of basic states for the initial and final macrostates from Table 19.2 and compute the differences.

3 EXECUTE PLAN (*a*)

$$\Delta E_A = E_{A,f} - E_{A,i} = 7 - 4 = +3;$$
$$\Delta E_B = E_{B,f} - E_{B,i} = 3 - 6 = -3;$$
$$\Delta E = \Delta E_A + \Delta E_B = 3 - 3 = 0. \checkmark$$

(*b*) $\Delta\Omega_A = \Omega_{A,f} - \Omega_{A,i} = 77{,}520 - 2380 = 75{,}140$

$\Delta\Omega_B = \Omega_{B,f} - \Omega_{B,i} = 56 - 462 = -406$

$\Delta\Omega = \Omega_f - \Omega_i = (\Omega_{A,f})(\Omega_{B,f}) - (\Omega_{A,i})(\Omega_{B,i})$

$= (4.34 \times 10^6) - (1.10 \times 10^6) = 3.24 \times 10^6. \checkmark$

4 EVALUATE RESULT My answer to part *a* shows that the change in the number of energy units in the system is zero, as I expect because the system is closed. My result in *b* shows that even though Ω_B goes down, Ω_A increases significantly more, and so there is a gain in the number of basic states, as should happen when a system evolves toward equilibrium. Because Ω is the product of Ω_A and Ω_B, $\Delta\Omega$ is not simply the sum of $\Delta\Omega_A$ and $\Delta\Omega_B$. My result for $\Delta\Omega$, however, shows an increase in the number of basic states, as I expect.

The evolution toward equilibrium in Figure 19.13 (or in any other system) is a gradual process that seeks out the most probable macrostates through a very large number of random collisions. Once the system has reached equilibrium, the probability of returning to the macrostate $E_A = 1$ energy unit is very small—even for a system of just 20 particles. For a more realistic system, in which the number of particles is much greater, the odds favor equipartitioning so strongly that the probability of observing a system away from equilibrium is virtually zero unless the system is disturbed by outside influences.

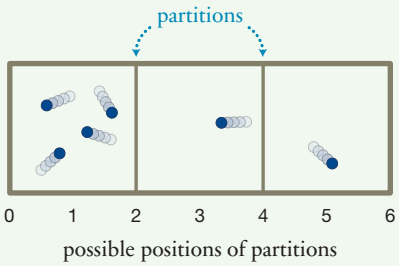
The irreversible evolution of a system toward equilibrium can be quantified by the number of basic states Ω:

> **A closed system always evolves so as to maximize the number of basic states Ω. When this number has reached a maximum, the system is at equilibrium.**

This irreversible tendency of closed systems to maximize Ω is called the **second law of thermodynamics.***

Often we cannot directly determine the number of basic states Ω for a system. The second law of thermodynamics, however, allows us to reach conclusions about Ω in a closed system without having to consider any details at the atomic level. Consider, for example, a closed system consisting of a drop of ink placed in a beaker of water. We know from experience that the ink diffuses until it is uniformly distributed in the water (equipartition of space). In Section 19.3 we saw that the spreading out of particles increases the number of basic states—Ω for six particles in a container is much greater at equilibrium than when all the particles are clustered in a corner. For the ink, too, Ω increases as the ink spreads out, and so we can use our intuitive sense of the direction of time to reach conclusions about the number of basic states: If a process in a closed system runs only one way (the process is irreversible), the number of basic states of that system must be increasing. Conversely, the number of basic states of a closed system undergoing a reversible process remains constant.

CONCEPTS



19.16 For which of these systems does Ω increase over time: (*a*) a thermos bottle containing warm water with an ice cube in it, (*b*) a cup of tea that is at the same temperature as the air in an insulated room, (*c*) a well-shaken bottle containing oil and water, (*d*) a seed germinating in soil inside a closed container, (*e*) the universe.

**Thermodynamics* is the branch of physics that deals with thermal energy and devices such as engines, subjects we discuss in the next two chapters. The second law of thermodynamics was first formulated (in a different form) in the context of this branch of physics. The formulation given here represents the modern and more general view of this law.

Self-quiz

1. Figure 19.4 shows that there are 15 basic states for four energy units distributed over three particles. List all 15.
2. Suppose a container holds three types of gas. The masses of the gas particles are m, $4m$, and $9m$. How do the average speeds of the particles compare?
3. In Figure 19.12 what is the probability of finding three particles in any compartment of the box?
4. The two partitions in the container shown in **Figure 19.17** can slide freely. Where will they be positioned when the space is equipartitioned?

Figure 19.17

5. A box with a fixed partition through which energy can be exchanged contains 50 particles, 40 on the left and 10 on the right. The system contains 250 energy units. As the system approaches equilibrium, how many energy units end up on the left? On the right?
6. If a closed system tends to change in a specific direction, such as ice melting in an insulated glass of water, what can you say about the number of basic states for this system?

Answers

1. 400, 040, 004, 310, 301, 031, 130, 013, 103, 220, 202, 022, 112, 121, 211.
2. According to the concept of equipartition of energy, the energy needs to be shared equally among all the gas particles, $\frac{1}{2}mv_1^2 = \frac{1}{2}(4m)v_2^2 = \frac{1}{2}(9m)v_3^2$, or $v_1^2 = 4v_2^2 = 9v_3^2$. Thus $v_1 = 2v_2 = 3v_3$.
3. Figure 19.12 shows that there are ten basic states with three particles in the top left compartment, regardless of the number of particles in the other compartments. When there are two particles in the top left compartment, there are six basic states with three particles in any other compartment. With one particle in the top left compartment, there are $6 + 3 = 9$ basic states with three particles in any other compartment. With no particles in the top left compartment, there are $6 + 3 = 9$ basic states with three particles in any other compartment. Therefore there are $10 + 6 + 9 + 9 = 34$ basic states with three particles in any compartment. The probability of finding three particles in any compartment is thus 34/84.
4. The partition shown at position 2 moves to position 4, and the partition shown at 4 moves to 5, so that there is 1 particle per unit length of the box.
5. Because at equilibrium the energy must be equipartitioned, the 250 units are evenly distributed across the 50 particles; with five units per particle. The 40 particles on the left have 200 units of energy, and the 10 particles on the right have 50 units.
6. According to the second law of thermodynamics, the system evolves to the macrostate that has the maximum number of basic states. Because the process is irreversible, the final macrostate must have a greater number of basic states than the initial macrostate.

19.5 Dependence of entropy on volume

In Sections 19.2 and 19.3, we saw that the equipartition of energy and space describes the most probable macrostate of any system—that is, the state that has the greatest number of basic states. The number of *atomic parameters*, such as the position and velocity of each particle, is intractably large for any real system, and so it is generally impossible to specify the basic state of the system. The macrostate, on the other hand, is readily specified by a few measurable *macroscopic parameters*, such as volume, pressure, or temperature.

To make the connection between macroscopic and atomic parameters, we consider a gas that consists of a very large number N of particles in a container of volume V. The particles occupy a negligible fraction of the volume V and interact with one another only during collisions that randomize both the energy distribution and the spatial distribution. All collisions between the particles and the walls of the container are elastic. A gas that satisfies these conditions is called an **ideal gas.** At high temperature and low pressure, an ideal gas is a good model for a real gas.

Let us now calculate how the number of spatial basic states depends on V and N. The system is closed so that the energy of the gas remains constant. Throughout this section we shall take this energy to be equipartitioned over the gas particles. At equilibrium each particle has an equal probability of occupying any location inside the container; the space is equipartitioned and each particle has its fair share of the volume V of the container. To count basic states, we divide the container into equal-sized compartments as we did in Section 19.3. If there are M equal-sized compartments and just one particle, that particle can be placed in any one of the M compartments. Thus there are M basic states for that one particle (**Figure 19.18**). A second particle can also be placed in any of the M compartments, and so, for two particles, there are M^2 basic states. Continuing this process for N particles, we see that Ω, the number of basic states, is*

$$\Omega = M^N \quad \text{(closed system)}. \tag{19.1}$$

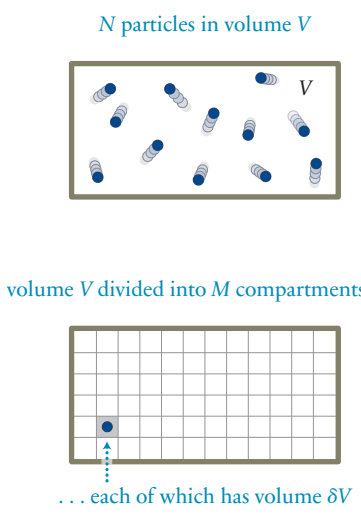


Figure 19.18 Each of the N particles inside the container can be placed in any one of the M equal-sized compartments.

EXERCISE 19.8 Number of basic states

Suppose ten distinguishable particles are equipartitioned in a container that is divided into 100 equal-sized compartments. (*a*) How many basic states are associated with this system? (*b*) What is the natural logarithm of this number of basic states?

SOLUTION (*a*) The number of basic states is $\Omega = M^N = 100^{10} = (10^2)^{10} = 10^{20}$, an unimaginably large number. ✔

(*b*) The natural logarithm of the number of basic states is $\ln \Omega = \ln(10^{20}) = 46$, a much more manageable number. ✔

19.17 If you decrease the size of the compartments in Exercise 19.8 by a factor of 10, what is the change (*a*) in the number of basic states and (*b*) in the natural logarithm of that number?

Exercise 19.8 and Checkpoint 19.17 illustrate that the natural logarithm of the number of basic states is much more manageable and less sensitive to a change in compartment size than the number itself. The natural logarithm of the number of basic states from Eq. 19.1 is

$$\ln \Omega = \ln(M^N) = N \ln M \quad \text{(closed system at equilibrium)}, \tag{19.2}$$

*We assume here that the particles are distinguishable from one another. In reality, the particles of an ideal gas are indistinguishable. In the case of indistinguishable particles and when $M \gg N \gg 1$, the number of basic states is found to be $M^N/N!$ instead of the result shown in Eq. 19.1. For simplicity, we shall limit the treatment in this section to systems of distinguishable particles.

QUANTITATIVE TOOLS

where we have used the identity $\ln(a^b) = b \ln a$. If the volume of the equal-sized compartments is δV, the number of compartments is $M = V/\delta V$, and so Eq. 19.2 becomes

$$\ln \Omega = N \ln\left(\frac{V}{\delta V}\right)$$
$$= N \ln V - N \ln \delta V \quad \text{(closed system at equilibrium)}, \qquad (19.3)$$

where we have used the identify $\ln(a/b) = \ln a - \ln b$.

Because the quantity $\ln \Omega$—the natural logarithm of the number of basic states—is so important, we define a quantity called **entropy:***

$$S \equiv \ln \Omega. \qquad (19.4)$$

Entropy is a unitless quantity that is a measure of the number of basic states in a system. The greater the number of basic states, the greater the entropy. Entropy allows us to quantify the spreading out of energy or particles over space.

As we saw in Section 19.4, a closed system always evolves so as to maximize the number of basic states. As the number of basic states increases, so does the entropy: $S_f > S_i$. Therefore,

$$\Delta S > 0 \quad \text{(closed system evolving toward equilibrium)}. \qquad (19.5)$$

At equilibrium, the number of basic states reaches its maximum value Ω_{max} and the entropy of the system no longer changes:

$$\Delta S = 0 \quad \text{(closed system at equilibrium)}. \qquad (19.6)$$

Equations 19.5 and 19.6 constitute the **entropy law,** a mathematical expression of the second law of thermodynamics. The entropy law implies that the entropy of a closed system never decreases (it can only increase or remain constant).

It is important to note that Eqs. 19.5 and 19.6 apply to only closed systems. For a system that is not closed, the entropy can increase, remain the same, or decrease. Back in Figure 19.16, for example, the particles in B transfer some of their energy to the particles in A, so B does not constitute a closed system. As we saw, Ω_B decreases and so the entropy of B decreases:

For systems that are not closed, the entropy can increase, decrease, or stay the same.

For a system of N gas particles equipartitioned over a volume V, we can obtain an expression for how entropy depends on volume by substituting Eq. 19.3 into Eq. 19.4:

$$S = N \ln V - N \ln \delta V \quad \text{(closed system at equilibrium)}. \qquad (19.7)$$

This expression describes a gas that is equipartitioned over a volume V—that is, at equilibrium. The value for S given by this expression thus represents the *maximum* value for the entropy of a gas of N particles in a volume V. If the gas is not at equilibrium, its entropy is smaller than that given by Eq. 19.7.

*Historically, entropy has been defined as $S \equiv k_B \ln \Omega$, where k_B is a constant that makes the entropy a much smaller number and gives it units of J/K (see Eq. 19.39). In this book, however, we shall use the definition given in Eq. 19.4. This definition is called a *statistical definition* of entropy.

The first term on the right in Eq. 19.7 shows that for a fixed number of particles N, the entropy (that is, the natural logarithm of the number of basic states) increases as we increase the volume V of the container. The second term on the right depends on the size of the compartments: The smaller the compartments, the smaller this term and therefore the greater the entropy. That the entropy depends on the volume δV of the compartments may seem disturbing—after all, the partitioning is completely arbitrary. In general, however, $\delta V \ll V$, and so the second term on the right in Eq. 19.7 is much smaller than the first one and can be ignored.

In general, we shall be concerned only with *changes* in entropy, in which case the second term in Eq. 19.7 drops out entirely. Consider, for example, the expansion of a gas made up of a fixed number of particles from an initial volume V_i to a final volume $V_f > V_i$. According to Eq. 19.7, the change in entropy is

$$\begin{aligned}\Delta S &= S_f - S_i = (N \ln V_f - N \ln \delta V) - (N \ln V_i - N \ln \delta V) \\ &= N \ln V_f - N \ln V_i = N \ln\left(\frac{V_f}{V_i}\right) \quad \text{(closed system at equilibrium)}.\end{aligned} \tag{19.8}$$

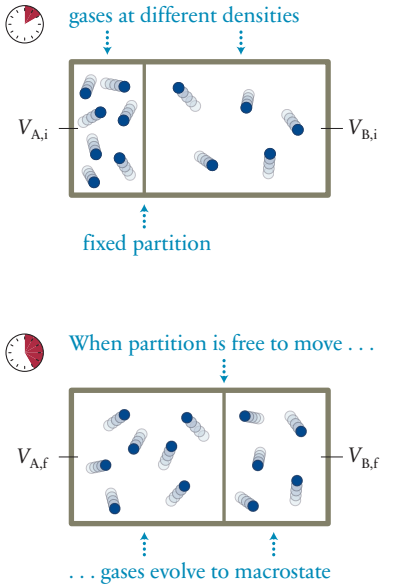
Because the second term on the right in Eq. 19.7 cancels out, the entropy change does not depend on the size of the compartments. Note that because $V_f > V_i$ the change in entropy is positive.

19.18 (*a*) What does a positive entropy change in a closed system imply about the change in the number of basic states? (*b*) How does Eq. 19.8 show that a gas expands if given more room? (*c*) How does it show that the gas does not contract spontaneously into a subvolume?

Let us next examine how entropy changes when a system of two interacting gases evolves to equilibrium. Consider, for example, two gases inside a container with a partition separating the gases into two compartments, one of volume V_A containing N_A particles and the other of volume V_B containing N_B particles (**Figure 19.19***a*).* If we let the partition move freely, the system evolves to the macrostate that has the maximum number of basic states. If the partition moves to the right, V_A increases, and so the number of basic states for gas A increases. As V_A increases, V_B decreases, and so the number of basic states for gas B decreases. Where does the partition come to rest? In other words, what value of V_A maximizes the number of basic states for the system as a whole?

In Section 19.4, we determined that the number of basic states for a system comprising two gases is the product of the number of basic states for the two separate gases:

$$\Omega = \Omega_A \Omega_B, \tag{19.9}$$



Using the definition of entropy (Eq. 19.4), we obtain

$$S = \ln(\Omega_A \Omega_B) = \ln \Omega_A + \ln \Omega_B = S_A + S_B, \tag{19.10}$$

where we have used the fact that $\ln(ab) = \ln a + \ln b$. Note that, unlike Ω, the natural logarithm of Ω and thus entropy are extensive properties:

The entropy of a combined system is the sum of the entropies of the individual systems.

Figure 19.19 (*a*) Two gases of unequal densities are placed on either side of a partition. (*b*) When the partition is free to move, the two gases evolve to the macrostate corresponding to the maximum number of basic states.

*We assume energy is equipartitioned over the system made up of both compartments and focus on only volume changes here. In the next section we shall examine the equipartitioning of energy.

QUANTITATIVE TOOLS

EXAMPLE 19.9 Partitioned gas

A partition divides a container into two equal compartments, A and B. Initially compartment A contains a gas of distinguishable particles and compartment B is empty. (*a*) What is the change in the entropy of the gas if the partition is removed and the gas is allowed to expand into the volume V of the container? (*b*) If the partition is reinserted after the gas has reached equilibrium in the volume V, what is the change in the entropy of the gas due to the reinsertion?

❶ **GETTING STARTED** When the partition is removed, the gas expands to fill the container, so the final volume occupied by the gas is twice the initial volume: $V_f = 2V_i$. Reinserting the partition divides the container into two equal compartments A and B again. The only difference is that now B is not empty; it contains half of the particles, and A contains the other half.

❷ **DEVISE PLAN** To obtain the change in entropy due to the removal of the partition, I substitute $V_f = 2V_i$ into Eq. 19.8. For part *b*, the entropy change due to the reinsertion is equal to the difference between the entropy of the gas after the partition is reinserted and its entropy before the partition is reinserted. To determine the entropy before the partition is reinserted, I use Eq. 19.7. Equation 19.10 tells me that after reinsertion the entropy of the gas is equal to the sum of the entropies in the two compartments. Because each compartment has half the volume of the container and contains half the gas particles, the entropies in the two compartments are equal to each other. To determine these entropies, I use Eq. 19.7 again.

❸ **EXECUTE PLAN** (*a*) Equation 19.8 gives $\Delta S = N \ln(2V_i/V_i) = N \ln 2$. ✔

(*b*) From Eq. 19.7, I obtain for the entropy before reinsertion of the partition: $S_i = N \ln V - N \ln \delta V$. Combining Eqs. 19.10 and 19.7, I obtain for the final entropy,

$$S_f = S_A + S_B = 2\left[\frac{N}{2}\ln\left(\frac{V/2}{\delta V}\right)\right] = N\ln\frac{V}{2} - N\ln\delta V$$
$$= N\ln V - N\ln 2 - N\ln\delta V.$$

The change in entropy is thus $\Delta S = S_f - S_i = -N \ln 2$. ✔

❹ **EVALUATE RESULT** My answer to part *a* shows that the removal of the partition and subsequent expansion of the gas result in a positive change in entropy. This is what I expect given that the system evolves toward equilibrium. My answer to part *b* is the negative of the answer to part *a*, which tells me that the change in entropy due to the combined removal and reinsertion of the partition is zero: $\Delta S = N \ln 2 - N \ln 2 = 0$. That is surprising because the gas has expanded into a larger volume. However, the particles in this problem are distinguishable, and in reality gas particles are indistinguishable. For distinguishable particles, the reinsertion reduces the number of basic states (a particle in compartment B can no longer be in compartment A, and vice versa). If the particles are indistinguishable, reinserting the partition causes no entropy change.

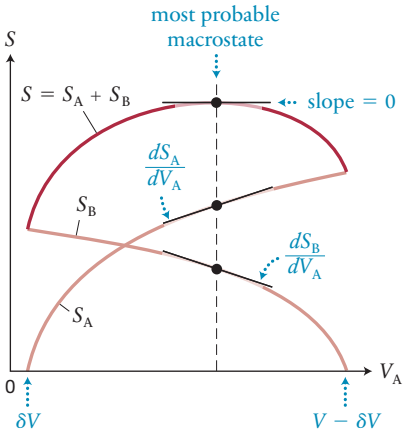
Assuming that the gases on each side of the partition in Figure 19.19 remain at equilibrium, we have from Eq. 19.7

$$S_A = N_A \ln V_A - N_A \ln \delta V \tag{19.11}$$

$$S_B = N_B \ln V_B - N_B \ln \delta V = N_B \ln(V - V_A) - N_B \ln \delta V, \tag{19.12}$$

where $V = V_A + V_B$ is the combined (constant) volume of the system. Increasing V_A thus increases S_A but decreases S_B. **Figure 19.20** shows how the entropies of the two compartments and the entropy of the combined system depend on V_A. When the number of basic states, and thus the entropy in Eq. 19.10, are maximum, Eq. 19.6 applies, so the partition comes to rest and the combined system is at equilibrium. We therefore would like to determine for what value of V_A the system's entropy S is maximized.

At the maximum value of S, the slope of the S curve in Figure 19.20 is zero. This slope is given by the derivative of S with respect to V_A, and so at equilibrium,



$$\frac{dS}{dV_A} = \frac{dS_A}{dV_A} + \frac{dS_B}{dV_A} = 0 \quad \text{(equilibrium)} \tag{19.13}$$

or

$$\frac{dS_A}{dV_A} = -\frac{dS_B}{dV_A} \quad \text{(equilibrium)}. \tag{19.14}$$

The quantities dS_A/dV_A and dS_B/dV_A represent the slopes of the S_A and S_B curves in Figure 19.20. Equation 19.14 thus tells us that these two curves must have opposite slopes at the equilibrium value of V_A.

Figure 19.20 As the partition in Figure 19.19 moves to the right and V_A increases, S_A increases and S_B decreases until the entropy of the system is maximum. At this value of V_A, the partition comes to rest, and the system is at equilibrium.

We can now show that the condition expressed in Eq. 19.14 leads to equipartitioning of the space by calculating the derivatives. Because V is constant,

$$\frac{dV_B}{dV_A} = \frac{d}{dV_A}(V - V_A) = -1, \tag{19.15}$$

we have $dV_A = -dV_B$ and so can rewrite Eq. 19.14 in the form

$$\frac{dS_A}{dV_A} = -\frac{dS_B}{(-dV_B)} = \frac{dS_B}{dV_B} \quad \text{(equilibrium)}. \tag{19.16}$$

Equation 19.16 tells us that at equilibrium the quantity dS/dV evaluated on either side of the partition is the same.

Taking the derivative of Eq. 19.7 with respect to V, we get

$$\frac{dS}{dV} = \frac{d}{dV}(N \ln V - N \ln \delta V) = \frac{d}{dV}(N \ln V) \tag{19.17}$$

because $N \ln \delta V$ does not depend on V (N is fixed and δV is a constant). Recalling that

$$\frac{d}{dx}\ln x = \frac{1}{x}, \tag{19.18}$$

we get

$$\frac{dS}{dV} = \frac{N}{V}. \tag{19.19}$$

The quantity N/V represents the number of particles per unit volume and is the number density of the gas (Eq. 1.3). Substituting Eq. 19.19 into Eq. 19.16, we obtain

$$\frac{N_A}{V_A} = \frac{N_B}{V_B} \quad \text{(equilibrium)}, \tag{19.20}$$

which is exactly the requirement for the equipartition of space: At equilibrium the number densities are the same on both sides of the partition, and so each particle has the same amount of space available to it.

EXAMPLE 19.10 Sliding partition

The box in Figure 19.19 contains seven gas particles in compartment A and five in compartment B, and the partition separating the compartments is free to move. Let the volume of the box be V and the initial ratio of the compartment volumes be $V_{B,i}/V_{A,i} = 3$. What is the change in the entropy of this gas as it evolves from this macrostate to equilibrium?

❶ **GETTING STARTED** Once the equilibrium state is reached, the number densities are equal on the two sides of the partition and the change in the entropy of the gas—which is my system—is the sum of the entropy changes in the two compartments.

❷ **DEVISE PLAN** Equation 19.20 gives me the volume ratio at equilibrium, which I call the final volume ratio. Knowing the initial and final ratios, I can use Eq. 19.8 to determine the entropy change in each compartment and then use Eq. 19.10 to determine the entropy change of the system.

❸ **EXECUTE PLAN** From the given initial volume ratio, I know that $V_{B,i} = 3V_{A,i}$. The volume of the box is the sum of the volumes of the compartments: $V = V_{A,i} + V_{B,i} = V_{A,i} + 3V_{A,i} = 4V_{A,i}$, and so $V_{A,i} = V/4$ and $V_{B,i} = 3V/4$. From Eq. 19.20 the ratio of the final volumes is equal to the ratio of the numbers of particles. I know that the number of particles in each compartment cannot change, so I can say that $V_{B,f}/V_{A,f} = N_B/N_A = 5/7$, which means $V_{B,f} = 5V_{A,f}/7$.

After the partition moves, the sum of the volumes is still V, and so I know $V = V_{A,f} + V_{B,f} = V_{A,f} + 5V_{A,f}/7 = 12V_{A,f}/7$.

QUANTITATIVE TOOLS

Thus $V_{A,f} = 7V/12$ and $V_{B,f} = 5V/12$. Substituting these volumes into Eq. 19.8 gives

$$\Delta S_A = N_A \ln \frac{V_{A,f}}{V_{A,i}} = 7 \ln \frac{7V/12}{V/4} = 7 \ln \tfrac{7}{3} = 5.93$$

$$\Delta S_B = N_B \ln \frac{V_{B,f}}{V_{B,i}} = 5 \ln \frac{5V/12}{3V/4} = 5 \ln \tfrac{5}{9} = -2.94.$$

Because the entropy of the system is the sum of the entropies of the particles in the two compartments (Eq. 19.10), I have

$$\Delta S = \Delta S_A + \Delta S_B = 5.93 - 2.94 = 2.99. \checkmark$$

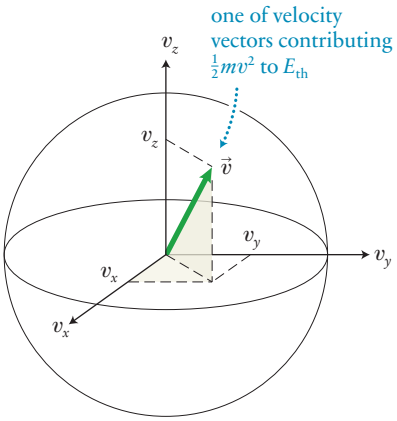
4 EVALUATE RESULT The volume of compartment A increases and the volume of compartment B decreases, so I expect the entropy of the particles in A to increase and the entropy of the particles in B to decrease, as my results show. Because the magnitude of the change in entropy is greater for A than for B, the entropy change of the system is positive, as it should be for a closed system evolving toward equilibrium.

19.19 Explain why the changes in entropy in Example 19.10 do not depend on the volume V of the box.

19.6 Dependence of entropy on energy

Let us now turn our attention to how entropy depends on the energy of a system. For simplicity we restrict ourselves to a *monatomic* ideal gas (that is, a gas made up of atoms for which we can ignore any internal structure), so that none of the atoms' kinetic energy can be converted to internal energy. The incoherent kinetic energy of all the atoms makes up the thermal energy of the gas. If the center of mass of the gas is at rest, the energy of the system is entirely in the form of thermal energy.

Let us now calculate how the number of basic states depends on the thermal energy E_{th} and the number of atoms N of a closed system. Throughout this section we shall take the atoms to be distributed uniformly over the (constant) volume V of the system. At equilibrium each atom has its fair share of the thermal energy E_{th} of the system. A single atom moving at speed v contributes an amount of energy $\frac{1}{2}mv^2$ to E_{th}. Because the atom is free to move in any direction, many velocities correspond to a given speed v (**Figure 19.21**) and thus to a given share of the thermal energy E_{th}. A basic state is specified by the components v_x, v_y, and v_z of all N atoms. To count the basic states, we can use the procedure from Section 19.5: We divide the available "velocity space" in Figure 19.21 into small compartments and count the number of ways we can distribute N atoms among these compartments.



What is the available velocity space? To determine this velocity space, we introduce the **root-mean-square speed,*** or *rms speed* for short:

$$v_{rms} \equiv \sqrt{(v^2)_{av}}, \tag{19.21}$$

where $(v^2)_{av}$ is the average of the squares of the speeds of all the atoms in a volume of gas. Applying the Pythagorean theorem to the two shaded triangles in Figure 19.21, we have

$$v^2 = v_x^2 + v_y^2 + v_z^2. \tag{19.22}$$

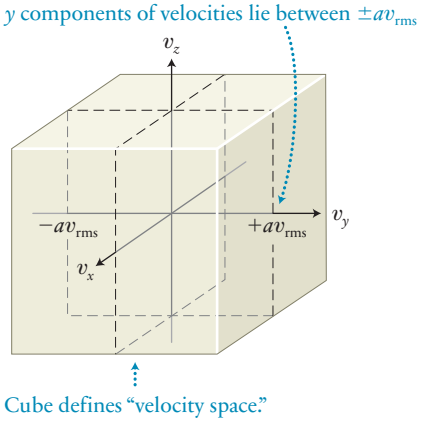
Figure 19.21 Velocity space determined by the components of velocity. All velocity vectors ending on the surface of the sphere correspond to the same speed and therefore the same kinetic energy.

*This value is obtained by taking the square *root* of the *mean* (average) of the *squares* of the speeds.

If we average over all atoms, this expression becomes

$$v_{\text{rms}}^2 = (v^2)_{\text{av}} = (v_x^2)_{\text{av}} + (v_y^2)_{\text{av}} + (v_z^2)_{\text{av}}. \tag{19.23}$$

Given that the gas is the same in all directions, there is no difference between the x, y, and z directions, and so



$$(v_x^2)_{\text{av}} = (v_y^2)_{\text{av}} = (v_z^2)_{\text{av}} \tag{19.24}$$

or

$$v_{\text{rms}}^2 = 3(v_x^2)_{\text{av}}. \tag{19.25}$$

19.20 Five atoms moving along the x axis have x components of velocities $+2.1$ m/s, -3.2 m/s, $+4.5$ m/s, -0.3 m/s, and -3.1 m/s. Determine (*a*) the x component of the average velocity, (*b*) the average speed, and (*c*) the rms speed.

Figure 19.22 Calculating the volume $\mathcal{V}$ of the velocity space.

To return to determining the volume of the velocity space, let us now assume that the components of the velocities of the atoms are limited to a range of a few times the rms speed. That is, let us assume that

$$-av_{\text{rms}} \le v_x \le av_{\text{rms}}, \tag{19.26}$$

and likewise for the y and z components, and where a is a number between, say, 1 and 10. This may seem like a totally arbitrary restriction, but you will see in a bit that the end result is not affected by this restriction. With this simplifying assumption the velocities of all the atoms in our system lie in a cube having sides of length $2av_{\text{rms}}$ (**Figure 19.22**). The "volume" $\mathcal{V}$ of the velocity space of the atoms in a gas-filled container is then $\mathcal{V} = (2av_{\text{rms}})^3$.

We can relate this volume to the thermal energy of the gas because we know that the average kinetic energy K_{av} of one atom is equal to the thermal energy of the gas divided by the number N of gas atoms in the container:

$$K_{\text{av}} \equiv \tfrac{1}{2}m(v^2)_{\text{av}} = \tfrac{1}{2}mv_{\text{rms}}^2 = \frac{E_{\text{th}}}{N} \quad \text{(monatomic ideal gas)}, \tag{19.27}$$

where we have used the definition of rms speed (Eq. 19.21). Now we can rewrite the rms speed as

$$v_{\text{rms}} = \left(\frac{2E_{\text{th}}}{mN}\right)^{1/2}, \tag{19.28}$$

and so we see that the volume $\mathcal{V}$ of the velocity space is proportional to $(E_{\text{th}})^{3/2}$:

$$\mathcal{V} = (2av_{\text{rms}})^3 = \left[2a\left(\frac{2E_{\text{th}}}{mN}\right)^{1/2}\right]^3 = \left(\frac{8a^2}{mN}\right)^{3/2}(E_{\text{th}})^{3/2} = b(E_{\text{th}})^{3/2}, \tag{19.29}$$

where $b = (8a^2/mN)^{3/2}$ is a constant.

19.21 Work out the algebra between the third and fourth terms in Eq. 19.29.

In analogy to what we did in Section 19.5, we now divide this volume $\mathcal{V}$ of the velocity space into smaller velocity-space compartments, each of volume $\delta\mathcal{V}$. The number of velocity-space compartments is

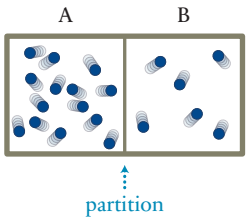
$$M_v = \frac{\mathcal{V}}{\delta\mathcal{V}} = \frac{b}{\delta\mathcal{V}}(E_{\text{th}})^{3/2}, \tag{19.30}$$

QUANTITATIVE TOOLS

and the number of ways we can distribute N distinguishable atoms in these M_v compartments is (see Eq. 19.1):

$$\Omega_v = (M_v)^N = \left[\frac{b}{\delta\mathcal{V}}(E_{\text{th}})^{3/2}\right]^N. \tag{19.31}$$

For a monatomic ideal gas in which the energy is equipartitioned, the entropy is maximum and given by



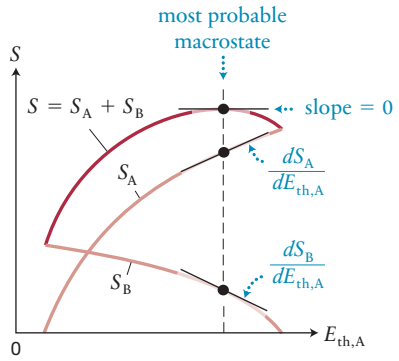
$$S \equiv \ln \Omega_v = \tfrac{3}{2}N \ln E_{\text{th}} - N \ln \frac{\delta\mathcal{V}}{b} \quad \text{(monatomic ideal gas at equilibrium).} \tag{19.32}$$

The first term to the right of the equals sign shows that for a fixed number of atoms N, the entropy increases as we increase the thermal energy E_{th} of the gas. The factors $\delta\mathcal{V}$ and b in Eq. 19.32 tell us that the entropy depends on the size of the velocity-space compartments in which the atoms are distributed and on the restriction we imposed in Eq. 19.26. However, the term that contains these factors drops out when we consider changes in entropy:

$$\Delta S = S_{\text{f}} - S_{\text{i}} = \tfrac{3}{2}N \ln E_{\text{th,f}} - \tfrac{3}{2}N \ln E_{\text{th,i}} = \tfrac{3}{2}N \ln\left(\frac{E_{\text{th,f}}}{E_{\text{th,i}}}\right). \tag{19.33}$$

Now we can examine how entropy changes when a system of two interacting gases initially having different amounts of thermal energy evolves toward a system-wide equilibrium state. Consider a closed system of two gases that can exchange energy with each other, as illustrated in **Figure 19.23**. The volume of each compartment and the number of atoms in each are fixed. In Section 19.4 we saw that such a system tends to evolve toward an equipartitioning of the system's thermal energy. If thermal energy is exchanged across the partition, one gas gains thermal energy and the other one loses thermal energy. Because the entropy of the gas depends on its thermal energy, the exchange of thermal energy causes the entropy to increase on one side of the partition and decrease on the other side. **Figure 19.24** shows how the entropies of the two gases and the entropy of the combined system depend on the thermal energy $E_{\text{th,A}}$ of gas A. When the number of basic states, and thus the entropy, are maximum, Eq. 19.6 applies and the exchange of thermal energy stops and the system is said to be in **thermal equilibrium.** We therefore would like to determine for what value of $E_{\text{th,A}}$ the system's entropy $S = S_{\text{A}} + S_{\text{B}}$ is maximized.

Figure 19.23 Container holding two gases separated by a partition. The gases can exchange energy with each other through collisions with the partition.



At the maximum entropy level, the slope of curve S in Figure 19.24 is zero, and so

$$\frac{dS}{dE_{\text{th,A}}} = \frac{dS_{\text{A}}}{dE_{\text{th,A}}} + \frac{dS_{\text{B}}}{dE_{\text{th,A}}} = 0 \quad \text{(closed system at thermal equilibrium)} \tag{19.34}$$

or

$$\frac{dS_{\text{A}}}{dE_{\text{th,A}}} = -\frac{dS_{\text{B}}}{dE_{\text{th,A}}} \quad \text{(closed system at thermal equilibrium).} \tag{19.35}$$

Figure 19.24 How the entropies of the gases in Figure 19.23 depend on the thermal energy $E_{\text{th,A}}$ of gas A.

The quantities $dS_{\text{A}}/dE_{\text{th,A}}$ and $dS_{\text{B}}/dE_{\text{th,A}}$ represent the slopes of curves S_{A} and S_{B} in Figure 19.24. Eq. 19.35 thus tells us that these two curves must have opposite slopes at thermal equilibrium. Because E_{th} is constant,

$$\frac{dE_{\text{th,B}}}{dE_{\text{th,A}}} = \frac{d}{dE_{\text{th,A}}}[E_{\text{th}} - E_{\text{th,A}}] = -1, \tag{19.36}$$

we have $dE_{\text{th,A}} = -dE_{\text{th,B}}$ and so Eq. 19.35 becomes

$$\frac{dS_A}{dE_{\text{th,A}}} = -\frac{dS_B}{d(-E_{\text{th,B}})} = \frac{dS_B}{dE_{\text{th,B}}} \quad \text{(closed system at thermal equilibrium).} \tag{19.37}$$

As you have probably noticed, there is a strong parallel between the quantity dS/dE_{th} in the above derivation and the quantity dS/dV we discussed in the preceding section (compare, also, Figures 19.20 and 19.24). In Eq. 19.19 we saw that the quantity dS/dV represents the number density of the gas and that at equilibrium the number density tends to be the same in all compartments of the system (Eq. 19.20).

To discover what physical concept dS/dE_{th} corresponds to, answer the following checkpoint.

19.22 (*a*) Using Figure 19.24, compare the kinetic energy of an atom in gas A with that of an atom in gas B in the thermal equilibrium state (that is, on the dashed line) and in a macrostate to the left of the dashed line. (*b*) In each of these two macrostates, which gas is "hotter"? (*c*) For the same two macrostates, compare the quantities $dS_A/dE_{\text{th,A}}$ and $dS_B/dE_{\text{th,B}}$.

As Checkpoint 19.22 suggests, the quantity dS/dE_{th} is smaller for a hot gas than for a cooler gas. We therefore define this quantity to be inversely proportional to a quantity called the **absolute temperature** T:

$$\frac{1}{k_B T} \equiv \frac{dS}{dE_{\text{th}}}. \tag{19.38}$$

The unit for absolute temperature, the **kelvin** (K), is one of the SI base units. In Section 20.2 we'll see how this unit is defined. The proportionality constant k_B, called the **Boltzmann constant,** is

$$k_B = 1.381 \times 10^{-23}\ \text{J/K}. \tag{19.39}$$

The constant k_B had been used to reconcile the units for absolute temperature with common temperature measurements (which we shall discuss in Chapter 20), but it is now defined as exactly 1.380649×10^{-23} J/K. For now, consider T to be a quantitative measure of the temperature obtained by adding 273.15 to the reading on a thermometer calibrated in degrees Celsius.

With this definition of absolute temperature, we see that thermal equilibrium (Eq. 19.37) implies that the absolute temperatures of the two gases are the same:

$$T_A = T_B \quad \text{(thermal equilibrium).} \tag{19.40}$$

We can obtain another consequence of the thermal equilibrium condition by taking the derivative of Eq. 19.32 with respect to E_{th}:

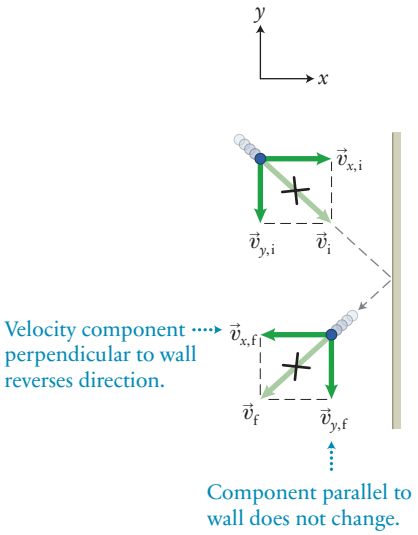
$$\frac{dS}{dE_{\text{th}}} = \frac{d}{dE_{\text{th}}}\left[\tfrac{3}{2}N \ln E_{\text{th}} - N \ln \frac{\delta \mathcal{V}}{b}\right] = \frac{d}{dE_{\text{th}}}\left[\tfrac{3}{2}N \ln E_{\text{th}}\right] = \tfrac{3}{2}\frac{N}{E_{\text{th}}}, \tag{19.41}$$

where the derivative of the term $N \ln(\delta \mathcal{V}/b)$ is zero because N, $\delta \mathcal{V}$, and b are constant. Substituting Eq. 19.41 into Eq. 19.37 and inverting the result yield

$$\frac{E_{\text{th,A}}}{N_A} = \frac{E_{\text{th,B}}}{N_B} \quad \text{(thermal equilibrium),} \tag{19.42}$$

which is exactly the requirement for equipartition of energy: At thermal equilibrium the amount of thermal energy per atom is the same on either side of the partition.

19.23 Suppose 14 atoms are in compartment A and six atoms are in compartment B, as shown in Figure 19.23. When thermal equilibrium energy is reached, what percentage of the thermal energy do you expect to find in each compartment?



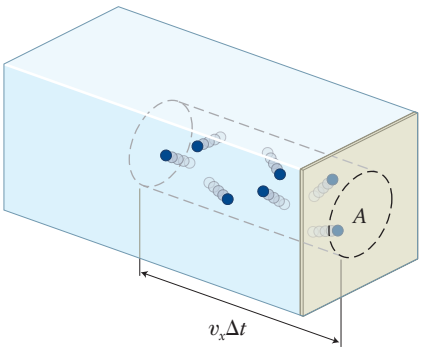
19.7 Properties of a monatomic ideal gas

Let us next connect some of the atomic parameters that describe an ideal gas to its macroscopic parameters. Consider a monatomic ideal gas that consists of a very large number N of indistinguishable atoms of mass m inside a closed rigid container of volume V. The collisions between the atoms and between the atoms and the walls of the container are all elastic. Figure 19.25 shows one atom-wall collision. Because the collision is elastic, the speed v of the atom does not change; the collision simply reverses the direction of the velocity component v_x perpendicular to the wall, leaving the velocity component v_y parallel to the wall unchanged.

What is true for the atom in Figure 19.25 is true for all the other gas atoms. Therefore the forces exerted by the wall and by the atoms are perpendicular to the wall. The collisions between the wall and the gas atoms are the origin of the pressure in the gas.

19.24 Let the system comprising the atoms and wall in Figure 19.25 be isolated. (*a*) What is the direction of the atom's change in momentum? (*b*) What is the direction of the change in momentum of the wall? (*c*) How are these momentum changes related to the forces that wall and atom exert on each other?

Figure 19.25 An atom collides elastically with a wall, reversing the perpendicular component of the incoming velocity. Its speed remains unchanged.



As we saw in Section 18.5, the pressure P in a gas is equal to the magnitude of the force $\vec{F}^{\,c}_{gA}$ exerted by the gas on a surface per unit area. Because the force exerted by the gas on the surface and the force exerted by the surface on the gas form a interaction pair, we have $F^c_{gA} = F^c_{Ag}$. Over a section of wall of area A, Eq. 18.1 then yields

$$P \equiv \frac{F^c_{gA}}{A} = \frac{F^c_{Ag}}{A}. \tag{19.43}$$

The force exerted by the wall on the gas is equal to the rate of change in the momentum of the gas (see Section 8.7), if we ignore other forces, and our task is to evaluate the magnitude of this rate of change. To simplify matters, we initially assume that the x component of the velocities of all the atoms in the gas have the same magnitude $|v_x|$. (We shall see shortly that our result doesn't depend on this oversimplification.) Let's begin by evaluating the change in momentum of a single gas atom when it collides with the wall. Each collision like the one in Figure 19.25 changes the sign of the x component of the atom's velocity, and so the magnitude of the atom's change in momentum is $2m|v_x|$.

To calculate the rate at which the magnitude of the momentum of the gas changes, we need to determine how many collisions occur within a finite time interval Δt. In order for an atom, for which the x component of its velocity is v_x, to collide with the wall in a time interval Δt, the atom has to be within a distance $|v_x|\Delta t$ of the wall. So let us consider all the atoms in a cylinder of cross-sectional area A and length $|v_x|\Delta t$ (Figure 19.26). At equilibrium, the atoms are uniformly distributed over the volume of the container, and so the number of atoms per unit volume is N/V. The volume of

Figure 19.26 On average, one half of the gas atoms contained in the cylinder strike the wall during a time interval Δt.

the cylinder is $A|v_x|\Delta t$, and so the number of atoms in the cylinder is $N_{\text{cyl}} = (N/V)A|v_x|\Delta t$. At any given instant, there should be as many atoms moving in the $+x$ direction as there are atoms moving in the $-x$ direction, and so half of the atoms in the cylinder in Figure 19.26 collide with the wall in the time interval Δt. The magnitude of the change in momentum for all gas atoms is thus equal to the number of collisions $N_{\text{cyl}}/2$ times the magnitude of the change in momentum $2m|v_x|$ for a single collision:

$$|\Delta p| = \tfrac{1}{2}\frac{N}{V}(A|v_x|\Delta t)(2m|v_x|) = \frac{NAmv_x^2}{V}\Delta t. \tag{19.44}$$

To calculate the magnitude of the rate of change of the momentum of the gas, we divide the left and right sides of the equation by Δt:

$$\frac{|\Delta p|}{\Delta t} = \frac{NAmv_x^2}{V}. \tag{19.45}$$

The quantity on the left, the magnitude of the rate of change of the momentum of the gas, is equal to the magnitude of the force exerted by the wall on the gas in the cylinder in Figure 19.26, and so, substituting Eq. 19.45 into Eq. 19.43, we obtain for the pressure in the gas

$$P = \frac{|\Delta p|/\Delta t}{A} = \frac{Nmv_x^2}{V}. \tag{19.46}$$

In deriving Eq. 19.46 we used the unlikely assumption that the x components of the velocities of all atoms have the same magnitude $|v_x|$. When we use this assumption, each atom contributes a force $(Amv_x^2)/V$, and the force in Eq. 19.45 is the sum of N such forces. If the atoms move at different speeds, we should replace v_x^2 in Eq. 19.46 by the average value $(v_x^2)_{\text{av}}$. (We can do this because N times the average value of a quantity is equal to the sum of N actual values.)

When we use the relationship between $(v_x^2)_{\text{av}}$ and v_{rms}^2 expressed in Eq. 19.25, $v_{\text{rms}}^2 = 3(v_x^2)_{\text{av}}$, Eq. 19.46 becomes

$$P = \frac{Nm\frac{1}{3}v_{\text{rms}}^2}{V} = \frac{2}{3}\frac{N(\frac{1}{2}mv_{\text{rms}}^2)}{V} \tag{19.47}$$

or, substituting $N(\frac{1}{2}mv_{\text{rms}}^2) = E_{\text{th}}$ (see Eq. 19.27),

$$P = \frac{2}{3}\frac{E_{\text{th}}}{V} \quad \text{(monatomic ideal gas)}. \tag{19.48}$$

Equation 19.47 shows that the pressure in a monatomic ideal gas is determined by two atomic parameters: the number density N/V and the average kinetic energy $\frac{1}{2}mv_{\text{rms}}^2$ of an atom.

We can obtain an expression for the thermal energy of a monatomic ideal gas by substituting Eq. 19.41, $dS/dE_{\text{th}} = \frac{3}{2}/E_{\text{th}}$, into Eq. 19.38, $1/k_{\text{B}}T = dS/dE_{\text{th}}$. Doing this we obtain

$$\frac{1}{k_{\text{B}}T} = \frac{3}{2}\frac{N}{E_{\text{th}}} \tag{19.49}$$

or

$$E_{\text{th}} = \tfrac{3}{2}Nk_{\text{B}}T \quad \text{(monatomic ideal gas)}. \tag{19.50}$$

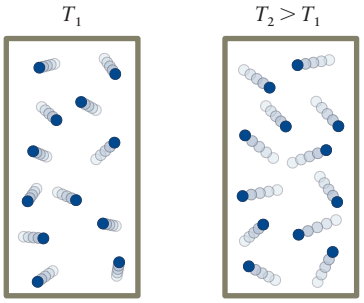
QUANTITATIVE TOOLS

Substituting Eq. 19.50 into Eq. 19.48, we obtain

$$P = \frac{N}{V} k_B T \quad \text{(ideal gas system at equilibrium)}. \tag{19.51}$$

This relationship among pressure, volume, temperature, and number of atoms is called the **ideal gas law.** We obtained this result among macroscopic parameters (pressure, volume, temperature) by considering what happens at the atomic scale for a monatomic ideal gas. Experiments show that, at low pressure and high temperature, the ideal gas law describes the behavior of *any* gas at equilibrium, not just monatomic gases.

Because the thermal energy of a gas is the sum of the average kinetic energies of its atoms, $E_{th} = NK_{av}$ (Eq. 19.27), we can use the Eq. 19.50 expression for E_{th} and write



$$K_{av} = \tfrac{1}{2} m v_{rms}^2 = \tfrac{3}{2} k_B T. \tag{19.52}$$

Equation 19.52 allows us to obtain an expression for the rms speed of an atom in a monatomic ideal gas:

$$v_{rms} = \sqrt{\frac{3k_B T}{m}}. \tag{19.53}$$

The rms speed of a monatomic ideal gas atom is inversely proportional to the square root of the mass of the atom and proportional to the square root of the temperature of the gas. If the temperature of a gas increases, the rms speed of the atoms goes up, too (**Figure 19.27**).

Figure 19.27 When the temperature of a monatomic ideal gas in a fixed volume is increased, the rms speed of the gas atoms increases.

19.25 Use the ideal gas law to express the equilibrium condition in Eq. 19.20 in terms of pressure.

EXAMPLE 19.11 Helium speed

A sample of helium gas containing 6.02×10^{23} atoms at atmospheric pressure (1.01×10^5 Pa) occupies a volume of 22.4×10^{-3} m^3. The mass of a helium atom is 6.646×10^{-27} kg. What is the rms speed of the helium atoms?

❶ **GETTING STARTED** I can treat the helium gas as a monatomic ideal gas. The rms speed of the atoms is determined by the temperature of the sample, which is not given.

❷ **DEVISE PLAN** Equation 19.53 gives the rms speed of atoms in a monatomic ideal gas. I am given the mass m of one helium atom, but not the temperature T. To determine T I can use the ideal gas law (Eq. 19.51).

❸ **EXECUTE PLAN** From Eq. 19.51, I obtain $T = PV/(Nk_B)$. Substituting this expression for the temperature into Eq. 19.53 yields

$$v_{rms} = \sqrt{\frac{3k_B PV/(Nk_B)}{m}} = \sqrt{\frac{3PV}{mN}} = 1.30 \times 10^3 \text{ m/s}. \checkmark$$

❹ **EVALUATE RESULT** Those helium atoms sure are zipping around fast! At 1.30×10^3 m/s, however, they are moving about ten times more slowly than the escape speed from Earth (1.12×10^4 m/s; see Checkpoint 13.22), and so my result is at least not unreasonable. I also note that using my calculated rms speed in Eq. 19.47 yields a value of 1.01×10^5 Pa for P, giving me confidence in my answer.

19.26 A certain number of helium atoms are placed in one container, and an equal number of argon atoms are placed in a separate identical container. The pressure is the same in both containers. Helium atoms have a smaller mass than argon atoms. For which gas, if either, (*a*) is the thermal energy smaller, (*b*) is the average kinetic energy of an atom smaller, (*c*) is the rms speed of an atom smaller?

19.8 Entropy of a monatomic ideal gas

Now that we have derived an expression that gives the thermal energy of a gas in terms of its temperature (Eq. 19.50), we can express the entropy in terms of temperature. Substituting Eq. 19.50 into Eq. 19.32 gives

$$S = \tfrac{3}{2}N \ln(\tfrac{3}{2}Nk_B T) - N \ln\frac{\delta\mathcal{V}}{b}$$

$$= \tfrac{3}{2}N \ln T + \tfrac{3}{2}N \ln(\tfrac{3}{2}Nk_B) - N \ln\frac{\delta\mathcal{V}}{b} \qquad (19.54)$$

or, taking all constant terms together,

$$S = \tfrac{3}{2}N \ln T + \text{constant} \quad \text{(monatomic ideal gas in thermal equilibrium).} \qquad (19.55)$$

This expression describes a gas for which the energy is equipartitioned over the N atoms—that is, in thermal equilibrium. As before, the constant drops out when we consider changes in entropy (Eq. 19.8). For example, if the temperature of the gas is raised from T_i to T_f while the volume is kept constant, the change in entropy is

$$\Delta S = \tfrac{3}{2}N \ln\left(\frac{T_f}{T_i}\right) \quad \text{(constant volume).} \qquad (19.56)$$

EXAMPLE 19.12 Entropy change for a cooling gas

A sample of a monatomic ideal gas consisting of 1.00×10^{23} atoms in a volume of 4.00×10^{-3} m^3 is initially at a temperature of 290 K. The gas is cooled until it reaches a pressure of 5.00×10^4 N/m^2. (*a*) What is the change in entropy for the gas and for each atom? (*b*) What is the ratio of the final rms speed of each atom to its initial rms speed? (*c*) How does the change in the entropy of the gas depend on this ratio $v_{rms,f}/v_{rms,i}$?

❶ **GETTING STARTED** Both rms speed and entropy depend on temperature. As the gas cools, its temperature decreases, and so the rms speed of the atoms and the entropy of the gas both change.

❷ **DEVISE PLAN** I can use the ideal gas law, Eq. 19.51, to determine the final temperature of the gas. Once I know the final temperature, I can calculate the entropy change from Eq. 19.56 and the ratio of final to initial rms speeds from Eq. 19.53. To determine how the change in entropy depends on the ratio of rms speeds, I combine Eqs. 19.53 and 19.56.

❸ **EXECUTE PLAN** (*a*) From Eq. 19.51, the final temperature of the gas is

$$T_f = \frac{P_f V}{Nk_B} = \frac{(5.00 \times 10^4 \text{ N/m}^2)(4.00 \times 10^{-3} \text{ m}^3)}{(1.00 \times 10^{23})(1.38 \times 10^{-23} \text{ J/K})} = 145 \text{ K}.$$

Equation 19.56 then yields for the change in the entropy of the gas:

$$\Delta S = S_f - S_i = \tfrac{3}{2}N \ln\left(\frac{T_f}{T_i}\right) = \tfrac{3}{2}(1.00 \times 10^{23}) \ln\left(\frac{145 \text{ K}}{290 \text{ K}}\right)$$

$$= -1.04 \times 10^{23}. \checkmark$$

Because there are 1.00×10^{23} atoms, the change in entropy per atom is -1.04. ✔

(*b*) From Eq. 19.53 I see that the ratio of final to initial rms speeds is $v_{rms,f}/v_{rms,i} = (T_f/T_i)^{1/2} = [(145 \text{ K})/(290 \text{ K})]^{1/2} = 0.707$. ✔

(*c*) Because $a \ln N = \ln N^a$, I can write Eq. 19.56 as $\Delta S = N \ln(T_f/T_i)^{3/2}$. From part *b* I know that $v_{rms,f}/v_{rms,i} = (T_f/T_i)^{1/2}$, so I can write $T_f/T_i = v^2_{rms,f}/v^2_{rms,i}$. Combining these two expressions, I see that the relationship between the entropy change of the gas and the rms speed ratio of the atoms is $\Delta S = N \ln(v_{rms,f}/v_{rms,i})^3$. ✔

❹ **EVALUATE RESULT** As the gas cools, the rms speed of the atoms decreases, as my answer to part *b* shows. As the rms speed decreases, the number of basic states possible decreases, and so the entropy should decrease, in agreement with my answer to part *a*. Because the system is not closed, there is no reason its entropy cannot decrease, as I have found here.

Equation 19.50, $E_{th} = \tfrac{3}{2}Nk_B T$, tells me that the term on the right in Eq. 19.52 is equal to E_{th}/N, and from this it follows that E_{th} is proportional to v^2_{rms}. Equation 19.32 shows that the entropy is proportional to $\tfrac{3}{2}\ln E_{th} = \ln E_{th}^{3/2}$ and so to $\ln(v^2_{rms})^{3/2} = \ln v^3_{rms}$, in agreement with my result in part *c*.

QUANTITATIVE TOOLS

19.27 (*a*) Does the negative change in entropy in Example 19.12 violate the Eq. 19.5 part of the entropy law? (*b*) What is the change in the thermal energy of the gas in Example 19.12?

We can combine Eq. 19.55 with Eq. 19.7 to obtain an expression that tells us how entropy depends on both volume and temperature. To do so, remember that if we consider both the basic states associated with the spatial distribution of the atoms in a gas and those associated with the velocity distribution, the number of basic states associated with both types of distributions is the product of the number of each type of basic state (Eq. 19.9):

$$\Omega = \Omega_{\text{space}}\,\Omega_{\text{vel}}. \tag{19.57}$$

Taking the natural logarithm of this equation, we have, from $S \equiv \ln \Omega$,

$$S = S_{\text{space}} + S_{\text{vel}}. \tag{19.58}$$

To obtain an expression for the entropy of a gas that provides the dependence on both the volume and the temperature of the gas, we must therefore substitute Eqs. 19.7 and 19.55 into Eq. 19.58:

$$S = N \ln V + \tfrac{3}{2}N \ln T + \text{constant} \quad \text{(equilibrium)}, \tag{19.59}$$

where the constant term $-N \ln \delta V$ in Eqs. 19.7 has been combined with constant terms in Eq. 19.55 to give a new constant term. Equation 19.59 can also be written as

$$S = N \ln(T^{3/2}V) + \text{constant} \quad \text{(equilibrium)}. \tag{19.60}$$

Like Eqs. 19.7 and 19.55, Eq. 19.60 describes a system at equilibrium: If different compartments of the system are not at equilibrium with each other, the entropy of the system is smaller than that given by Eq. 19.60.

Equation 19.60 is in agreement with what we saw in the conceptual part of this chapter: As we increase either the temperature or the volume, the number of basic states—and therefore the entropy—increases. If the system changes from an equilibrium state with temperature T_i and volume V_i to a new equilibrium state with temperature T_f and volume V_f, the change in entropy is

$$\Delta S = \tfrac{3}{2}N \ln\left(\frac{T_f}{T_i}\right) + N \ln\left(\frac{V_f}{V_i}\right). \tag{19.61}$$

Most important, the change in entropy is independent of *how* the system is changed: ΔS depends on only the initial and final equilibrium states of the system. Note that for a system that is not closed, there are no constraints on ΔS: It can be positive, negative, or zero.

19.28 Does the entropy of a gas whose temperature is halved and volume doubled increase, decrease, or stay the same?

Chapter Summary

Entropy of a closed system (Sections 19.1, 19.2, 19.3, 19.5)

Concepts The **probability** of an event is the fraction of times it occurs in a large number of repetitions.

The **macrostate** of a system is that state described by its large-scale properties (on a scale much larger than molecular size), such as volume, pressure, and temperature. The **basic state** of a system is that state described in terms of the properties of the particles that make up the system, such as their position and velocity.

If the interaction between different parts of a system randomizes the distribution of energy in the system, then each particle in the system tends to have an equal share of that energy (**equipartition of energy**), and the particles tend to distribute themselves uniformly in the available volume (**equipartition of space**).

Quantitative Tools If a closed volume of space containing N distinguishable particles is divided into M distinguishable equal-sized compartments, the number of basic states Ω in the system is

$$\Omega = M^N. \tag{19.1}$$

The **entropy** S of a system is a unitless quantity that is a measure of the number of basic states in the system and is defined as

$$S \equiv \ln \Omega. \tag{19.4}$$

For a gas that contains N particles confined to a closed system, if the volume of the gas changes from V_i to V_f, the entropy change of the gas is

$$\Delta S = N \ln\left(\frac{V_f}{V_i}\right). \tag{19.8}$$

The second law of thermodynamics (Sections 19.4, 19.5)

Concepts The **equilibrium state** of a system is the macrostate that has the greatest number of basic states and is therefore the most probable macrostate. At equilibrium, the number of basic states reaches its maximum value Ω_{max}, and the entropy of the system is a maximum.

Second law of thermodynamics (entropy law): A closed system always evolves so as to maximize the number of basic states Ω. When this number has reached a maximum, the system is in equilibrium.

For a system that is not closed, the entropy can increase, decrease, or stay the same.

An **ideal gas** consists of a very large number of particles that occupy a very small fraction of the volume of their container and interact with one another only during collisions that randomize the energy distribution and the spatial distribution of the particles.

Quantitative Tools For a closed system evolving toward equilibrium, the entropy increases:

$$\Delta S > 0. \tag{19.5}$$

For a closed system at equilibrium, $\Omega = \Omega_{max}$ and the entropy does not change:

$$\Delta S = 0. \tag{19.6}$$

These two equations, collectively called the **entropy law,** are a mathematical expression of the second law of thermodynamics.

If a system consists of two subsystems, A and B, the number of basic states for the system is

$$\Omega = \Omega_A \Omega_B \tag{19.9}$$

and the entropy of the system is

$$S = S_A + S_B. \tag{19.10}$$

Entropy and energy (Section 19.6)

Concepts In a monatomic ideal gas, the internal structure of the atoms can be ignored. For this reason, the thermal energy E_{th} of the gas is the incoherent kinetic energy of all the atoms.

Quantitative Tools The **root-mean-square speed** v_{rms} of a gas is the square root of the average of the squares of the speeds of all the atoms of the gas:

$$v_{rms} \equiv \sqrt{(v^2)_{av}}. \tag{19.21}$$

If two gases are in **thermal equilibrium,** their absolute temperatures are the same. In this condition, thermal energy is equipartitioned over the system and the entropy of the system is a maximum.

If a monatomic ideal gas contains N atoms, each of mass m, the average kinetic energy of an atom is

$$K_{\text{av}} \equiv \tfrac{1}{2}m(v^2)_{\text{av}} = \tfrac{1}{2}mv_{\text{rms}}^2 = \frac{E_{\text{th}}}{N}. \tag{19.27}$$

If the thermal energy of a monatomic ideal gas changes from $E_{\text{th,i}}$ to $E_{\text{th,f}}$, the resulting entropy change is

$$\Delta S = \tfrac{3}{2}N\ln\left(\frac{E_{\text{th,f}}}{E_{\text{th,i}}}\right). \tag{19.33}$$

The **absolute temperature** T of a gas, measured in **kelvins,** is related to the rate at which the entropy of the gas changes with respect to its thermal energy:

$$\frac{1}{k_{\text{B}}T} \equiv \frac{dS}{dE_{\text{th}}}, \tag{19.38}$$

where k_{B} is the **Boltzmann constant:**

$$k_{\text{B}} = 1.381 \times 10^{-23}\ \text{J/K}. \tag{19.39}$$

Properties of a monatomic ideal gas (Sections 19.7, 19.8)

Quantitative Tools The pressure in a monatomic ideal gas containing N atoms at an absolute temperature T and occupying a volume V is

$$P = \tfrac{2}{3}\frac{E_{\text{th}}}{V}, \tag{19.48}$$

and the thermal energy of the gas is

$$E_{\text{th}} = \tfrac{3}{2}Nk_{\text{B}}T. \tag{19.50}$$

The **ideal gas law** applied to the gas is

$$P = \frac{N}{V}k_{\text{B}}T. \tag{19.51}$$

The average kinetic energy of its atoms is

$$K_{\text{av}} = \tfrac{1}{2}mv_{\text{rms}}^2 = \tfrac{3}{2}k_{\text{B}}T, \tag{19.52}$$

where m is the mass of each atom, and their root-mean-square speed is

$$v_{\text{rms}} = \sqrt{\frac{3k_{\text{B}}T}{m}}. \tag{19.53}$$

If the gas is in equilibrium, its entropy is

$$S = N\ln(T^{3/2}V) + \text{constant}. \tag{19.60}$$

If the gas changes from an equilibrium state having T_{i} and V_{i} to one having T_{f} and V_{f}, its entropy change is

$$\Delta S = \tfrac{3}{2}N\ln\left(\frac{T_{\text{f}}}{T_{\text{i}}}\right) + N\ln\left(\frac{V_{\text{f}}}{V_{\text{i}}}\right). \tag{19.61}$$

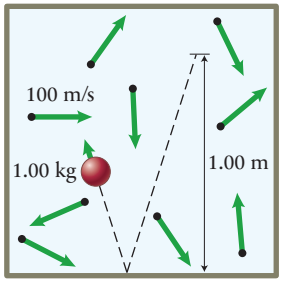
Questions and Problems

For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy,* •• = *intermediate,* ••• = *hard;* CR = *context-rich problem.*

Unless told otherwise, assume all gas particles in these problems behave like the particles of a monatomic ideal gas.

19.1 States



1. With a standard deck of 52 playing cards, what is the probability of randomly picking any (*a*) ace; (*b*) spade; (*c*) black-faced card; and (*d*) an even-numbered card? ••
2. When a pair of standard dice are thrown, what is the probability that the two dice show the (*a*) same number; and (*b*) a pair of odd numbers? ••
3. Particles in a closed container move around and collide with one another and with the walls of the container. There are 5.00×10^{13} basic states possible for this system, and the recurrence time is 365 days. How long is the average time interval between collisions? •
4. A bag contains 13 blue balls, 7 red balls, 10 green balls, and 5 yellow balls. What is the probability of drawing two green balls consecutively? ••
5. A manufacturer sells three types of motorcycles—call them types A, B, and C—each available in yellow, red, glossy black, or matte black and each offered with either a 600-cc motor or an 850-cc motor. (*a*) How many configurations are available? (*b*) If each motorcycle is available with 26 different options packages, how many configurations are available? ••
6. When three standard dice are rolled, find the probability that the sum of the dots on the three top faces will be 5? ••
7. A pendulum is in a container that has been evacuated so that there are only two atoms A and B in the container with the pendulum. If the pendulum initially has six units of energy and the two atoms have none, what is the probability that all six energy units will leave the pendulum and be absorbed by the atoms? ••
8. A pendulum is released from an elevation of 1.15 m and allowed to swing in a room filled with 1.50×10^{21} nitrogen molecules having an average speed of 550 m/s. If the energy of the pendulum is equal to the energy distributed over all the nitrogen molecules, what is the pendulum's mass? The mass of a nitrogen molecule (N_2) is 4.65×10^{-26} kg. ••
9. (*a*) When a coin is tossed five times, which sequence of outcomes is more likely: HHHHH or HTHTH? (*b*) Without regard to order, which is more likely: that in five tosses the coin lands heads-up five times or lands heads-up three times? ••
10. Some musical instruments have valves that can be either opened or closed to produce different tones. How many tones can be produced by a horn that has (*a*) two valves, (*b*) three valves, and (*c*) six valves? (*d*) Some trumpet players do something called *half-valve work*, where they play a valve that is neither fully open nor fully closed. If this technique adds a third possible valve setting, how many tones can be produced with a trumpet that has three valves by a player doing half-valve work? ••
11. Six particles in a container can move in only one of six directions: up, down, left, right, forward, and backward. If the particles move randomly such that each collides and changes direction every 1.0×10^{-6} s, for how many seconds during a 24-h day are all six particles moving in the same direction? •••
12. An adsorbing filter allows gas particles to stick to locations on the filter surface. Once a particle sticks to a location, that location is filled. The filter can no longer remove gas particles when all locations are filled. Each 1.0 nm^2 of the filter surface has six adsorbing locations, each capable of adsorbing one gas particle. In the volume just adjacent to one 1.0-nm^2 area, there are 100 gas particles. Each of these particles has a slightly different energy, making each particle unique. In how many ways can these 100 particles adsorb onto the six locations? •••

19.2 Equipartition of energy

13. A system contains three particles—A, B, and C—and three units of thermal energy. Determine the probability of any one particle having all the energy. •
14. In a system of three particles—A, B, and C—that share nine units of energy, which energy distribution is more likely at a given instant: particle A has two units of energy or particle A has three units of energy? •
15. The air in a room held at a steady temperature T is made up largely of nitrogen molecules ($m_{N_2} = 4.652 \times 10^{-26}$ kg) and oxygen molecules ($m_{O_2} = 5.3135 \times 10^{-26}$ kg). At equilibrium, what is the ratio of the average speed of the nitrogen molecules to the average speed of the oxygen molecules? Even though both gases are diatomic, assume they behave as monatomic gases. ••
16. A closed container holds 35 monatomic A particles that have a combined energy of 90 units. 85 monatomic B particles with an unknown amount of combined energy are then added to the container. If, at thermal equilibrium, each particle have 2 units of energy, how much combined energy do the B particles have? •
17. A certain container holds 50 monatomic particles with a combined energy of 200 units. 25 diatomic particles, with each particle having 2 units of energy, str then added and the system is allowed to reach thermal equilibrium. How many units of energy does each particle in the container have? ••
18. The mass of an oxygen atom is 2.6567×10^{-26} kg. Calculate the rms speed of an oxygen molecule with an average kinetic energy of 1.38×10^{-25} J. ••
19. What is the average kinetic energy of a system made up of 1.00 mol of krypton atoms having an average speed of 125 m/s? The mass of a krypton atom is 1.39×10^{-25} kg. •
20. To a vessel that contains 1.00 mol of monatomic ideal gas A is added 0.100 mol of monatomic ideal gas B. The mass of each atom of gas A is 3.35×10^{-26} kg, and the mass of each atom of gas B is 1.39×10^{-25} kg. What is the final average speed of the A atoms if the final average speed of the B atoms is 123 m/s? ••

21. Inside a box, a 1.00-kg ball is gently dropped from a height of 1.00 m (Figure P19.21). The box contains 1.00 mol of argon atoms, each having a mass of 6.63×10^{-26} kg and moving at an average speed of 100 m/s before the ball is dropped. The ball rebounds elastically against the floor of the box, and so its energy is transferred only to the argon atoms. (*a*) What is the average energy of each argon atom before the ball is dropped? (*b*) After a long time interval has passed, the ball stops bouncing and rests on the box floor. What is the average speed of the argon atoms now? •••

Figure P19.21

22. A spherical balloon that has a diameter of 0.500 m and contains 1.00 mol of helium gas is left in the Sun for 10.0 min. During that interval, the Sun irradiates the balloon with an average intensity of 1120 W/m^2, all of which is absorbed. Before being warmed by the Sun, the average speed of the helium atoms is 367 m/s. What is their average speed after being warmed? Assume the balloon diameter remains constant. The mass of a helium atom is 6.646×10^{-27} kg. •••

19.3 Equipartition of space

23. A cube can be envisioned as an assembly of identical octants (numbered 1–8 in no particular order). The cube contains three identical particles. How many basic states in this system yield a macrostate (*a*) in which all three particles are in octant 1 and (*b*) in which two particles are in octant 8? •

24. A box sitting in a room occupies 1/64 of the room volume. When the box is opened, two identical particles are released into the room. What is the probability that at any instant after they are released, the two particles (*a*) return to the box simultaneously and (*b*) occupy the same 1/64 of the room? •

25. Three particles are released into a box that can be thought of as a set of four identical quadrants. How many basic states are possible if the particles are (*a*) indistinguishable from one another and (*b*) distinguishable from one another? ••

26. Four distinguishable particles move freely in a room divided into octants (there are no actual partitions). Let the basic states be given by specifying the octant in which each particle is located. (*a*) Give an example of a macrostate for this system. (*b*) How many basic states are there? (*c*) The door to this room is opened, allowing the particles to move into an adjacent, identical room, also divided into octants. Now that the amount of space that can be occupied has been doubled, by what factor has the number of basic states increased? ••

27. You have six identical particles in a box divided into four quadrants. For a certain experiment, you need to have a certain number of particles in the upper left quadrant. You observe that in a given day, the distribution of particles you need occurs for 51.43 min. How many particles do you need to be in the upper left quadrant in your experiment? ••

28. A cube that has a volume of 1.00 m^3 contains N distinguishable particles. Determine the probability that all the particles are in a smaller volume V of the cube if (*a*) $N = 1$, $V = 0.500$ m^3; (*b*) $N = 1$, $V = 0.250$ m^3; (*c*) $N = 1$, $V = 0.0100$ m^3; (*d*) $N = 2$, $V = 0.500$ m^3; and (*e*) $N = 4$, $V = 0.500$ m^3. ••

29. A space probe measures the number density of particles of interstellar gas by enclosing 1.00 m^3 of space and measuring the number of atoms that pass from that volume through a detector in the shape of a cylinder 15.0 mm in diameter and 5.00 mm long. In one area of space, the number density of particles of interstellar gas is assumed to be 1 atom/1.00×10^{-6} m^3. Out of a hundred tests, how many times does the detector register the presence of a particle in the cylindrical volume? •••

30. A box divided into four quadrants can hold a maximum of 30 particles in each quadrant. (*a*) If 114 particles are placed in the box, how many basic states and macrostates are possible, if the macrostates are defined as the number of particles in the upper left quadrant? (*b*) What is the most probable number of particles in the upper left quadrant? (*c*) What is the average number of particles in the upper left quadrant? (Hint: Instead of considering where the particles are located, consider where they are not located.) •••

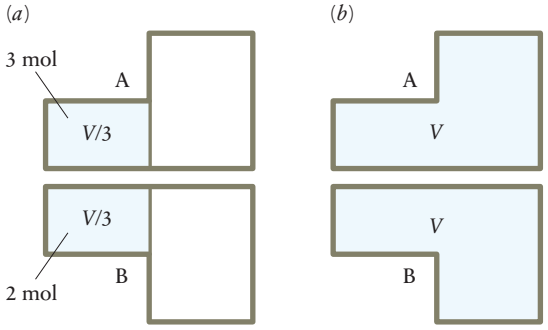
19.4 Evolution toward the most probable macrostate

31. A box divided into compartments A and B contains 14 particles in A and 6 in B. The separating partition allows energy exchange between compartments as the particles collide with the partition. Table 19.2 (page 674) lists the numbers of basic states possible when 10 energy units are distributed in various combinations over the 20 particles. How much more likely is it for compartment A to contain 7 energy units (macrostate $E_A = 7$, $E_B = 3$) than for this compartment to contain 3 energy units (macrostate $E_A = 3$, $E_B = 7$)? •

32. In how many ways can you distribute 10 indistinguishable energy units over 14 distinguishable particles? (Hint: Use Table 19.2, page 674.) •

33. A system has the numbers of macrostates and basic states shown in Table P19.33. (*a*) In which macrostate is the system in equilibrium? (*b*) Which macrostates are least likely? (*c*) How many basic states are possible for the system? (*d*) What is the probability that the system occupies macrostate B? •

Table P19.33



Macrostate	Associated number of basic states
A	1
B	4
C	6
D	4
E	1

34. A box divided into identical compartments A and B contains 25 distinguishable particles in A and 20 distinguishable particles in B. There are nine energy units in the box, initially distributed only among the particles in B. The system is closed, but the energy units can move from one compartment to the other as the particles collide with the separating partition. If one energy unit is exchanged during each partition-particle collision, what is the smallest number of collisions between the particles in B and the partition that must occur before the system reaches equilibrium? ••
35. A box divided into identical compartments A and B contains two distinguishable particles in A and three distinguishable particles in B. There are five energy units in the box, initially shared by the two particles in A. The system is closed, but particles can exchange energy through collisions with the partition. Calculate the number of basic states (*a*) initially and (*b*) once the system has reached equilibrium. ••
36. A box like the one in Problem 31 has two particles in compartment A, two particles in compartment B, and four energy units to be distributed. (*a*) Construct a table like Table 19.2 (page 674) for this setup. (*b*) Does equipartition of energy take place even with such a small number of particles? ••
37. System 1 is in equilibrium, and a separate system 2 is also in equilibrium. The systems are independent of each other but have an equal probability of being in equilibrium. The number of basic states possible in system 1 is 3422 times greater than the number possible in system 2. In system 2, the equilibrium state has 489 possible basic states. How many possible basic states does the equilibrium state of system 1 have? ••
38. A system has three macrostates. Macrostates 1 and 3 are least likely and have one basic state each. Macrostate 2 is the equilibrium state and is six times more likely to occur than either of the other two macrostates. (*a*) What is the probability that the equilibrium state 2 occurs? (*b*) What is the probability that macrostate 1 or 3 occurs? (*c*) What is the sum of the probabilities for all macrostates? ••
39. A cylindrical box is divided into three equal-volume, pie-shaped regions—A, B, and C—by vertical partitions that allow the transfer of energy but not of particles from one region to another. Each region shares a partition with the other two. Each region contains 13 particles, and the system contains 39 energy units, initially all located in region A. If each particle-partition collision transfers one energy unit, is it possible for the system to evolve to its most probable state in (*a*) 18 collisions, (*b*) 27 collisions, (*c*) 29 collisions? •••

19.5 Dependence of entropy on volume

40. What is the entropy of a closed system in which 25 distinguishable grains of sand are distributed among 1000 distinguishable equal-sized compartments? •
41. A number of distinguishable spherical beads, each having a radius of 15.0 mm, are placed into individual compartments in a 1.00-m^3 container. The same number of beads, each having a radius of 20.0 mm, are placed into different compartments in a container of the same volume. Which system has the greater entropy, and by what factor? Assume that each compartment is a cube, with each side equal to the diameter of the bead. •
42. You have 80 particles moving randomly in a closed container, and the system contains 80 energy units. Which is less likely: that a single particle has all 80 energy units, or that each particle has one energy unit? •
43. The volume of a cylindrical chamber is controlled by a movable piston. A sample of gas is placed in the chamber, and the volume is allowed to change from 0.0100 m^3 to 0.100 m^3 at a constant temperature. If the entropy of the system increases by 6.91×10^{18} during the volume change, how many gas particles are there in the chamber? ••
44. A closed box contains 20 particles, 10 on each side of a movable partition. The particles in the left compartment are small and occupy a volume δV_{left}. Those in the right compartment are larger and occupy a volume $\delta V_{\text{right}} = 8\delta V_{\text{left}}$. (*a*) If the box dimension along which the partition moves is 1.00 m long and the partition starts out pushed far to the right, what is the position of the partition when the system reaches equilibrium? (*b*) Does it matter what volume the particles occupy? ••
45. Rank the following systems according to their entropy, lowest first:
    A. 1,000,000 different colors that can be assigned to each of the 70×10^{21} stars in the observable universe
    B. The particles in 1 mol of an ideal gas that can be adsorbed (one particle per site) at any of 83 sites on an adsorbent material
    C. The particles in 0.8 mol of an ideal gas that can be adsorbed (one per site) at any of 106 sites on an adsorbent material
    D. The 100 trillion cells in the human body when each is to be classified as having one of three levels of relative cellular health
    E. The 1×10^{14} microbes in the average human body when each is to be classified as either alive or dead ••
46. Figure P19.46 shows a device consisting of two units, A and B. Each unit has a volume V, and at one end a partition separates off a small compartment that has volume $V/3$, as shown in part *a*. Initially, unit A has 3 mol of a gas in its smaller compartment, and unit B has 2 mol of the same gas in its smaller compartment. When the partitions are removed and the gas in each unit is allowed to expand into the volume V as shown in part *b*, what is the change in the entropy of the two-unit system? ••

Figure P19.46

47. Suppose each of 50 distinguishable objects has a volume of 1.00×10^{-9} m^3 and are initially in a box that has a volume of 1.00×10^{-6} m^3. If the volume of the box is doubled, (*a*) by what factor does the number of basic states change and (*b*) by what factor does the entropy increase? ••
48. A box of volume V has a movable partition separating it into two compartments. The left compartment contains 3000 particles, the right one contains 1000 particles, and initially the partition is in the middle so that the compartments are of equal volume. The partition is released and slides horizontally until the system is in a new equilibrium state. (*a*) In terms of V, what is the volume of each compartment once the new equilibrium state is reached? (*b*) What is the change in the system's entropy during this process? ••
49. A change in the volume occupied by a set of distinguishable particles increases the number of basic states by a factor of 6633 and increases the entropy per particle by a factor of 1.10. How many distinguishable particles are there in the system? •••
50. A box that is 1.00 m long measured from left to right has a sliding partition that separates it into two compartments. The left compartment contains 10 particles, the right one contains 60 particles, and initially the partition is 0.750 m from the left wall of the box. If the partition is allowed to move freely, what is the change in entropy after the system reaches equilibrium? •••

19.6 Dependence of entropy on energy

51. A container holds 1.0 mol of an ideal monatomic gas at 72 K, and then 0.50 mol of another monatomic ideal gas at 126 K is added. What is the equilibrium temperature? •
52. What is the change in entropy of a half a mole of ideal monatomic gas having an initial thermal energy of 75.0 J when this energy is doubled? ••
53. A theory predicts a reaction that produces ideal monatomic gas particles that have the following speeds: 6.2 m/s, 7.4 m/s, 7.4 m/s, 7.8 m/s, 8.3 m/s, 12.6 m/s, 20.1 m/s, 20.1 m/s. What are (*a*) the average speed of the particles and (*b*) their root-mean-square speed? •
54. Three monatomic ideal gas particles have the following velocities (written in component form) in a coordinate system: (3.0, 4.0) m/s, (−6.0, 8.0) m/s, (−5.0, −7.0) m/s. Calculate the (*a*) average speed and (*b*) root-mean-square speed of the particle? ••
55. An ideal monatomic gas is at 125 °C. If you increase the thermal energy of the gas and the root-mean-square speed of the gas particles triples, by what factor does the absolute temperature change? ••
56. Find the rate of change of entropy with respect to thermal energy of a system with an absolute temperature of 100 °C. •
57. The entropy for a certain monatomic gas has been empirically determined to be given by the expression $S = \frac{7}{2}N \ln E_{\text{th}} + NE_{\text{th}}^{2/15}$. Express the factor $1/k_{\text{B}}T$ for this gas in terms of N and E_{th}. ••
58. In (x, y, z) notation, four ideal monatomic gas particles have the velocities $\vec{v}_1 = (-6.0, 5.0, 1.0)$ m/s, $\vec{v}_2 = (4.0, 5.0, -2.0\text{ m/s})$, $\vec{v}_3 = (7.0, 0, 8.0)$ m/s, and $\vec{v}_4 = (-4.0, -9.0, -6.0)$ m/s. (*a*) What is the average velocity of the particles? (*b*) What is the root-mean-square speed of the particles? (*c*) Why is Eq. 19.25, $v_{\text{rms}}^2 = 3(v_x^2)_{\text{av}}$, unlikely to give the correct answer here? ••
59. A box is divided into four equal-sized quadrants. Each quadrant contains gaseous hexane (C_6H_{14}), which we treat as monatomic. The partition that separates the quadrants allows energy to be exchanged, but not particles. However, there is a tiny hole in the partition between quadrants 1 and 2 that allows gas particles to be exchanged. The initial values for the mass of gas in each quadrant and the root-mean-square speed of the particles are Q_1: 3.00 g, 400 m/s; Q_2: 5.50 g, 500 m/s; Q_3: 2.00 g, 420 m/s; Q_4: 6.75 g, 445 m/s. After the system sits for a long time interval, what is the root-mean-square speed for the particles in quadrant 2? •••

19.7 Properties of a monatomic ideal gas

60. Find the rms speed of an oxygen molecule at 0 °C. The mass of an oxygen atom is 2.657×10^{-26} kg? •
61. The molar mass of oxygen (32 g) is slightly greater than that of nitrogen (14 g). But in a tank, the molecules of oxygen have the same rms speed as the molecules of nitrogen in another identical tank. How could this be possible? ••
62. A 1.00-m long cylindrical container with a diameter of 1.20 m contains monatomic ideal gas at 2.00 atm. (*a*) How much thermal energy do the particles of this gas contain? (*b*) If this thermal energy were converted to the gravitational potential energy of a 1400-kg object, how high from the ground must the object be? ••
63. An empty 2.00-L soft drink bottle is filled with 0.0100 mol of a monatomic ideal gas at atmospheric pressure (1.01×10^5 N/m^2). (*a*) What is the average kinetic energy of each gas particle in the bottle? (*b*) Compare the value you obtained in part *a* with the kinetic energy of a bacterium of mass 1.0×10^{-14} kg moving at 1.0×10^{-7} m/s and with the kinetic energy of a 0.0010-kg garden slug moving at 0.0100 m/s. ••
64. A particle accelerator exerts a force on particles that are initially at rest. Each of the particles has a mass of 1.6726×10^{-27} kg, and the point of application of the force is along the entire 100-m length of the accelerator. The particles traverse this distance in 0.0179 s and then collide with a target that is in thermal contact with a monatomic ideal gas. If the particles distribute their kinetic energy elastically, what is the temperature of the gas after the accelerator has been running for a long time interval? ••
65. Very dilute, monatomic cool gases A and B are separated by a partition but allowed to exchange energy through the partition. After a long time interval, $v_{\text{rms,A}} = 6v_{\text{rms,B}}$. What is the relationship between the mass of a particle of gas A and the mass of a particle of gas B? ••
66. A thermally insulated 3.00-L flask contains monatomic xenon gas at an initial temperature of 50.0 °C and pressure of 2.50 atm. You now add enough energy to double the thermal energy of the gas. The mass of a xenon atom is 2.18×10^{-25} kg. (*a*) How many atoms does the flask contain? (*b*) How much energy did you add to the flask? (*c*) By what factor did you change the root-mean-square speed of the atoms? ••

67. In a sample of a monatomic ideal gas that has a number density of 3.61×10^{24} particles/m^3, the average kinetic energy of the gas particles is 7.50×10^{-21} J. If the particles are colliding with a wall that has an area of 1.00×10^{-2} m^2, what is the average change in momentum per unit of time for the gas? ••

68. Chamber X contains monatomic ideal gas X. The gas particles have a root-mean-square speed of 42 m/s. Chamber Y, identical to chamber X, contains a different monatomic ideal gas with the same mass as the gas in chamber X but with twice the number of gas particles as the gas in chamber X. If the absolute temperatures in the chambers are T_X and $T_Y = 1.2T_X$, what is the root-mean-square speed of the particles in Y? ••

69. A jar contains a mixture of helium gas and krypton gas, with the sample containing equal masses of the two gases, $m_{\text{sample,He}} = m_{\text{sample,Kr}}$. Both gases are monatomic, they behave ideally, and the system is in equilibrium. (*a*) What percentage of the pressure in the mixture is due to the helium? What percentage is due to the krypton? (*b*) Explain why your answer in part *a* is reasonable. The atom masses are $m_{\text{He}} = 6.646 \times 10^{-27}$ kg and $m_{\text{Kr}} = 1.391 \times 10^{-25}$ kg. ••

70. Neon atoms at 260 K pass through a fan that gives each mole of neon gas an additional kinetic energy of 16.0 J. (*a*) What is the average temperature of the neon atoms immediately after coming through the fan? (*b*) If you found an increase in temperature in part *a*, how do you explain the fact that fans are usually used to make people cooler rather than hotter? ••

71. A pollution-control device installed in the smokestack of equipment used to run an industrial process measures the root-mean-square speed of pollutant particles given off by the process. If v_{rms} exceeds a given limit, the process is shut down to prevent the release of pollutants into the air. (Consider the particles to be ideal and monatomic.) The safety operator knows that the average mass density of the particles involved in this process is 5600 kg/m^3. (*a*) At what threshold should he set the device if the process is running at 936 °C and the particle diameter is 10 nm? (*b*) As the particles rise and exit the smokestack, the 10-nm particles coalesce to an average diameter of 1.0 μm and cool to 190 °C. What is the root-mean-square speed of the particles as they exit the smokestack? (Ignore viscosity and drag.) •••

72. You are constructing an improvised detector for radon gas, using the cooling core from an old refrigerator capable of cooling air to 255 K, a detector tube 50 mm long, a vacuum pump to evacuate the tube, and an electric circuit that can measure the time interval needed for gas particles to travel a given distance. To determine if there is radon in the air in your room, you intend to inject samples of the air into the evacuated tube and measure the time interval needed for particles in the sample to travel from one end of the tube to the other and their root-mean-square speed for the trip. (*a*) To what scale of measurement should you set the time-interval sensor if you want to detect the monatomic radon atoms? (Ignore any collisions between these atoms and other particles in the sample.) (*b*) Can you suggest any modifications to this device to improve accuracy? (*c*) Do you think you will need to calibrate your system if you have to make the more realistic assumption that the collisions between radon atoms and other particles in the sample cannot be ignored? If so, why? •••

19.8 Entropy of a monatomic ideal gas

73. What is the change in entropy per particle of a monatomic ideal gas heated from 300 K to 400 K? Assume constant volume, and thermal equilibrium in both the initial and final states. •

74. If 1.85×10^5 atoms of a monatomic ideal gas are heated from 300 K to 500 K in a sealed container that has a fixed volume of 0.0560 m^3, what is the change in entropy of the gas? •

75. A monatomic ideal gas in a container of fixed volume contains 4.20×10^{24} atoms. If you add enough thermal energy to double the root-mean-square speed of the gas atoms, by how much have you changed the entropy of the gas? •

76. A container of fixed volume contains 8.72×10^{23} helium atoms, each of mass 6.646×10^{-27} kg. You put the container in a freezer and decrease its temperature from 25.0 °C to −135 °C. What are (*a*) the change in the thermal energy of the gas and (*b*) the change in its entropy? ••

77. A 3.50-L expandable chamber contains monatomic neon gas at 2.00 atm and 30.0 °C. Thermal energy is slowly added to the gas until its volume is 8.00 L while its pressure remains constant. What is the entropy change during this expansion? ••

78. A monatomic ideal gas has its volume halved while its pressure is held constant. What is the change in entropy per atom? ••

79. As a sample of argon gas is heated in a sealed container, its root-mean-square speed changes from 350 m/s to 540 m/s. By how much has the entropy been increased per argon atom? The mass of an argon atom is 6.63×10^{-26} kg. ••

80. A monatomic ideal gas is enclosed in a cubic box of side length ℓ. While preserving the cubic shape, the container volume is decreased until the side length is halved, and this change causes the pressure in the box to triple. (*a*) What is the change in entropy per particle of gas in the box? (*b*) Is this system closed? ••

81. A sample containing 3.65 mol of a monatomic ideal gas is heated from 289 K to 458 K, and the entropy remains constant. If the initial volume of the sample was 0.0980 m^3, by what factor did the pressure increase or decrease during this process? ••

82. A constant-volume encasement vessel surrounds a liquid-nitrogen bath that has cooled 1.00 mol of a monatomic ideal gas to 77.2 K. This system is initially in thermal equilibrium at this temperature, but over time the liquid nitrogen evaporates, and then the ideal gas and the nitrogen gas are in equilibrium in the encasement vessel at room temperature, 297 K. (*a*) What is the change in entropy of the ideal gas as it undergoes this temperature change? (*b*) The nitrogen gas is then condensed and again cools the ideal gas. What is the entropy change for the ideal gas as it returns to 77.2 K? (*c*) Where

in this process did entropy increase, as required by the second law of thermodynamics for an irreversible process? ••

83. Ten particles of a monatomic ideal gas are initially at thermal equilibrium with their surroundings. When the sample is then heated to 634 K while the volume is held constant, the entropy doubles. What was the initial temperature of the sample? ••

84. In a cylindrical chamber that initially has a volume of 2.25 L, a sample of helium gas is at equilibrium at 3.20 atm and 85.0 °C. The gas is slowly compressed to a new equilibrium state at a volume of 1.10 L and pressure of 4.40 atm. What is the entropy change during this compression? ••

85. A thermally insulated chamber is divided by a partition into two compartments of equal volume. The left side contains 9.00×10^{23} helium atoms, and the right side contains 2.70×10^{24} argon atoms. The gases in both compartments are in equilibrium and at the same temperature. A small hole develops in the partition so that after a long time interval both gases leak through the hole and eventually the system comes to a new equilibrium state. (*a*) What is the difference in entropy between the two equilibrium states? Which state, if either, has the greater entropy? (*b*) What is the change in the thermal energy of the gases during this process? Assume ideal behavior for all atoms. ••

86. A rigid 1.20-L bottle contains helium gas at 150 °C and 2.75 atm. If you slowly add 755 J of thermal energy to the gas, what is the entropy change for the gas? Assume the helium gas is ideal. ••

Additional Problems

87. Suppose you are dropping five small pieces of clay randomly onto a chessboard (eight squares by eight squares). If basic states are determined by the squares on which each piece of clay lands, how many basic states are possible? Assume a square can be occupied by multiple pieces. •

88. Consider two egg cartons, one with spaces for a dozen eggs and one with spaces for a half-dozen eggs. If each carton contains six eggs, all of different colors, what is the ratio of the number of possible basic states in the one-dozen carton to the number of possible basic states in the half-dozen carton? •

89. Two boxes each have a volume of 1.50 m^3. Box A contains 1000 helium atoms, and box B contains 2000 neon atoms. When the boxes are connected together by a very small tube, the atoms redistribute themselves throughout both boxes. What is the entropy change of the two-box system during the redistribution? •

90. A sample of neon gas is at 100 °C. The mass of a neon atom is 3.35×10^{-26} kg. (*a*) What is the average kinetic energy of a neon atom? (*b*) If the thermal energy of the sample is 175 J, how many neon atoms does it contain? •

91. At 35 °C, the root-mean-square speed of a certain monatomic ideal gas is 186 m/s. (*a*) What is the mass of each atom? (*b*) What is the average kinetic energy of a typical atom at that temperature? •

92. A 0.00126-kg sample of an ideal gas in a fixed-volume, 0.750-L container at 50.0 °C exerts a pressure of 2.24 atm. What is the mass of one particle of this gas? ••

93. The atoms of an element can come in different forms, depending on the number of neutrons in the nucleus. These different forms are called *isotopes* of the element. The two most common isotopes of uranium are uranium-235 (143 neutrons) and uranium-238 (146 neutrons), having masses of 3.90×10^{-25} kg and 3.95×10^{-25} kg, respectively. In a sample of uranium gas, these isotopes have slightly different root-mean-square speeds, and this difference can be used to separate the isotopes for use in nuclear reactors or nuclear weapons. When both gases are at the same temperature, what is the percent difference in the root-mean-square speeds of the atoms of each isotope? Which isotope has the greater root-mean-square speed? ••

94. A sealed 1.50-L chamber filled with helium gas initially at 20 °C and 1.00 atm is heated until the gas temperature is 232 °C. (*a*) How much thermal energy is added to the gas during this process? (*b*) What is the entropy change of the gas during this process? (*c*) What was the final pressure inside the container? Ignore any thermal expansion of the container; the mass of a helium atom is 6.646×10^{-27} kg. ••

95. (*a*) At what temperature is the root-mean-square speed of neon atoms (mass 3.35×10^{-26} kg) equal to the speed of sound in a typical room, 344 m/s? (*b*) At the temperature you found in part *a*, how much thermal energy do 6.02×10^{23} neon atoms have? ••

96. A monatomic ideal gas is in a fixed-volume flask. (*a*) By what factor must you increase the root-mean-square speed of the gas particles to double the gas pressure? (*b*) By what factor does the thermal energy of the gas change when you increase v_{rms} by this factor? ••

97. A sample of a monatomic ideal gas contains N atoms. You want to compress the gas slowly to one-fourth of its original volume. (*a*) By what factor must you change the absolute temperature of the sample in order to increase its entropy by $3N$? (*b*) For the process in part *a*, by what factor does the root-mean-square speed of the gas particles change? ••

98. The temperature of the Sun's corona (the outermost gas layer) is 1.0×10^6 K, and this layer is just above the photosphere layer, which has a radius of 6.96×10^8 m. The mass of the Sun is 1.99×10^{30} kg. Is the root-mean-square speed of helium atoms in the corona great enough to allow the atoms to escape from the Sun's gravitational pull? The mass of a helium atom is 6.646×10^{-27} kg. ••

99. Consider a helium atom that is part of Earth's atmosphere and is initially at the planet's surface, where the temperature is 20 °C. To what maximum altitude can this atom rise if its speed is equal to the root-mean-square speed of the helium in the atmosphere? The mass of a helium atom is 6.646×10^{-27} kg, the mass of Earth is 5.97×10^{24} kg, and Earth's radius is 6.38×10^6 m. (Careful! The value of g varies with altitude.) ••

100. A box initially divided into two equal halves by a partition contains some number of particles. When the partition is removed, the particles are free to move throughout the volume of the box. Assume that all the

particles have an average speed that allows them to cross from one side of the box to the other every 2.50 s, on average. Note that this does not mean that they uniformly switch sides; it means that they move randomly in such a way that they enter a new random distribution every 2.50 s. Determine the probability of all particles being in the left half of the box and the average time interval required for this to happen for (*a*) two particles and (*b*) ten particles. ●●

101. A cylindrical chamber is oriented with its long central axis along the vertical *y* axis of an *xyz* coordinate system. The top face of the chamber is a piston that can slide up and down to change the chamber volume. The chamber is initially filled with a monatomic ideal gas. When the chamber temperature is lowered, the piston slides downward very slowly at constant velocity until the chamber volume is one-fifth of its original value. At this instant, the contraction stops with the gas in an equilibrium state. (*a*) By what factor does the root-mean-square speed of the gas particles change during this contraction? Does this speed increase or decrease? (*b*) By what factor does the thermal energy of the gas change during this contraction? Does the energy increase or decrease? ●●●

102. A cylindrical canister fitted with a piston at one end contains an ideal gas and floats at the surface of a freshwater lake, where the temperature is 300 K. The gas pressure inside the canister is just enough to balance atmospheric pressure, and so the piston does not slide downward. Initially the canister volume is 3.64 L. The canister is lowered into the lake until it is 12.0 m below the surface, where the temperature is 280 K. (*a*) What is the canister volume once equilibrium is reached at this depth? (*b*) What is the change in entropy of the gas during this process? Ignore friction and ignore the effect of gravity on the piston. ●●●

103. Your work in a laboratory requires a certain dangerous ideal gas, which you will be using for the next three weeks. You know that the gas is corrosive and that gas particles are constantly colliding with one another and, more worrisome, with the walls of the container. Thus there is some finite probability that a gas particle will react with a particle of the container and weaken the container wall. You have 4.00×10^{-3} kg of this gas in a spherical 6.45-L container in which the walls are 10.0 mm thick. The mass of each gas particle is 6.054×10^{-26} kg. The temperature of the gas is always close to room temperature and certainly never rises above 30 °C. After a little online search, you realize that each time a gas particle hits the container wall there is a one in 3 million chance of a corrosive reaction. That causes you to wonder about safety issues. ●●● CR

104. A tank filled with helium gas has been left in a hot car for hours. The mass of the filled tank is 21.2 kg, and after you use all the helium to fill 100 balloons for a child's birthday party, the tank mass is 20.8 kg. You notice that the filled balloons are shrinking over time. Each filled balloon is roughly spherical and started out with a radius of 200 mm, but now each radius has shrunk to 100 mm. Some of the children are afraid the balloons will deflate completely. You estimate that the gauge pressure inside the balloon was initially 50.0 kPa and that this pressure must increase linearly with balloon surface area. You are puzzled by the shrinking because the air temperature at the party is 35.0 °C. That causes you to wonder whether the balloons have an equilibrium radius or you should prepare the children for complete deflation. ●●● CR

CONCEPTS

QUANTITATIVE TOOLS

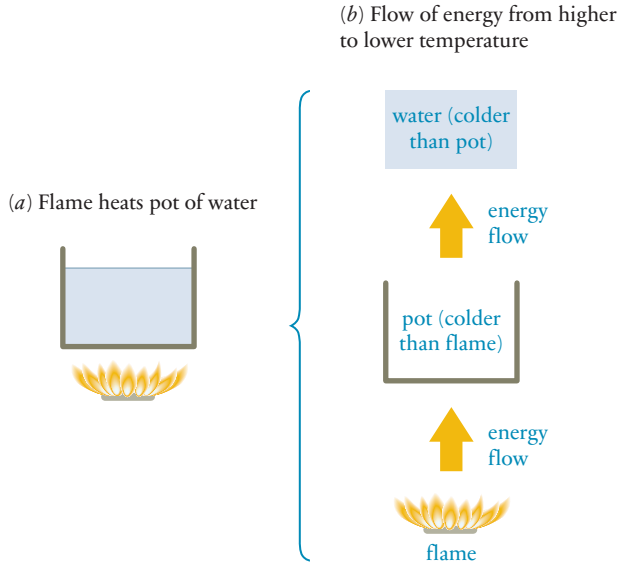
We use terms like *hot* and *cold*, *heating* and *temperature* based on our everyday interpretations of these words. We know from experience that to raise the temperature of water to the boiling point for a cup of tea, we need to heat the water, which requires energy. The branch of physics that deals with these concepts, called *thermodynamics* (from the Greek *therme*, meaning "heat," and *dunamis*, meaning "power"), was developed in the early 19th century to describe the working of steam engines. The concepts of entropy and absolute temperature introduced in Chapter 19 were developed as a consequence of that work. In this chapter we connect the statistical ideas from Chapter 19 to the macroscopic concepts of temperature, pressure, and volume.

20.1 Thermal interactions

The concept of temperature is familiar: It's a measure of "hotness." According to what we saw in Chapter 19, if two objects that are not at the same temperature are placed in contact with each other, energy is transferred from the object at the higher temperature to the object at the lower temperature until the temperatures of the two are equal. We attribute this transfer of energy to a **thermal interaction** between the two objects at different temperatures. As we saw in Chapter 19, this thermal interaction is the overall effect of countless interactions at the atomic scale.

Let us begin by considering the familiar situation shown in **Figure 20.1**: heating a pot of water on a stove. As we heat the water, energy flows from the flame to the pot and then from the pot to the water. The flame, which is hotter (that is, at a higher temperature) than the pot, heats the pot, and the pot, which is hotter than the water, heats the water. If we consider the water as our system and make an energy diagram for that system, we obtain the result shown in **Figure 20.2**. As the water gets hotter, its thermal energy increases. The burning flame provides that energy, but it is not part of the system, and so there is no change in our system's source energy. The system's kinetic energy and potential energy do not change either, and so the system's energy increases because of the increase in thermal energy.

Figure 20.1 When a gas burner heats a pot of water, energy flows from higher temperature to lower temperature.



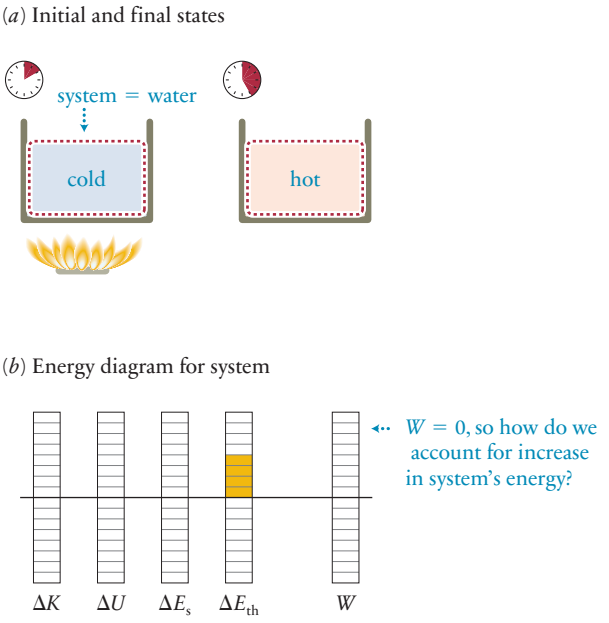


Figure 20.2 When a pot of water is heated, the energy diagram for a system comprising only the water is unbalanced.

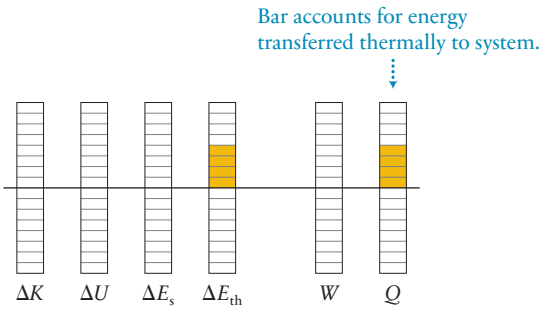


How do we account for this increase in the energy of the system? Although there are external forces exerted on the water—the force of gravity and a normal force exerted by the pot on the water—neither force causes any displacement, and so does no work on the system.

Consequently the energy diagram of Figure 20.2 is unbalanced: The energy changes are not equal to the work done on the system. The reason for this unbalance is that this energy diagram does not account for the energy transferred into the system by the heating. To make the diagram complete, we need to add a bar that represents the energy transferred into the system by the thermal interactions among the flame, pot, and water. The amount of energy transferred by thermal interactions ("thermally") is denoted by the letter Q (**Figure 20.3**). The law of conservation of energy requires that the change in the energy of the system be equal to the energy transferred into it, so the height of the bar representing Q in Figure 20.3 has to be equal to the height of the bar representing the increase in thermal energy.

20.1 (*a*) What are the SI units of Q? (*b*) For the process depicted in Figure 20.2*a*, make an energy diagram for each of these systems: (*i*) water, pot, and flame; (*ii*) pot and flame; (*iii*) pot.

CONCEPTS

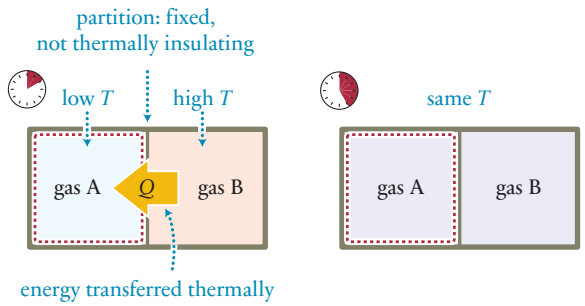
Figure 20.3 To complete the energy diagram of Figure 20.2, we must add a bar to account for the energy transferred thermally into the system (represented by the symbol Q).

The quantity Q is frequently called *heat*, a term we shall avoid because it is easy to confuse the verb *to heat* with the noun and to think of "heat" as a property of an object instead of a quantity of energy transferred across a boundary. When it is necessary to refer to Q by name, we shall use the term **energy transferred thermally,** reserving the verb *to heat* to refer to the process of increasing the thermal energy of a system. (For example, *I am heating a pot of water* means that I am increasing its thermal energy.)

Now consider the situation in **Figure 20.4*a***, where two gases are separated by a fixed partition that is not thermally insulating. Initially gas A in the left compartment is at a lower temperature than gas B in the right compartment. Because the partition is not thermally insulating, the gases interact thermally, and energy is transferred thermally from the hotter gas to the colder one until their temperatures are the same. The energy transferred thermally is represented by the arrow labeled Q. The energy diagram for gas A in Figure 20.4*b* consequently shows an increase in thermal energy and the energy transferred thermally, Q, is positive.

20.2 Make an energy diagram for gas B in Figure 20.4.

As Checkpoint 20.2 shows, the sign of Q depends on the direction of the energy transfer. Just as for work, if the transfer is into the system (that is, the energy of the system increases), Q is positive (Figure 20.4*b*); if the transfer is out of the system, Q is negative (Checkpoint 20.2).



Let us examine in more detail the difference between transferring energy by doing work on a system (that is, through mechanical interactions) and by transferring energy thermally to it. In **Figure 20.5*a*** a spring-loaded piston compresses an ideal gas into a smaller volume, doing work on the gas. We shall ignore any friction between the piston and the container walls. The ideal gas is *thermally insulated;* that is, it is not interacting thermally with its surroundings. A process that does not involve any thermal transfer of energy is called an **adiabatic process** ($Q = 0$).

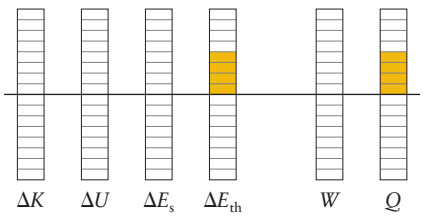
Because the process depicted in Figure 20.5*a* is adiabatic, the amount of energy transferred to the gas is equal to the work done on the gas by the piston and is determined by the force $\vec{F}^{c}_{pg}$ exerted by the piston on the gas and the force displacement $\Delta\vec{x}_F$.

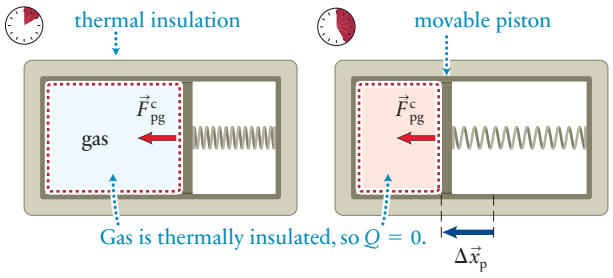
How is the energy of the gas raised? There are no changes in the kinetic energy of the center of mass of

Figure 20.4 When gases of different temperatures are placed in thermal contact, energy is transferred thermally from the hotter to the cooler gas until the temperatures of the two gases are the same.

(*a*) Gases at different temperatures are placed in thermal contact

(*b*) Energy diagram for gas A





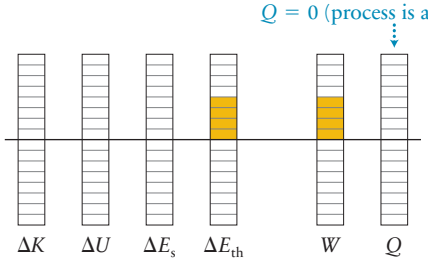


Figure 20.5 A piston does work on a thermally insulated ideal gas, increasing the gas's temperature.

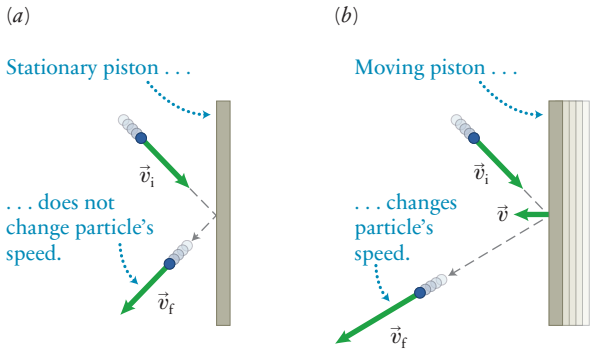
(*a*) Spring-loaded piston compresses thermally insulated ideal gas



(*b*) Energy diagram for gas

CONCEPTS

Figure 20.6 A stationary piston does not change the speed of a gas particle that collides with it, but a moving piston does.

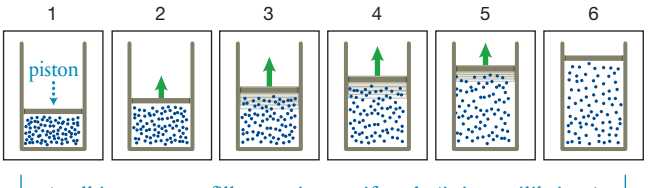
the gas because the gas as a whole remains at rest. There are also no changes in the potential energy of the gas because there is no potential energy associated with the interactions between particles in an ideal gas. Nor are there any changes in the source energy. Therefore the work W done on the gas must raise the thermal energy of the gas (Figure 20.5*b*). We can understand how this happens by considering the (elastic) collisions of the gas particles with the piston. If a particle collides with the stationary piston (**Figure 20.6*a***), the particle's speed is unaltered by the collision. When the piston is moving toward the incoming particle, however, the particle gains speed because of the collision and therefore its kinetic energy increases, just as a tennis ball bounces faster off your racquet when you swing it toward the ball. So, as the piston moves in, the particles colliding with it speed up (Figure 20.6*b*), increasing their incoherent kinetic energy and thus the thermal energy of the gas.

Note that in Figure 20.5*a* the volume decreases. During this decrease, the force exerted by the piston on the gas and the force displacement are in the same direction. Consequently the work done on the gas is positive. Had the piston moved in the opposite direction (expanding the volume), the work done on the gas would have been negative.

> **When the volume of a gas decreases, the work done on the gas is positive. When the volume increases, the work done on the gas is negative. When there is no change in volume, the work done on the gas is zero.**

Summarizing the information from Figures 20.4 and 20.5, we see that there are two ways to transfer energy to a system: mechanically (by doing work on the system) and thermally (see the box "Transferring energy to a system"). Both types of transfer can occur simultaneously. In that case the change in the energy of the system ΔE is equal to the sum of the work done on the system, W, and the energy transferred thermally to it, Q.

Let us now turn our attention to the transformation of a system from one macrostate to another. Such a transformation is a called a **process,** and if the process is carried out in such a way that the system remains very close to equilibrium at all instants during the process, the process is said to be **quasistatic.**



CONCEPTS

Transferring energy to a system

	DOING WORK	TRANSFERRING ENERGY THERMALLY
Technical term:	Mechanical interaction between system and its environment	Thermal interaction between system and its environment
Mediated by:	Macroscopic pushes and pulls	Atomic and/or molecular collisions
Requires:	A nonzero external force $\vec{F}_{ext}$ exerted on the system and a nonzero force displacement $\Delta\vec{x}_F$	A nonzero temperature difference ΔT between the system and its environment
Amount of energy transferred *into* system:	W ("work done on system")	Q ("energy transferred thermally to system")
Sign:	$W > 0$ when external force and force displacement are in the same direction (energy of system increases in absence of other transfers)	$Q > 0$ when environment is at a higher temperature than system (energy of system increases in absence of other transfers)
	$W < 0$ when external force and force displacement are in opposite directions (energy of system decreases in absence of other transfers)	$Q < 0$ when environment is at a lower temperature than system (energy of system decreases in absence of other transfers)
Equilibrium:	The vector sum of the external forces is zero, and the force displacement of each external force is zero (mechanical equilibrium)	System is at same temperature as its environment (thermal equilibrium)

Figure 20.7 Quasistatic versus non-quasistatic expansion of a cylinder containing a gas.

(*a*) Quasistatic expansion: piston rises gradually

(*b*) Non-quasistatic expansion: piston rises suddenly

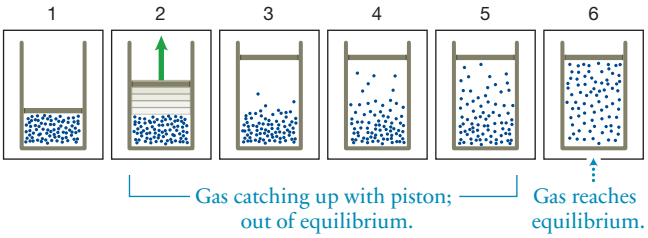


Figure 20.7*a* shows the expansion of a volume of gas in a cylinder. To make the expansion quasistatic, the piston is moved slowly so that the gas always uniformly fills all the available space, and each particle has its equipartition share of the thermal energy. In each frame shown in the drawing, the gas is in a different state, but each state is an equilibrium state. In a quasistatic process, therefore, the pressure may change during the process, but at any given instant the pressure has a uniform, well-defined value at all locations in the volume of gas. The same is true of the temperature: The final temperature may differ from the initial temperature, but at any given instant the temperature has a uniform, well-defined value at all locations in the volume of gas. There are no locations where the pressure is greater and no spots that are hotter than others. In Figure 20.7*a*, the entropy changes as the gas expands (because the entropy of an ideal gas changes with volume and temperature, Eq. 19.60), but at each instant it has the maximum value for that equilibrium state.

Suppose, however, that the piston moves at a rapid speed, as illustrated in Figure 20.7*b*. The motion of the piston is so fast that the gas can't keep up with it. In frame 2, for example, the gas still mostly occupies the original volume. Consequently, the pressure at the bottom of the cylinder is still nearly the same as it was in frame 1, while it is nearly zero at the top, where we still have a vacuum. Although the piston reaches its final position in frame 3, it takes the gas another three frames before it is evenly distributed and in equilibrium. In frames 2–5 of Figure 20.7*b*, the gas is not in equilibrium, and so the entropy is not maximum. Because particles in a gas typically move at very great speeds, they redistribute themselves rapidly. Thus, in practice, even if a piston such as the one in Figure 20.5 moves rapidly, the resulting process can still be quasistatic.

20.3 Suppose you were to play the two film clips shown in Figure 20.7 backward. Would the resulting processes be possible?

Let us now examine how the entropy changes when energy is transferred to a system in a quasistatic process. First consider the process shown in Figure 20.4, where energy is transferred thermally between two gases. The energy transferred thermally to gas A is positive ($Q > 0$). The temperature of gas A increases. Therefore by Eq. 19.56 the entropy of the gas increases. Conversely, Q is negative for gas B, the temperature of B decreases, and so its entropy decreases. Consequently, the sign of the entropy change of a system is the same as the sign of Q for that system:

> ***Transferring energy thermally to a system increases its entropy. Transferring energy thermally from a system decreases its entropy.***

Next, let us determine what happens to the entropy of a system when work is done on it in the absence of any thermal interaction ($Q = 0$). Consider, for example, the quasistatic compression of the thermally insulated gas in Figure 20.5 again. As the piston does work on the gas, the thermal energy of the gas goes up, but at the same time the volume goes down. In Chapter 19 we saw that an increase in the thermal energy of a system raises its entropy. A decrease in the system volume, however, lowers the entropy, so we can't say offhand what happens to the entropy of the gas as it is compressed.

Let us therefore consider the closed system consisting of the contents of the box in Figure 20.5*a*. In contrast to the equilibration of temperatures in Figure 20.4, which is an irreversible process, the compression of the gas and the expansion of the spring are reversible. Because the process is quasistatic, the system remains in equilibrium at all instants during the compression, and therefore the entropy law tells us that the entropy of the (closed) system doesn't change: $\Delta S = 0$ (Eq. 19.6).

Because we are interested in the process (which takes place in the gas), we divide the system into two parts: the gas and the spring-loaded piston ("piston" for short). Because entropy is an extensive quantity, we can write the change in the system's entropy as $\Delta S = \Delta S_{\text{gas}} + \Delta S_{\text{piston}} = 0$.

In the spring-loaded piston, potential energy is converted to kinetic energy, both of which are coherent forms of energy (see Figure 7.10). Regardless of the speed of the piston and the configuration of the spring, there is only one way to distribute the energy and atoms such that all the energy is coherent. At any instant, therefore, the number of basic states of the spring-loaded

piston is 1, and so the entropy of the spring-loaded piston does not change: $\Delta S_{\text{piston}} = 0$.

If $\Delta S_{\text{piston}} = 0$ and $\Delta S = 0$, then the entropy of the gas cannot change either: $\Delta S_{\text{gas}} = 0$. So we can conclude that in a quasistatic process during which we do work on a gas without thermally transferring any energy to it ($Q = 0$), the entropy of the gas does not change. Generalizing this idea to any type of system undergoing a quasistatic adiabatic process, we can state:

The entropy of a system undergoing a quasistatic adiabatic process does not change.

In a quasistatic adiabatic process, the temperature and volume changes are coordinated in such a way as to keep the entropy constant. This conclusion holds for only *quasistatic* adiabatic processes. For instance, in Example 19.9, a gas adiabatically expands into a larger volume, increasing the entropy of the gas. The expansion is adiabatic, but not quasistatic. Therefore the entropy of a system undergoing a non-quasistatic adiabatic process can change.

20.4 Which of the following systems undergo a quasistatic process? (*a*) A gas-containing balloon is popped inside a vacuum container. System: container, gas, and balloon. (*b*) A cup of coffee cools down. System: coffee. (*c*) A sample of compressed gas in a cylinder fitted with a heavy piston is allowed to expand, pushing the piston outward. System: gas. (*d*) An ice cube melts in a glass of hot water. System: water and ice cube.

20.2 Temperature measurement

In Chapter 19 we defined the absolute temperature as a rather abstract concept related to the rate at which entropy changes with changes in thermal energy. Entropy is a measure of the number of available basic states in a system, and thermal energy is the energy associated with the incoherent internal motion of the system. Neither of these quantities can be measured directly. We must therefore figure out some convenient way to measure the temperature of an object.

Most of the methods that have been developed to measure temperature rely on measuring some physical quantity that varies with temperature. For example, in a glass thermometer, illustrated in Figure 20.8, the thermal expansion of a liquid provides a means of measuring temperature. A glass tube is connected to a bulb filled with glycerin, mercury, or some other liquid whose mass density decreases with rising temperature. Because the mass of the liquid is constant, its volume increases and therefore the temperature can be determined by measuring the height of the liquid in the glass tube. To calibrate this type of thermometer, it is placed in melting ice and allowed to come to thermal equilibrium. Once equilibrium is reached, a mark is made on the glass tube at the height of the liquid in the tube. The thermometer is then placed in boiling water and allowed to come to thermal equilibrium. The tube is marked at the new height of the liquid in the tube. The two marks on the tube are assigned some standard values representing the freezing and boiling points of water—historically 0 °C and 100 °C, respectively.

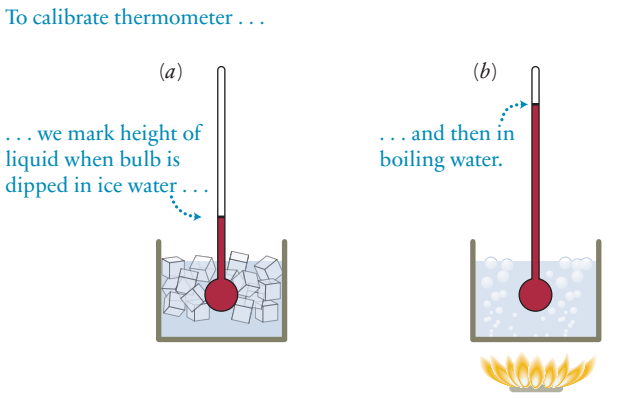

Figure 20.8 Calibrating a gas thermometer by immersing its bulb in ice water and then in boiling water.

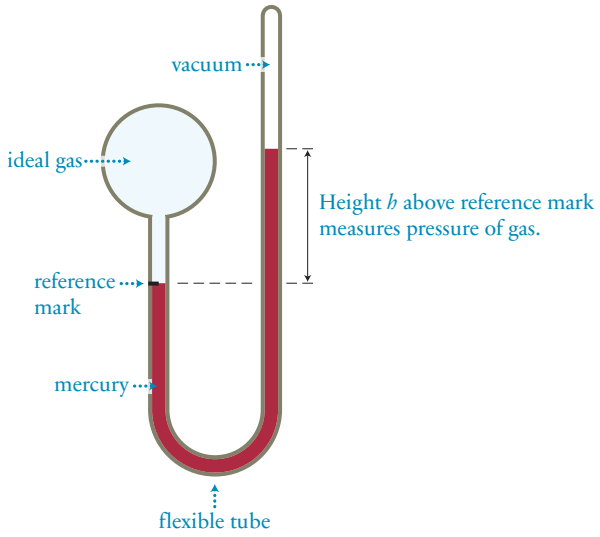
If a liquid's change in volume is proportional to its change in temperature, the temperature of any substance can be measured by immersing the thermometer in the substance and noting how far up the glass tube the enclosed liquid rises. If the thermometer is immersed in a cup of milk and the liquid in the tube rises, say, 27/100 of the distance between the 0 °C and 100 °C marks, the temperature of the milk is 27 °C. Of course, in commercial thermometers there is no need to measure heights in fractions because the glass tube is marked all along its length and the temperature is read directly.



Is the expansion of a liquid proportional to the absolute temperature we defined in Chapter 19? No—as a matter of fact, the expansion of one liquid isn't even proportional to that of another liquid. For this reason, glass thermometers are accurate over only a relatively narrow range of temperatures.

How, then can we measure temperature accurately? In Section 19.7 we derived the ideal gas law, $P = Nk_{\text{B}}T/V$, which relates the absolute temperature to two macroscopic quantities that are easily measured: pressure and volume. This law is a direct consequence of our definition of absolute temperature and is valid for an ideal gas, that is, it is valid as long as the pressure, volume, and absolute temperature are such that we can ignore the internal structure of the gas particles and the interactions between particles (except for collisions between them). No gas is ideal, but many gases can approximate ideal behavior. For a dilute gas of helium atoms, for instance, the conditions for ideal behavior are satisfied down to temperatures that are quite low.

Figure 20.9 illustrates the basic principle of an **ideal gas thermometer**, which measures the pressure in a gas

CONCEPTS

Figure 20.9 An ideal gas thermometer.

sample kept enclosed in a fixed volume. A bulb filled with a gas at low pressure is connected to a thin, flexible U-shaped tube that contains mercury. The end of the tube opposite the gas-filled bulb is capped and evacuated. The difference in height between the levels of mercury in the two arms of the tube determines the pressure in the gas in the bulb (see Section 18.6). For a fixed value of V, the ideal gas law, $P = Nk_BT/V$, tells us that the pressure P is proportional to the absolute temperature T.

Suppose now that the absolute temperature of the gas in the bulb is raised. The pressure in the gas increases, pushing the mercury in the left arm down below the reference mark and increasing the volume V of the gas, as illustrated in **Figure 20.10*a***. To restore the gas to its original volume, we raise the right arm of the flexible U-tube until the mercury level in the left arm is back at the reference mark (Figure 20.10*b*).

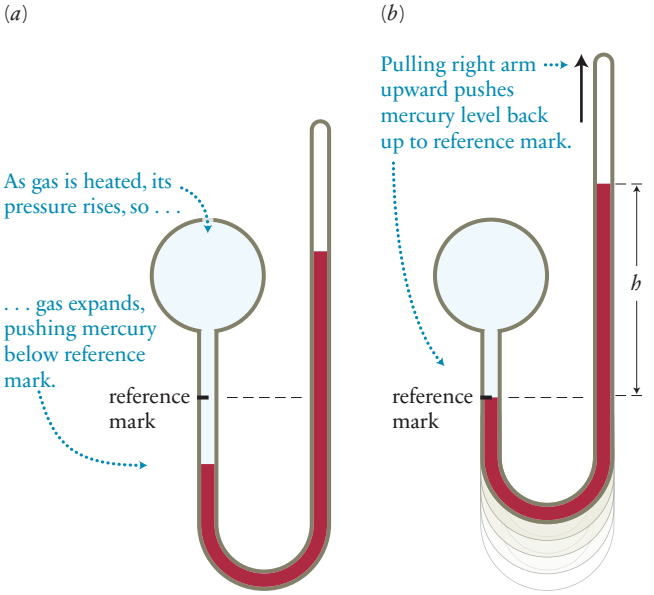
Provided the mercury level in the left arm is always kept at the reference mark, the volume V of the gas is fixed and the height h of the mercury in the right arm measures the pressure in the gas at a constant volume. Under these conditions, the height h is a direct measure of the pressure and therefore the absolute temperature T. The ideal gas law tells us that at $T = 0$ the pressure is zero, which means there is a vacuum above both arms of the U-shaped tube. So we know that at $T = 0$ the height h should be zero.

To calibrate the thermometer, we need to find some reproducible thermal phenomenon and assign it a fixed value. Until 2019, the standard of absolute temperature was based on the **triple point of water**—the unique conditions under which liquid water, solid ice, and water vapor (a gas) coexist in thermal equilibrium. To relate absolute temperature to historical definitions of temperature, the absolute temperature at the triple point of water is set at 273.16 K:*

$$T_{tp} \equiv 273.16 \text{ K}.$$

Once the height of the mercury column in an ideal gas thermometer has been measured at the triple point of water, we can draw a straight line between the origin at $T = 0$, where we know h should be zero, and the triple point. We can then determine any other absolute temperature simply by reading off the absolute temperature corresponding to the measured height (**Figure 20.11**). The important point is that the curve is linear: As long as the gas behaves like an ideal gas and is kept at constant volume, the pressure (and therefore the height of the mercury column) is directly proportional to the absolute temperature.

Figure 20.10 Using an ideal gas thermometer to measure temperature.



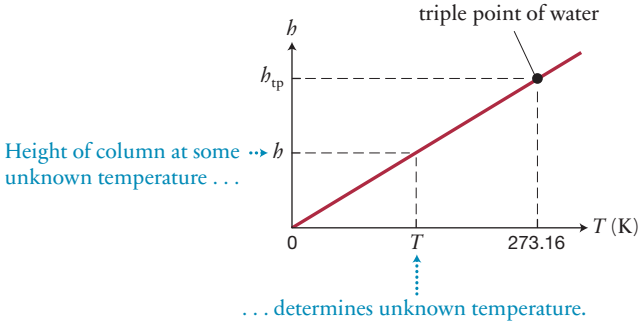


Figure 20.11 The height-versus-temperature graph is linear for an ideal gas thermometer. The thermometer is calibrated at the triple point of water. Any temperature can then be read from the graph.

*The triple point of water occurs at a temperature of 0.01 °C (roughly 32 °F) and a pressure of 610 Pa (about one-hundredth of atmospheric pressure).

CONCEPTS

Temperature measurement scales

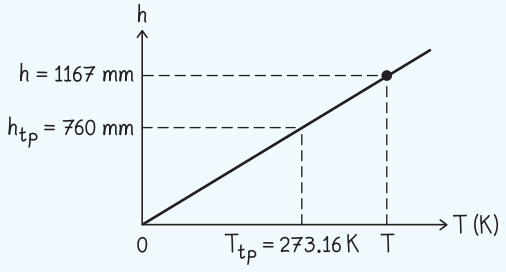
Methods for measuring and defining temperature were developed long before the development of the gas thermometer and the concept of absolute temperature. Starting in the early 18th century, several scales were defined for measuring temperature, two of which are still in use. The most widely used scale is the *Celsius scale*. Temperatures on this scale are measured in units that are called *degrees Celsius* (°C) and that have the same magnitude as the kelvin (a temperature change of 1 °C is the same as a temperature change of 1 K). The zero of the Celsius scale is the freezing point of water, and the boiling point of water (at a pressure of 101.325 kPa) is set at 100 °C.

We can convert between the Celsius and Kelvin scales as follows. If T_C represents the temperature expressed in degrees Celsius and T the absolute temperature expressed in kelvins, we have

$$T_C = \frac{1\ °C}{1\ K} T - 273.15\ °C. \qquad (1)$$

The older *Fahrenheit scale* is used in the United States. Temperatures on this scale are measured in units called *degrees Fahrenheit* (°F). On this temperature scale, the freezing point of water is 32 °F and the boiling point is 212 °F, placing the boiling and freezing points of water exactly 180 °F apart. If T_F is the temperature expressed in degrees Fahrenheit, the relationship between the Celsius and the Fahrenheit scales is

$$T_C = \frac{5\ °C}{9\ °F}(T_F - 32\ °F). \qquad (2)$$



The triple point of water had been used to define the kelvin, but this unit was redefined in terms of the Boltzmann constant (see Section 19.6), which is fixed at exactly 1.380649×10^{-23} J/K. Notice that no degree symbol, °, is used with kelvins: 13.0 °C, 55.4 °F, but 286 K. Readings in degrees Celsius or Fahrenheit can be negative, but readings in kelvins are always positive.

EXAMPLE 20.1 Measuring absolute temperature

When the bulb of an ideal gas thermometer is immersed in water at the triple point, the height of the mercury column above the reference mark is 760 mm. The same thermometer is then immersed in a sample of unknown temperature, and the height of the mercury column moves to 1167 mm above the reference mark. What is the absolute temperature of the sample?

1 GETTING STARTED The height of the mercury column is linearly proportional to the absolute temperature. I therefore begin by making a graph like Figure 20.11, summarizing the information given in the problem (**Figure 20.12**). I denote the unknown absolute temperature by T and the height of the mercury at this unknown temperature by $h = 1167$ mm.

Figure 20.12

2 DEVISE PLAN Because the line giving height as a function of absolute temperature goes through the origin, its slope is equal to the ratio h_{tp}/T_{tp}. From my graph I see that the ratio h/T must have the same value: $h/T = h_{tp}/T_{tp}$. From this expression I can calculate the unknown temperature.

3 EXECUTE PLAN Solving for T, I get $T = T_{tp}h/h_{tp} = (273.16\ K)(1167\ mm)/(760\ mm) = 419\ K$. ✔

4 EVALUATE RESULT The absolute temperature I obtain is about 50% higher than T_{tp}, which is what I would expect, given that the mercury height is about 50% higher than that at the triple point.

In principle, the operation of the ideal gas thermometer as described above is independent of the gas used—we can use *any* gas we want. In practice, deviations from the ideal gas law complicate matters a bit, and the science and technology of gas thermometers are more complex than presented here. Nonetheless, gas thermometers serve as the standard reference for all other types of thermometers. Commercial thermometers typically give the temperature on a different scale (see the box "Temperature measurement scales" and **Table 20.1**). In thermodynamics, and in physics in general, it makes the most sense to use absolute temperatures. For simplicity we shall henceforth refer to the absolute temperature T expressed in kelvins simply as *temperature*.

In drawing Figure 20.11 we assumed that we can extrapolate the linear relationship between pressure and temperature from the ideal gas law down to zero. In practice, it is impossible for any gas to reach this temperature because as the temperature decreases, the gas condenses into a liquid. Of all gases, helium becomes liquid at the lowest temperature (4.22 K, which corresponds to −269 °C or −452 °F), and so its useful range extends below that of any other gas. Zero temperature ($T = 0$) is called **absolute zero.** Any system at absolute zero has zero entropy (that is, it has only one available basic state), and its thermal energy is a minimum. Absolute zero therefore is the limit of low temperature.

CONCEPTS

Table 20.1 Comparison of temperature scales (defining points in bold)

Temperature	Kelvin (K)	Celsius (°C)	Fahrenheit (°F)
Absolute zero	0	–273.15	–459.67
Water freezes (at a pressure of 101.325 kPa)	273.15	**0**	**32**
Triple point of water	**273.16**	0.01	32
Room temperature	293	20	68
Average human body temperature	310	37.0	98.6
Water boils (at a pressure of 101.325 kPa)	373.12	**100**	**212**
Titanium melts	1941	1668	3034
Surface of the Sun	5778	5505	9941

EXERCISE 20.2 Temperature conversions

Derive an expression for converting a temperature (*a*) from the Celsius scale to the Fahrenheit scale, (*b*) from the Kelvin scale to the Fahrenheit scale, and (*c*) from the Fahrenheit scale to the Kelvin scale.

SOLUTION (*a*) To obtain an expression for the temperature T_F measured in degrees Fahrenheit in terms of the temperature T_C measured in degrees Celsius, I use Eq. 2 from the "Temperature measurement scales" box, solving this expression for T_F:

$$T_F = \frac{9\ °F}{5\ °C} T_C + 32\ °F. \checkmark$$

(*b*) Substituting the expression for converting degrees Celsius to kelvins yields

$$T_F = \frac{9\ °F}{5\ °C}\left(\frac{1\ °C}{1\ K} T - 273.15\ °C\right) + 32\ °F. \checkmark$$

(*c*) I can use the expression for T_F I obtained in part *b*. Solving for T yields:

$$T = \left[\frac{1\ K}{1\ °C}\frac{5\ °C}{9\ °F}(T_F - 32\ °F)\right] + 273.15\ K. \checkmark$$

20.5 (*a*) During a certain day the outdoor temperature ranges between 60 °F and 80 °F. What is the corresponding range in degrees Celsius and in kelvins? (*b*) The filament temperature of an incandescent light bulb is about 2800 K. What is the corresponding temperature in degrees Celsius and in degrees Fahrenheit? (Assume only two significant digits in 2800 K.)

20.3 Heat capacity

The amount of energy it takes to raise the temperature of an object depends on the amount and kind of material in the object. Indeed, we know from experience that it takes longer to heat a large pot full of water than to heat the same pot containing only a cup of water. The larger quantity of water requires more energy, and therefore more gas needs to be burned.

We can characterize how much energy it takes to raise the temperature of an object by a scalar quantity called the object's **heat capacity.** The heat capacity of an object is equal to the amount of energy transferred thermally to the object divided by the resulting change in temperature.* The SI unit of heat capacity is J/K.

20.6 Which is greater in each pair: (*a*) the thermal energy of a pool of water or that of a glass of water at the same temperature, (*b*) the heat capacity of a pool of water or that of a glass of water at the same temperature, (*c*) the thermal energy of a cold glass of water or that of an equal amount of warm water?

Because heat capacity is an extensive quantity (it depends on the amount of material in an object), it makes sense to introduce a related intensive quantity so that we can compare the thermal properties of different materials. Traditionally, heat capacity is turned into an intensive quantity by dividing it by the mass of the object. The resulting quantity, called **specific heat capacity** and denoted by the lowercase letter c, is a measure of how much energy is required to raise the temperature of 1 kg of a certain material by 1 K. The adjective *specific* means "per unit mass." The SI unit of specific heat capacity is J/K · kg.

Table 20.2 on the next page gives the specific heat capacities of a variety of materials. As you can see, different materials have very different specific heat capacities. For example, it takes about ten times less energy to raise the temperature of a 1-kg block of copper by 1 K (385 J) than it takes to raise the temperature of an equal mass of water by 1 K (4181 J).

Why are these values so different from one another, and what determines the specific heat capacity of a material? Remember from Chapter 19 that when an object is in thermal equilibrium, its thermal energy is equally distributed among all the parts of the object that can store energy. Clearly, different materials have different abilities to store thermal energy. To understand these differences, let us first examine the heat capacity of an ideal gas.

*Strictly speaking this quantity is the average heat capacity, but because the heat capacity does not depend much on temperature, we can omit the word "average".

CONCEPTS

Table 20.2 Specific heat capacities

Material	c (J/K · kg)
alcohol	2436
aluminum	897
brass	385
carbon graphite	685
copper	385
glass	837
gold	130
helium	3116
ice (268 K)	2090
iron	449
lead	130
marble	860
mercury	140
nickel	443
platinum	133
silver	235
steam (373 K)	1556
titanium	527
water	4181
wood	1700
zinc	388

All values are reported at a temperature of 298 K (unless otherwise noted) and atmospheric pressure and with the gases held at constant volume.

Table 20.3 Heat capacities per particle in units of k_B

Class	Material	C_V/k_B
Monatomic gases	helium	1.50
	argon	1.50
	krypton	1.50
	xenon	1.51
	radon	1.51
Polyatomic gases	ammonia	3.37
	hydrogen	2.47
	nitrogen	2.50
Liquids	mercury	3.38
	water	8.97
Solids	aluminum	2.91
	copper	2.94
	gold	3.08
	iron	3.02
	silver	3.05
	titanium	3.04
	zinc	3.05

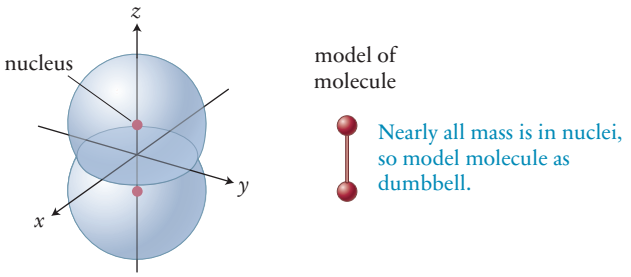
All values are reported at a temperature of 298 K and atmospheric pressure and with gases held at constant volume (as indicated by the subscript V on C_V).

In Chapter 19 we found that the thermal energy of a monatomic ideal gas is given by $E_{th} = \frac{3}{2}Nk_BT$ (Eq. 19.50). Each of the N ideal gas atoms thus has an average amount of thermal energy equal to $\frac{3}{2}k_BT$, where $k_B = 1.381 \times 10^{-23}$ J/K is the Boltzmann constant. We arrived at this result by considering the kinetic energy associated with the motion of an ideal gas atom along the x, y, and z directions (see Section 19.6). The motion along each axis is called a **degree of freedom.** Because there are three independent axes for translation, there are three "translational degrees of freedom." In thermal equilibrium, the equipartition of energy provides each translational degree of freedom of each atom with an equal share of the thermal energy—the **equipartition energy share** $\frac{1}{2}k_BT$—for a total of $\frac{3}{2}k_BT$ per atom.

If we raise the temperature of an ideal gas by 1 K, the thermal energy of the gas goes up by $\frac{3}{2}Nk_B$ (1 K), and that of each atom goes up by $\frac{3}{2}k_B$ (1 K). If this energy is transferred thermally to the gas, we expect the heat capacity per atom to be equal to $\frac{3}{2}k_B$.

Table 20.3 lists the heat capacities per particle, denoted by the uppercase letter C, in units of k_B for a number of substances. As you can see, it is indeed $\frac{3}{2}$ for monatomic gases, such as helium and argon, but deviates from this value for polyatomic gases. For hydrogen, for example, the value is closer to $\frac{5}{2}$ than to $\frac{3}{2}$, suggesting that a hydrogen molecule has two additional degrees of freedom that can store energy.

The reason for this discrepancy is that we treated each ideal gas particle as an atom that has only kinetic energy associated with translational motion along three independent axes. A dumbbell-shaped hydrogen molecule (Figure 20.13*a*), however, also has energy associated with rotational motion. The molecule can rotate about three independent axes (Figure 20.13*b*). Rotation about the z axis does not store any appreciable energy, because the rotational inertia about that axis is negligibly small.* So each hydrogen molecule has two additional "rotational degrees of freedom" for a total of five (three translational and two rotational). If each degree of freedom stores its equipartition share of $\frac{1}{2}k_BT$, we should obtain an energy per molecule of $\frac{5}{2}k_BT$. Consequently we expect a heat capacity per particle of $\frac{5}{2}k_B$, in good agreement with the experimental value of $2.47k_B$.



20.7 Consider the four-atom ammonia molecule illustrated in Figure 20.14. (*a*) Which of the three rotational degrees of freedom can store thermal energy? (*b*) Based on your answer to part *a*, what is the thermal energy per molecule? (*c*) What is the heat capacity per molecule? (*d*) Does your prediction in part *c* agree with the experimental value listed in Table 20.3?

*Although the atoms have a diameter of about 10^{-10} m and are separated by about the same distance, nearly all the mass is concentrated in the nucleus, which has a smaller diameter of about 10^{-15} m. Therefore the "bar" connecting the two atoms at the end of the H_2 dumbbell is about 10^5 times greater than the diameter of the atoms, and so the rotational inertia about the axis running through the length of the bar of the dumbbell is essentially zero (see Checkpoint 11.4).

CONCEPTS

Figure 20.13 A diatomic molecule has energy associated with rotation about two axes, as well as energy associated with translation along three axes.

(*a*) Diatomic molecule

(*b*) Rotational degrees of fredom for diatomic molecule

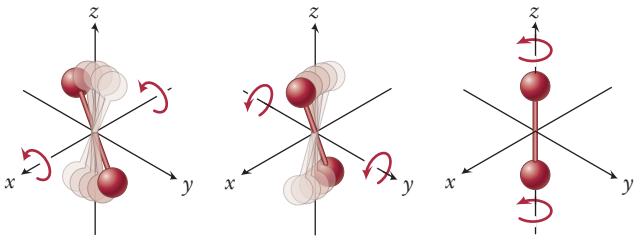


Figure 20.15 shows how, for a gas of diatomic hydrogen molecules, the heat capacity per particle in units of k_B varies with temperature. Notice how the heat capacity per particle in units of k_B is close to 2.5 (the value listed in Table 20.3) only around room temperature. As the temperature is lowered to about 50 K, the heat capacity per particle in units of k_B decreases to 1.5 $\left(\text{or } \frac{3}{2}\right)$. Why does hydrogen gas behave like a monatomic ideal gas at low temperatures? To ask the same question another way, why doesn't the rotational-degrees-of-freedom argument presented above for hydrogen hold at low temperatures? The experimental data suggest that, at low temperatures,

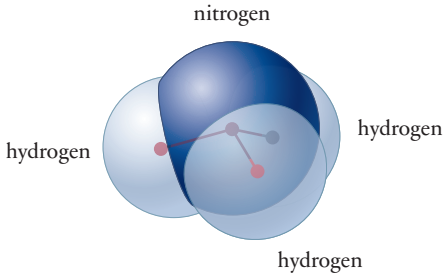
Figure 20.14 Ammonia molecule.



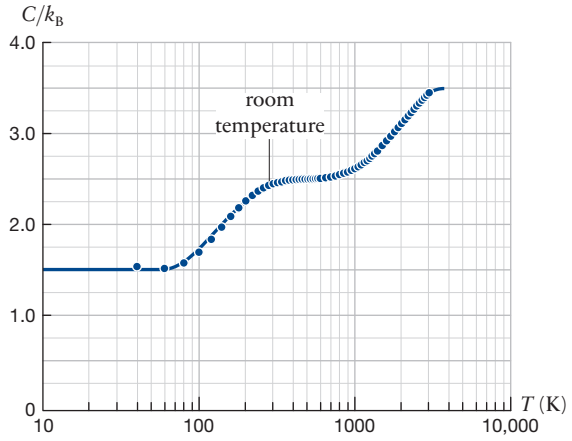


Figure 20.15 Temperature dependence of the heat capacity per particle C in units of k_B for hydrogen gas molecules.

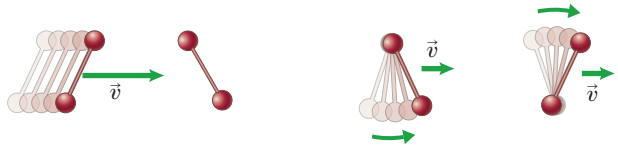
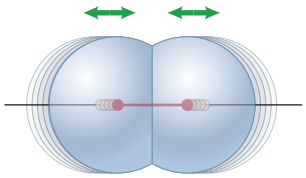
the rotational motions of the molecules do not contribute to their thermal energy.



The reason for this behavior is that, according to quantum mechanics, vibrational and rotational energy comes in small fixed amounts, called quanta. Below about 100 K, the equipartition share $\frac{1}{2}k_BT$ is smaller than the quantum of energy needed to make a molecule rotate about one of the possible rotation axes. Therefore when one molecule collides with another, the amount of energy transferred during the collision is not great enough to set either molecule rotating (**Figure 20.16*a***). Above 100 K, the hydrogen molecules have sufficient kinetic energy to set each other spinning (Figure 20.16*b*). At room temperature (about 298 K),

Figure 20.16 Collisions between hydrogen molecules. (*a*) At low temperatures ($T < 100$ K), the molecules have insufficient kinetic energy to cause any changes in rotational motion. (*b*) At higher temperatures, molecules can be set into rotational motion.

(*a*)



(*b*)

CONCEPTS

Figure 20.17 At temperatures above 1000 K, diatomic molecules begin to vibrate along the axis connecting the two atoms.

the value $\frac{1}{2}k_BT$ is equal to several rotational quanta, and so the equipartition of energy includes the two independent rotations of the hydrogen molecules, as described in the text preceding Checkpoint 20.7.

Figure 20.15 shows that at temperatures above 1000 K, the heat capacity per particle increases further. At such temperatures, the equipartition share becomes comparable to the quantum associated with another type of repetitive motion: vibration of the two hydrogen atoms along the axis of the molecule (**Figure 20.17**). Although there is only one axis for this type of motion in hydrogen, this vibrational motion contributes two degrees of freedom because it involves both potential and kinetic energy, each of which can store an amount of energy $\frac{1}{2}k_BT$. So the number of degrees of freedom for hydrogen is seven (three translational, two rotational, and two vibrational). If each degree of freedom contributes $\frac{1}{2}k_BT$, we expect a thermal energy per molecule of $\frac{7}{2}k_BT$. Indeed, experiments show that the heat capacity per hydrogen molecule approaches $\frac{7}{2}k_B$ around 3000 K. To summarize:

Only degrees of freedom for which $\frac{1}{2}k_BT$ is greater than the quantum of energy associated with that degree of freedom contribute to the heat capacity of a gas. In thermal equilibrium, each contributing degree of freedom of a particle in an ideal gas stores $\frac{1}{2}k_BT$ of thermal energy.

So, for a gas in which each particle has d contributing degrees of freedom, we expect the heat capacity per particle to be equal to $\frac{d}{2}k_B$.

CONCEPTS

EXAMPLE 20.3 Energy quanta for nitrogen

At room temperature, do collisions between nitrogen molecules have enough energy to set a nitrogen molecule rotating? Enough to set it vibrating? The quantum of energy associated with rotation is $E_{rot} = 4.0 \times 10^{-23}$ J and the quantum of energy associated with vibration is $E_{vib} = 4.7 \times 10^{-20}$ J.

1 GETTING STARTED At a given absolute temperature T each molecule stores $\frac{1}{2}k_BT$ of thermal energy per contributing degree of freedom. If the quantum of energy associated with a certain degree of freedom is greater than the energy stored per degree of freedom, then that degree of freedom cannot store any energy.

2 DEVISE PLAN To solve this problem, I need to compare the equipartition energy share at room temperature with the energy quanta associated with rotation and vibration. I can obtain the equipartition energy share at room temperature by substituting $T = 300$ K (room temperature) into $\frac{1}{2}k_BT$.

3 EXECUTE PLAN At 300 K the equipartition energy share is $\frac{1}{2}k_BT = \frac{1}{2}(1.38 \times 10^{-23}\ \text{J/K})(300\ \text{K}) = 2.07 \times 10^{-21}$ J. This value is greater than E_{rot} but smaller than E_{vib}, which means that at room temperature the nitrogen molecules rotate but do not vibrate. ✔

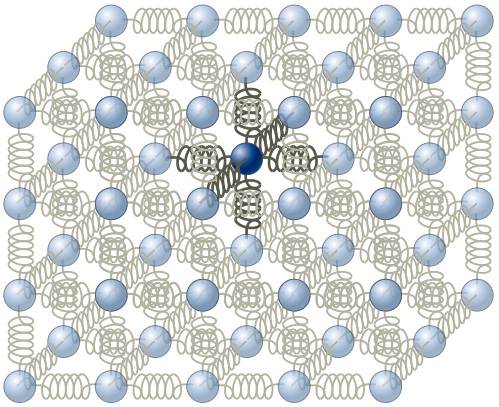
4 EVALUATE RESULT Table 20.3 confirms my conclusion: At room temperature the heat capacity per particle of nitrogen molecules is $2.50 \approx \frac{5}{2}$, indicating that rotations contribute to the storing of thermal energy but vibrations do not.

We can apply the same treatment to the vibrating atoms in a solid crystal. Consider, for example, the simple cubic arrangements of atoms shown in **Figure 20.18**. Each atom is "tied" in place by elastic bonds with neighboring atoms, so there are no translational or rotational degrees of freedom. However, each atom can vibrate along the three independent axes of the crystal. As we have seen, each vibration contributes two degrees of freedom, and so each atom should have six degrees of freedom, each storing $\frac{1}{2}k_BT$ of thermal energy. We therefore expect a heat capacity per atom of $3k_B$, which is in good agreement with the values for a number of simple crystalline solids (see Table 20.3).

Figure 20.19 shows the temperature dependence of the heat capacity per atom for a number of solids. Again we see that quantum effects affect the heat capacity. Below certain temperatures, the heat capacity of each solid decreases to zero because $\frac{1}{2}k_BT$ is smaller than the quantum of energy associated with the vibrations.

The interplay between the various degrees of freedom and the number of basic states available for the equipartition of energy explains the heat capacities for different materials over a broad range of temperatures. For a more accurate and complete description, however, we need *quantum mechanics*—a branch of physics that accounts for the discrete nature of energy and is beyond the scope of this text.

Figure 20.18 Each atom in a crystal can vibrate along three independent axes.



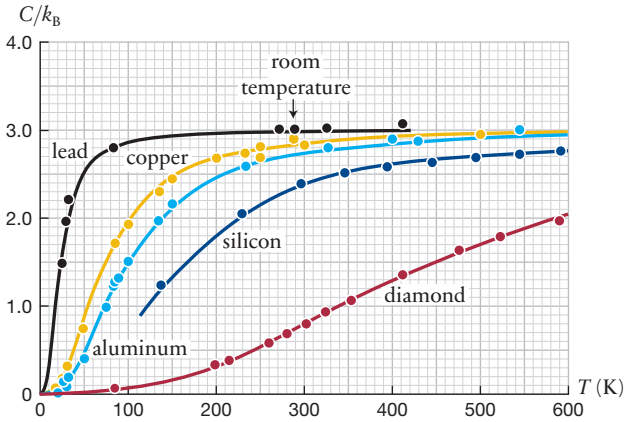


Figure 20.19 Temperature dependence of the heat capacity per atom for a number of solids.

In all of this discussion we have considered materials that do not undergo any phase transition from one state of matter to another. During a phase transition, adding energy thermally to a system does not change the temperature, but instead goes to changing the state of matter. (See the box "Phase transitions.")

20.8 Two identical volumes of gases—one monatomic and the other diatomic—are at the same pressure at room temperature. The temperature of each is raised by the same amount by thermally transferring energy to each of them. Is the energy transferred to the monatomic gas smaller than, equal to, or greater than the energy transferred to the diatomic gas?

20.4 *PV* diagrams and processes

We have seen that a system can exchange energy with its surroundings in two ways: by work done on it and by a thermal transfer of energy. The exchange of energy changes the state of the system. As we saw in Section 20.1, the system might get hotter, or expand, or the pressure might increase. In this section we examine the interplay between energy exchanges and changes in state for an ideal gas.

The equilibrium state of a gas can be completely specified by the four macroscopic measurable quantities we discussed in Chapter 19: the pressure P of the gas, its volume V, its temperature T, and the number of molecules N in that volume. Generally we shall consider samples that consist of a fixed number N of particles, so we can represent the equilibrium state of a gas by the triplet of values (P, V, T).

As we saw in Chapter 19, for an ideal gas the four macroscopic variables are related to one another by Eq. 19.51: $P = (N/V)k_BT$.* This means that if the number of particles in a gas is fixed, we need only two variables to completely specify the equilibrium state of the gas. If we choose these two variables to be P and V, then the equilibrium state of a fixed amount of ideal gas can be represented by a point on a *PV diagram* such as the ones shown in **Figure 20.20** on the next page.

*For a nonideal gas the four macroscopic variables are also related to one another, but the relationship is more complicated than that expressed by the ideal gas law.

Phase transitions

Most substances occur in several *states of matter* (also called *phases*): the solid state, the liquid state, and the gaseous state. (Plasma, a fourth state, contains ionized gas and free electrons.) H_2O, for example, exists in the solid state as ice, in the liquid state as water, and in the gaseous state as water vapor. The transition from one state of matter to another is called a *phase transition*. During a phase transition any energy transferred thermally does not change the temperature, but instead goes toward changing the state. At a given pressure, therefore, phase transitions occur at a fixed temperature and are accompanied by a change in volume.

For example, at normal atmospheric pressure ice changes to water at a temperature of 0 °C. To melt 1 kg of ice requires a thermal transfer of energy of 3.34×10^5 J. This energy is required to break the bonds that hold the water molecules together in ice.

Because the energy transferred thermally to a substance undergoing a phase transition is an extensive quantity, we introduce an intensive quantity by dividing the energy transferred thermally by the mass of the substance undergoing the transition. The resulting quantity, $L \equiv Q/m$, is called the *specific transformation energy* (traditionally often called *latent heat*, although the term *heat*, which is an energy and not a specific energy, is a misnomer). Because there are two phase transitions between the three states of matter, each substance has two specific transformation energies: one associated with the solid-liquid transition (*specific transformation energy for melting* L_m) and one with the liquid-gas transition (*specific transformation energy for vaporization* L_v).

Phase transitions are reversible. Energy must be added to a substance to make it undergo a transition from a lower- to a higher-temperature phase. In the other direction, energy must be removed from the system. For example, to change 1 kg of water at 100 °C to water vapor at 100 °C at normal atmospheric pressure requires thermally transferring 2.256×10^6 J to the water. When that vapor condenses back to water at 100 °C and normal atmospheric pressure, the same 2.256×10^6 J must be removed from the vapor.

Table 20.4 on the next page lists the specific transformation energies and associated phase transition temperatures for the melting and vaporization of a number of substances at normal atmospheric pressure.

CONCEPTS

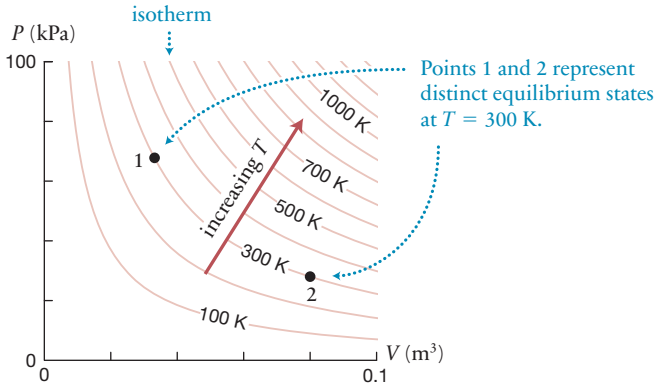
Table 20.4 Phase transition temperatures and specific transformation energies for melting (m) and vaporization (v)

Substance	T_m (K)	L_m (10^3 J/kg)	T_v (K)	L_v (10^3 J/kg)
Helium	–	–	4.230	20.8
Hydrogen	13.84	58.6	20.37	449
Nitrogen	63.18	25.5	77.36	199
Oxygen	54.36	13.8	90.19	213
Ammonia	195	331	239.8	1369
Carbon tetrachloride	250.3	16	349.8	194
Ethanol	159	100.7	351	837
Water	273.15	334	373.12	2256
Mercury	234	11.8	630	272
Aluminum	933.6	395	2740	10,500
Lead	600.5	24.5	2023	871
Sulfur	392	38.1	717.75	326
Gold	1336.15	64.5	2933	1578
Copper	1356	134	2840	5069

We can read the corresponding pair of values (P, V) from the axes and determine the temperature from the ideal gas law (assuming we know N). Once we know the temperature, we can calculate the thermal energy and the entropy of the gas (see Eqs. 19.50 and 19.59 for monatomic ideal gases).

Any point on a *PV* diagram represents an equilibrium state in which the gas has a well-defined temperature, thermal energy, and entropy.

The ideal gas law implies that all equilibrium states (P, V) at a fixed temperature lie on a curve such that the product PV is constant or, to express this information another way, $P \propto 1/V$. These curves are called **isotherms.** Figure 20.20*a* shows a number of isotherms, each corresponding to a fixed temperature and therefore a fixed thermal energy of the gas. Isotherms that are higher on the PV diagram represent higher temperatures and greater thermal energy.



20.9 Consider the equilibrium states represented by points 1 and 2 in Figure 20.20*a*. Compare these quantities for an ideal gas in these two states: pressure P, volume V, temperature T, entropy S, and thermal energy E_{th}.

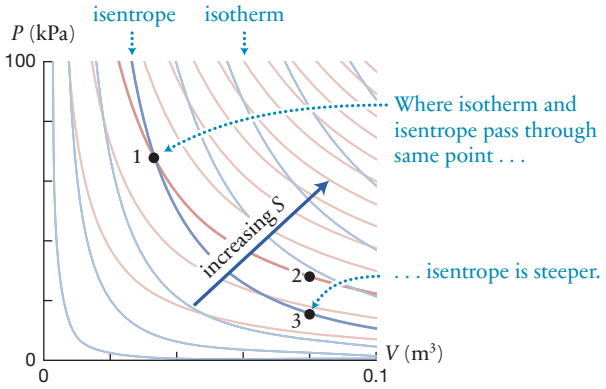
Another important family of curves associated with the PV diagram for an ideal gas is shown in Figure 20.20*b*. Each curve in this family connects all

CONCEPTS

Figure 20.20 Isotherms and isentropes in a PV diagram for an ideal gas. Points 1 and 2 represent two equilibrium states, both at $T = 300$ K. In general, on a PV diagram, the isentrope passing through a given point is steeper than the isotherm passing through that point.

(*a*) *PV* diagram showing isotherms (curves of constant temperature *T*) for an ideal gas

(*b*) Isentropes (curves of constant entropy *S*) superimposed on isotherms



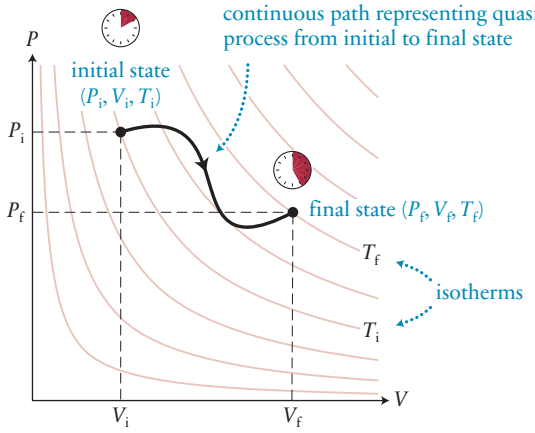


Figure 20.21 A path on a *PV* diagram represents a succession of equilibrium states that takes the system from some initial state to some final state. Such a transformation is called a quasistatic process.

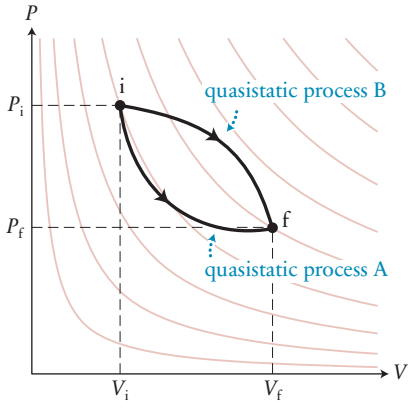
points that correspond to equilibrium states that have the same entropy. Such curves are called **isentropes.**

An isentrope passing through a given point on a *PV* diagram is steeper than the isotherm passing through that point. To see why this is so, consider the isentrope and isotherm passing through point 1 in Figure 20.20*a*. As we saw in Checkpoint 20.9, the entropy of state 2 on the isotherm is greater than the entropy of state 1.* Equation 19.60, $S = N \ln(T^{3/2}V) + \text{constant}$, tells us that in order to return the entropy to its original value, the temperature must decrease as we go at constant volume from state 2 to state 3, which lies on the isentrope. So the isentrope passing through state 1 has to be steeper than the isotherm (Figure 20.20*b*).

Isentropes that are higher on the *PV* diagram represent greater entropies. You can see this by going from state 3 to state 2 in Figure 20.20*b*. The volume is the same for both states, but the fact that you move from one isotherm to a higher isotherm means that the temperature and thus the entropy (see Eq. 19.60) increase.



Let us now turn our attention to the transformation of a system from one equilibrium state to another. If the process is quasistatic, it is a succession of near-equilibrium states. Provided these states are very close to equilibrium, we can represent them by points on a *PV* diagram, and the succession of points then constitutes a path on the *PV* diagram, such as the one shown in **Figure 20.21**.

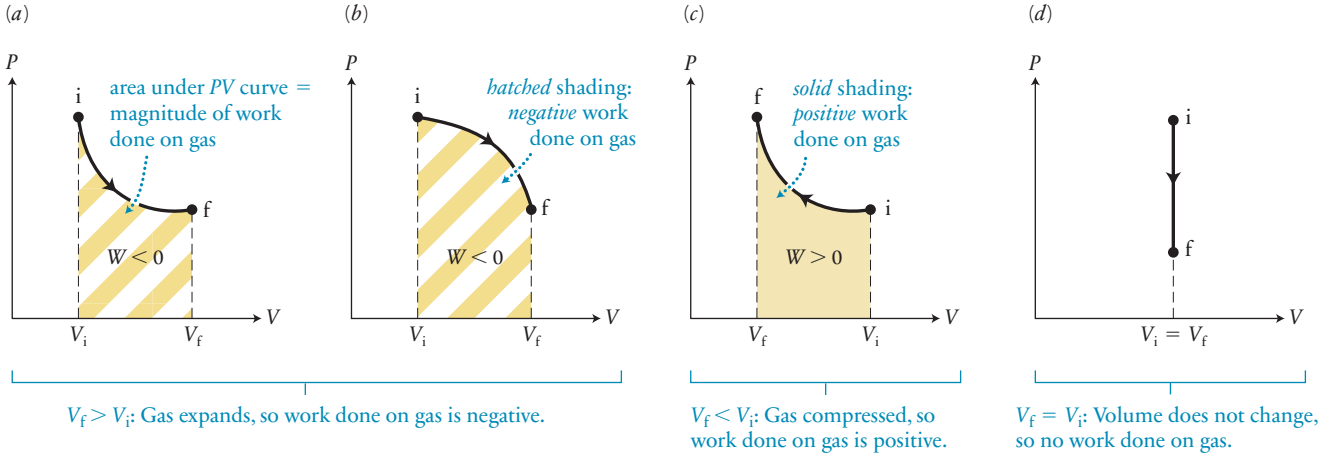
> *During a quasistatic process, the system remains near equilibrium at all instants. Such a process can be represented by a continuous path on a PV diagram.*

Processes that are not quasistatic cannot be represented on a *PV* diagram. For such processes we can only show the points that correspond to the initial and final equilibrium states.

*For simplicity, we shall omit the word *equilibrium* when referring to states presented by specific points on *PV* diagrams. For example, "state 1" stands for "the *equilibrium* state represented by point 1."

Figure 20.22 Two quasistatic processes that transform a gas from an initial state i to a final state f.

There are infinitely many ways to change the state of a gas. **Figure 20.22** shows two quasistatic processes that transform a gas from the same initial state i to the same final state f. Because the two processes have the same initial and final equilibrium states and because each state has a well-defined thermal energy and entropy, the change in these two quantities is independent of the process. For an ideal gas whose center of mass is at rest, there are no changes in the kinetic, potential, or source energy. Thus the change in the energy of the gas is equal to the change in the thermal energy, and we can state:



> *When an ideal gas is transformed from one equilibrium state to another, the changes in the thermal energy and entropy of the gas are independent of the process.*

Note that this statement holds even for non-quasistatic, irreversible processes between equilibrium states. The changes in thermal energy and entropy depend on only the initial and final states—what happens in between does not matter. If the change in thermal energy is independent of the process, then the energy transferred to the system $(W + Q)$ must also be independent of the process. Are W and Q each independent of the process, too?

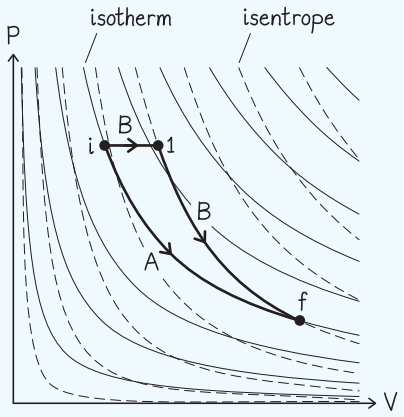
As we shall see in Section 20.5, the magnitude of the work done on a gas during any quasistatic process carried out on the gas is given by the area under the path that represents the process in a *PV* diagram. **Figure 20.23** on the next page shows a number of quasistatic processes, with the area under the path representing each process shaded; the larger the shaded area, the greater the magnitude of the work done on the gas. If the path is in the direction of increasing volume (Figures 20.23*a* and *b*), the work done on the gas is negative. If the path is in the direction of decreasing volume (Figure 20.23*c*), the work done on the gas is positive. For a vertical path (Figure 20.23*d*), the work is zero.

CONCEPTS

Figure 20.23 The magnitude of the work done on a gas during a quasistatic process is equal to the area under the path on the PV diagram representing that process.

Comparing the sizes of the hatched areas in parts *a* and *b* of Figure 20.23 tells us that the amount of work done on the gas is different in the two graphs. These graphs represent processes A and B of Figure 20.22, telling us that the magnitude of the work needed to carry out process B is greater than the work needed to carry out process A. Unlike changes in thermal energy that occur during a process, the amount of work done does depend on the path taken.

20.10 (*a*) For which of the two quasistatic processes shown in Figure 20.22, if either, is the change in entropy greater? (*b*) Is the energy transferred thermally to the gas the same along both paths?



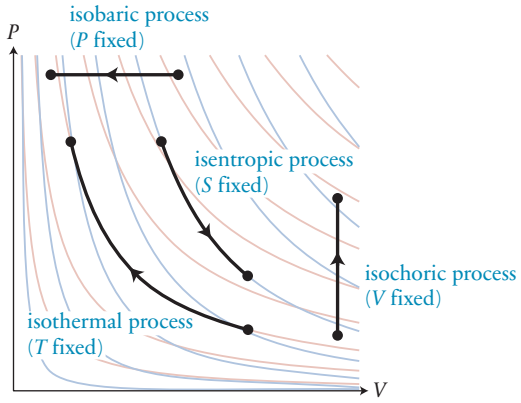
As Checkpoint 20.10 makes clear, the quantity of energy Q transferred thermally to the system, like the work W done on it, depends on the path taken.

CONCEPTS

EXAMPLE 20.4 Different process, same change?

In quasistatic process A of **Figure 20.24**, an ideal gas is brought from an initial to a final state while its temperature is held fixed. In quasistatic process B, an identical gas is brought in two steps from the same initial state as in process A to the same final state. In the first step, the gas expands at constant pressure from the initial state to an intermediate state 1, and in the second step, the gas is brought adiabatically to the final state. Is the quantity of energy transferred thermally to the gas during process B greater than, equal to, or smaller than during process A?

Figure 20.24 States i and f are on the same isotherm.



1 GETTING STARTED During both processes, the gas expands, and so the work done on the gas is negative in both cases. The quantity of energy transferred thermally depends on both the work done on the gas and the change in the thermal energy of the gas.

2 DEVISE PLAN The initial and final states lie on the same isotherm, which means the temperature of the gas is the same in the two states. Therefore the thermal energy of the gas is the same in the two states, and so the change in thermal energy is zero for both processes. This means that the quantity of energy transferred thermally to the gas is the negative of the work done on the gas.

3 EXECUTE PLAN The area under the path for process B in Figure 20.24 is larger than the area under the path for process A, and so the magnitude of the work done on the gas is greater for process B. This means that the quantity of energy transferred thermally must be greater during process B. ✔

4 EVALUATE RESULT I am told that the second step in process B is adiabatic, which means that $Q = 0$. The problem therefore boils down to comparing the energy transferred thermally during process A with the energy transferred thermally during the first step of process B. During process A, the change in the thermal energy is zero, and so all the energy transferred thermally to the gas can be used by the gas to do work on its environment. That state 1 is on a higher isotherm than state i tells me that the temperature of the gas increases during the first step of process B. Therefore part of the energy transferred thermally is required to raise the thermal energy of the gas. It therefore makes sense that Q is greater for process B.

Figure 20.25 Four types of constrained quasistatic processes.

The quasistatic processes in Example 20.4 are examples of *constrained processes*: Their path on a *PV* diagram is determined by a constraint placed on the system.

Figure 20.25 shows four important constrained quasistatic processes in ideal gases that we shall study in the second part of this chapter. When the pressure in the gas is held fixed during a quasistatic process, the path in the *PV* diagram is a horizontal line at the fixed pressure *P*; such a process is called isobaric (Greek for "same weight"). When the volume is held fixed, the path is a vertical line, and the process is called isochoric ("same volume"). Because the volume doesn't change, no work is done on (or by) the gas in an isochoric process (Figure 20.23*d*).

When the temperature is held fixed, the path lies along an isotherm, and the process is called isothermal ("same temperature"). As we saw in Chapter 19, the thermal energy of an ideal gas is proportional to the temperature of the gas, and so in an isothermal process, the thermal energy does not change.

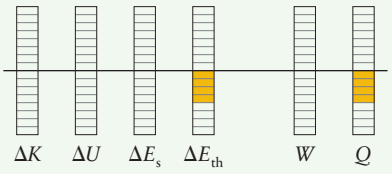
Table 20.5 Constrained quasistatic processes

Process	Constraint	Consequence
isochoric	V fixed	$W = 0$
isentropic (adiabatic)	S fixed	$Q = 0$
isobaric	P fixed	
isothermal	T fixed	$\Delta E_{\text{th}} = 0$

When the entropy is constant during a process, the path lies along an isentrope and the process is called isentropic ("same entropy"). As we saw in Section 20.1, the entropy of a system remains constant during quasistatic adiabatic processes, and therefore these processes are isentropic. Paths along isentropes thus represent processes for which no energy is transferred thermally to the system ($Q = 0$). Isentropes are sometimes also called *adiabats*, and isentropic processes are also called *adiabatic processes*.*

Table 20.5 summarizes these constrained quasistatic processes and the consequences of the constraints imposed.

20.11 For each process in Figure 20.25, determine whether the following quantities are positive, negative, or zero: W, Q, ΔE_{th}, ΔS.



*Note, however, that an adiabatic process need not be isentropic. Only a *quasistatic* adiabatic process is isentropic.

CONCEPTS

Self-quiz

1. **Figure 20.26** shows the energy changes for a certain system over a short time interval. Describe what is happening to the system. From the diagram, what can you conclude about the temperature of the environment at the beginning of the time interval?

Figure 20.26

2. On a really hot day, which temperature scale (°F or °C) registers the greater number? On a really cold day, which temperature scale registers the smaller number? At what temperature do the two scales register the same number?
3. Which material in Table 20.2 has the greatest specific heat capacity? The smallest? Imagine that objects made of these materials are placed on your hand. The objects have the same mass and are initially at the same temperature. Each object equilibrates thermally with your hand, which is at a higher temperature. Describe any differences in the equilibration process.
4. What is the approximate thermal energy of a molecule that has three degrees of translational freedom, two degrees of rotational freedom, and two degrees of vibrational freedom? The molecule is in a gas at temperature T.
5. Which types of processes are represented in Figure 20.24? For each process, determine whether the following quantities are positive, negative, or zero: ΔT, ΔV, ΔP.

Answers

1. The thermal energy of the system is decreasing ($\Delta E_{\text{th}} < 0$) because energy is leaving the system ($Q < 0$) and entering the environment. That energy leaves the system means that initially the temperature of the environment must be lower than the temperature of the system.
2. The Fahrenheit scale registers the greater number on a really hot day. If the Fahrenheit temperature is 110 °F, the Celsius temperature is 43.3 °C. The Celsius scale registers the smaller number on a really cold day. If the Fahrenheit temperature is −20 °F, the Celsius temperature is −29 °C. The scales read the same temperature at −40 °C = −40 °F.
3. Water is the highest, gold and lead the lowest. Because water has such a high specific heat capacity, a large amount of energy must leave your hand and enter the water as your hand and the water equilibrate, much more than the gold or lead would. This, in part, is why it is so hard to keep warm if you are wet and why gold jewelry so quickly comes to the same temperature as your skin.
4. With seven degrees of freedom and an equipartition energy share of $\frac{1}{2}k_{\text{B}}T$, the molecule has roughly $\frac{7}{2}k_{\text{B}}T$ of thermal energy.
5. Process A in Figure 20.24 is isothermal because it follows an isotherm. $\Delta T = 0$ because the process is isothermal, $\Delta V > 0$ because $V_{\text{f}} > V_{\text{i}}$, and $\Delta P < 0$ because $P_{\text{f}} < P_{\text{i}}$. The first step of process B is isobaric because the pressure is constant. $\Delta T > 0$ because T_{i} is on a lower isotherm than T_1, $\Delta V > 0$ because $V_1 > V_{\text{i}}$, and $\Delta P = 0$ because $P_1 = P_{\text{i}}$. The second step of process B is isentropic because it follows an isentrope. $\Delta T < 0$ because T_{f} is on a lower isotherm than T_1, $\Delta V > 0$ because $V_{\text{f}} > V_1$, and $\Delta P < 0$ because $P_{\text{f}} < P_1$.

20.5 Change in energy and work

If we take into account both the transfer of mechanical energy (work) W and the energy transferred thermally Q, the energy law (Eq. 9.1) becomes

$$\Delta E = W + Q. \tag{20.1}$$

Remember that this law is a direct consequence of conservation of energy: The only way the energy of a system can change is by a transfer of some form of energy to or from the surroundings.

Let's first consider only situations where the system is an ideal gas and where the translational kinetic energy, potential energy, and source energy of the gas remain constant ($\Delta K = \Delta U = \Delta E_s = 0$). The energy law then reduces to

$$\Delta E_{th} = W + Q \quad \text{(ideal gas)}. \tag{20.2}$$

Equation 19.50 tells us that the thermal energy of a monatomic ideal gas consisting of N atoms is

$$E_{th} = \tfrac{3}{2} N k_B T \quad \text{(monatomic ideal gas)}. \tag{20.3}$$

As we saw in Section 20.3, at thermal equilibrium each degree of freedom of an ideal gas particle contributes $\frac{1}{2} k_B T$ to the particle's thermal energy. For a monatomic ideal gas, each atom has three degrees of freedom, yielding the factor 3 in Eq. 20.3. Generalizing this result for an ideal gas with d contributing degrees of freedom, we have

$$E_{th} = \frac{d}{2} N k_B T \quad \text{(ideal gas)}. \tag{20.4}$$

20.12 What is the thermal energy associated with a gas sample that contains N hydrogen molecules at temperature $T = 300$ K?

When the temperature of an ideal gas sample that contains a fixed number N of particles changes, Eq. 20.4 tells us that the thermal energy of the sample changes by an amount

$$\Delta E_{th} = \frac{d}{2} N k_B \Delta T. \tag{20.5}$$

As we noted in Section 20.4, this change in thermal energy depends on only the initial and final equilibrium states and is independent of the path taken from initial state to final state.

To calculate the work done on a gas, consider the situation shown in **Figure 20.27**: A piston with surface area A quasistatically compresses a gas in a cylinder. The x component of the force exerted by the piston on the gas is F^c_{pgx}. The work done by this external force on the gas is (Eq. 9.22)

$$W = \int_{x_i}^{x_f} F^c_{pgx}\, dx. \tag{20.6}$$

The magnitude of the force exerted by the piston on the gas is related to the gas pressure P by Eq. 19.43:

$$P = \frac{F^c_{pg}}{A} \tag{20.7}$$

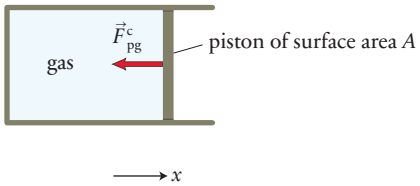


Figure 20.27 A piston that has a surface area A exerts a force on a gas, compressing it.

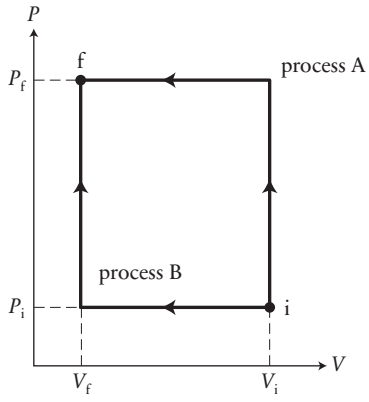
or $F^c_{pg} = PA$. If we take the positive x axis to the right as in Figure 20.27, we have $F^c_{pg,x} = -F^c_{pg} = -PA$. When the piston moves a distance dx, the volume of the gas changes by an amount $dV = A\,dx$, and so the work done on the gas is



$$W = -\int_{x_i}^{x_f} PA\,dx = -\int_{V_i}^{V_f} P\,dV. \tag{20.8}$$

The integral to the right of the minus sign in this expression represents the area under the path taken in the PV diagram, as we discussed in Section 20.4 (see Figure 20.23). If the process is in the direction of increasing volume (expansion), the integral in Eq. 20.8 is positive, making the work done on the gas negative (Figures 20.23*a* and *b*). If the process is in the direction of decreasing volume (compression), the work done on the gas is positive (Figure 20.23*c*).

When the pressure is constant (that is, during a quasistatic isobaric process), we can pull the pressure out of the integral, and the work done on the gas is

$$W = -P\int_{V_i}^{V_f} dV = -P(V_f - V_i) = -P\Delta V \quad \text{(quasistatic isobaric process)}. \tag{20.9}$$

Figure 20.28 Checkpoint 20.13 and Example 20.5.

20.13 Which quasistatic process from the initial state i to the final state f in **Figure 20.28** requires more work done on the gas?

From Checkpoint 20.13 we see that the work done on a gas depends on the manner in which the gas is transformed from its initial state to its final state.

EXAMPLE 20.5 Same change, different process

In Figure 20.28, an ideal gas is brought from an initial state i to a final state f by two processes. The initial volume and pressure are 0.50 m^3 and 100 kPa, and the final values for these variables are 0.10 m^3 and 500 kPa. How much energy is transferred thermally to the gas during (*a*) process A and (*b*) process B?

❶ **GETTING STARTED** Both processes are represented by a continuous path on a PV diagram and so are quasistatic. From the graph and the data given, I know that $V_i = 0.50$ m^3, $V_f = 0.10$ m^3, $P_i = 100$ kPa, and $P_f = 500$ kPa.

❷ **DEVISE PLAN** To calculate the quantity of energy transferred thermally, I can use the energy law as given in Eq. 20.2, $\Delta E_{th} = W + Q$, which gives me $Q = \Delta E_{th} - W$. From Checkpoint 20.13, I know that work is done on the gas only during the constant-pressure legs. To calculate W during these legs, I can use Eq. 20.9. The change in the thermal energy ΔE_{th} is given by Eq. 20.5, but I do not know d, N, or ΔT. The ideal gas law, however, relates pressure and volume to temperature: $PV = Nk_BT$ (Eq. 19.51). I note that the product PV is the same for the initial and final states: $P_iV_i = (100\text{ kPa})(0.50\text{ m}^3) = 50\text{ kPa}\cdot\text{m}^3$ and $P_fV_f = (500\text{ kPa})(0.10\text{ m}^3) = 50\text{ kPa}\cdot\text{m}^3$. This tells me that the initial and final states lie on an isotherm, so $\Delta T = 0$. Therefore Eq. 20.5 becomes $\Delta E_{th} = 0$, so Eq. 20.2 yields $Q = -W$.

❸ **EXECUTE PLAN** The change in volume for both processes is $\Delta V = V_f - V_i = (0.10\text{ m}^3) - (0.50\text{ m}^3) = -0.40\text{ m}^3$.

(*a*) From Eq. 20.9, the work done on the gas for process A is $W = -P\Delta V = -(500\text{ kPa})(-0.40\text{ m}^3) = 2.0\times10^2$ kJ. Therefore $Q_A = -2.0\times10^2$ kJ. ✔

(*b*) $W = -P\Delta V = -(100\text{ kPa})(-0.40\text{ m}^3) = 40$ kJ, which leads to $Q_B = -40$ kJ. ✔

❹ **EVALUATE RESULT** The work done on the gas during process A is five times greater than the work done during process B. This is not surprising because in A the compression from V_i to V_f is done at a pressure that is five times greater than the pressure at which the compression is done in B. Because the thermal energy of the gas does not change, any energy acquired in the form of work done on the gas has to leave as energy transferred thermally out of the gas. Both Q_A and Q_B should therefore be negative, and Q_A should have a greater negative value than Q_B, which is what I found.

As we have seen, the change in thermal energy for an ideal gas undergoing some quasistatic process is independent of the process and is given by Eq. 20.5. Checkpoint 20.13 and Example 20.5, however, show that the work done on the gas and the energy transferred thermally depend on the process.

20.14 Consider the three processes shown in **Figure 20.29**. Process B is isothermal. (*a*) For which of the three processes is the energy transferred thermally greatest? (*b*) For which of the three processes is the energy transferred thermally smallest?

20.6 Isochoric and isentropic ideal gas processes

Let us now take a deeper look at what the energy law tells us about the transfers of mechanical and thermal energy that occur during constrained quasistatic processes. We begin by examining isochoric (constant volume) and isentropic (constant entropy) quasistatic processes in this section and then isobaric (constant pressure) and isothermal (constant temperature) quasistatic processes in the next section.

An example of an isochoric quasistatic process is shown in **Figure 20.30**. An ideal gas sample consisting of N particles enclosed in a fixed volume is heated. The energy diagram for the volume of ideal gas during this process is shown in Figure 20.30*b*. Because the gas is heated, its temperature and therefore its thermal energy increase. Because the volume is fixed, no work is done on the gas. The amount Q of energy transferred thermally to the gas raises the thermal energy of the gas.

Figure 20.30*c* shows the corresponding PV diagram. The ideal gas law, $P = Nk_B T/V$ (Eq. 19.51), tells us that if the volume is kept fixed, the pressure in the gas increases as the temperature increases. Because the volume is fixed and the pressure increases, the path that represents the heating process is straight up. The arrow representing Q has solid shading because energy is transferred to the gas ($Q > 0$).

Because $V_i = V_f$, the integral in Eq. 20.8 is zero, and so the work done on the gas is zero:

$$W = 0 \quad \text{(isochoric process)}. \tag{20.10}$$

The energy law for an ideal gas, $\Delta E_{th} = W + Q$, then reduces to

$$\Delta E_{th} = Q \quad \text{(isochoric process)}. \tag{20.11}$$

Substituting the expression given for ΔE_{th} in Eq. 20.5, we see that

$$Q = \frac{d}{2} N k_B \Delta T \quad \text{(isochoric process)}. \tag{20.12}$$

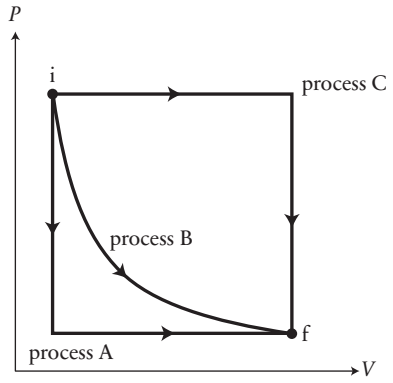
In Section 20.3, we introduced the quantity **heat capacity per particle**. Mathematically this quantity is defined as the energy transferred thermally divided by the number of particles and by the temperature change:

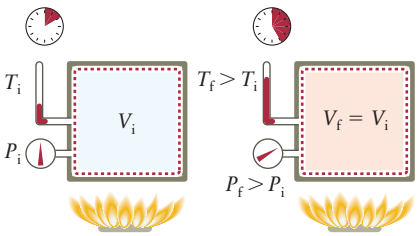
$$C_V \equiv \frac{Q}{N\Delta T} \quad \text{(constant volume)}, \tag{20.13}$$

where here we add a subscript V to remind ourselves that this result is obtained at constant volume. Substituting Eq. 20.12 into this definition for C_V yields

$$C_V = \frac{d}{2} k_B \quad \text{(constant volume)}. \tag{20.14}$$

Figure 20.29 Checkpoint 20.14.





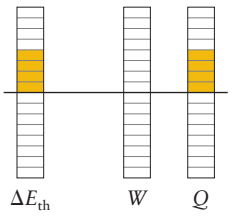


Figure 20.30 An example of an isochoric quasistatic process.

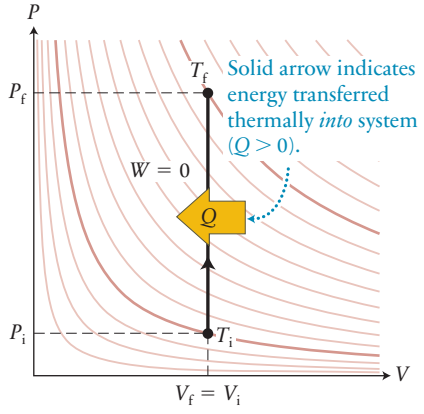
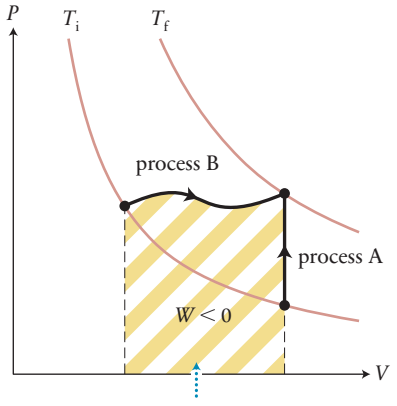


(*a*) Fixed volume of gas is heated, raising T and P

(*b*) Energy diagram for gas

(*c*) PV diagram showing the isochoric process



Note that this result predicts that the heat capacity per particle is determined by the number of degrees of freedom, in agreement with the experimental results we discussed in Section 20.3.

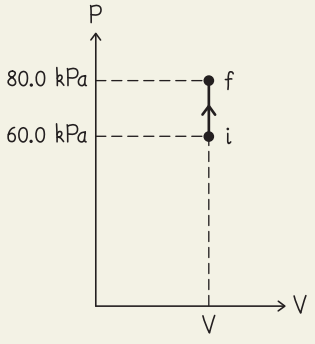
Equation 20.14 allows us to rewrite Eq. 20.5 in the form

$$\Delta E_{\text{th}} = NC_V\Delta T \quad \text{(any ideal gas process)}. \tag{20.15}$$

Even though we used Eq. 20.5 to arrive at Eq. 20.15 for ΔE_{th} under isochoric conditions, Eq. 20.15 holds for all ideal gas processes, not just isochoric ones. To see why, consider two samples of N ideal gas particles undergoing the two processes in **Figure 20.31**. Both samples are initially at temperature T_i and end at temperature T_f. Process A is isochoric; process B is some arbitrary process. Because the temperature change is the same for the two processes, Eq. 20.5 tells us the thermal energy change must also be the same. This means we can use Eq. 20.15 to calculate ΔE_{th} for any process, given the change in temperature ΔT in the process and knowing C_V for the gas. In contrast to Eq. 20.5, which expresses the thermal-energy change in terms of the number of degrees of freedom of each ideal gas particle, Eq. 20.15 gives the thermal-energy change in terms of macroscopically measured quantities.

Figure 20.31 Two ideal gas processes. Process A is isochoric; process B is not.

Hatched shading: Work done on gas in process B is *negative*.



20.15 Is Eq. 20.15 valid for an isothermal process ($\Delta T = 0$)?

EXAMPLE 20.6 Energy transferred thermally

A sample of hydrogen gas that contains 1.00 mol of H_2 molecules at a temperature of 300 K and a pressure of 60.0 kPa undergoes an isochoric process. The final pressure is 80.0 kPa. How much energy is transferred thermally to the gas?

1 GETTING STARTED I begin by making a PV diagram of the process, treating the hydrogen as an ideal gas (**Figure 20.32**). Because the process is isochoric, I represent it by a vertical line. Because $P_f > P_i$, I indicate that the path representing the process points upward.

Figure 20.32

2 DEVISE PLAN The quantity of energy transferred thermally during an isochoric process is given by Eq. 20.12. To use this equation, I need to know N, d, and ΔT. I know from Avogadro's number that my 1.00-mol sample contains $N = 6.02 \times 10^{23}$ molecules, and I can obtain d from Eq. 20.14 if I use Table 20.3 to get the value of C_V/k_B for H_2 molecules. For ΔT, I am given the initial temperature but not the final temperature. I know the initial and final pressures, however, and because the volume is fixed in this isochoric process, I can use the ideal gas law to determine the final temperature and so have a value for ΔT.

3 EXECUTE PLAN From Table 20.3 I see that, for H_2 molecules, $C_V/k_B = 2.47$ at room temperature (about 300 K). From Figure 20.15 I see that C_V/k_B stays at that value through 700 K, and so, from Eq. 20.14, I know that $d/2 = C_V/k_B = 2.47$.

Next I rewrite the ideal gas law (Eq. 19.51) in the form $V = Nk_BT/P$. Because V, N, and k_B are constant, I know that T/P is constant, and so $T_i/P_i = T_f/P_f$. Solving for T_f, I get

$$T_f = \frac{T_iP_f}{P_i} = \frac{(300\text{ K})(80.0\text{ kPa})}{60.0\text{ kPa}} = 400\text{ K},$$

so $\Delta T = 400\text{ K} - 300\text{ K} = 100\text{ K}$. Substituting my values for N, d, and ΔT in Eq. 20.12 gives me

$$Q = \frac{d}{2}Nk_B\Delta T = 2.47(6.02\times10^{23})(1.38\times10^{-23}\text{ J/K})(100\text{ K})$$
$$= 2.05\times10^{3}\text{ J}. \checkmark$$

4 EVALUATE RESULT Because the temperature of the gas increases, its thermal energy must increase. The process is isochoric, so no work is done on the gas. Therefore the value of the quantity of energy transferred thermally must be positive, as my result is.

The quantity of energy transferred is significant—approximately equal to the kinetic energy of a 1-kg object moving at about 65 m/s—but I know that thermal energies tend to be large relative to kinetic energies. (See, for example, the box "Coherent versus incoherent energy" in Chapter 7.)

QUANTITATIVE TOOLS

Next we consider a quasistatic isentropic process, a process for which the entropy remains unchanged:

$$\Delta S = 0 \quad \text{(isentropic process)}. \tag{20.16}$$

As we saw in Section 20.4, no energy is transferred thermally in an isentropic quasistatic process:

$$Q = 0 \quad \text{(isentropic quasistatic process)}. \tag{20.17}$$

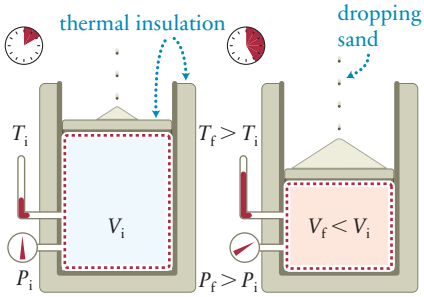
An example of an isentropic quasistatic process is shown in **Figure 20.33*a***. An ideal gas sample consisting of N particles is compressed very slowly by grains of sand dropped on the piston to ensure that the process is quasistatic. The gas is thermally insulated so that $Q = 0$. The increasing force exerted on the piston increases the pressure in the gas and decreases its volume. The corresponding energy diagram for the volume of ideal gas is shown in Figure 20.33*b*. The work done by the piston on the gas is positive, increasing the thermal energy of the gas. Because $Q = 0$, Eq. 20.2 becomes

$$\Delta E_{\text{th}} = W \quad \text{(isentropic quasistatic process)}. \tag{20.18}$$

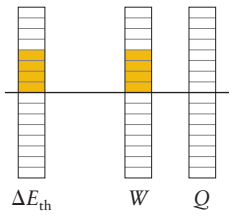
The increase in thermal energy means that the temperature of the gas goes up even though the gas is not being heated. During an isentropic compression, work done on the gas raises the temperature of the gas. You may have noticed this effect while using a bicycle pump: If you pump vigorously, the air in the pump—and therefore the pump and the tire tube—becomes noticeably hotter.

Figure 20.33*c* shows the PV diagram for the isentropic process. The shaded area under the path is the work done by the piston on the gas. As the solid shading indicates, this work is positive ($W > 0$). Because the entropy of the gas doesn't change when $Q = 0$, the path in Figure 20.33*c* lies along an isentrope, and because the gas is compressed, the final volume is smaller than the initial volume. As you can see from the PV diagram, the path crosses the isotherms and ends on an isotherm at a higher temperature, indicating that the process raises the temperature of the gas, as we saw before.

If we substitute Eq. 20.15 into Eq. 20.18, we obtain an expression that relates the work done on the gas W to the temperature change:

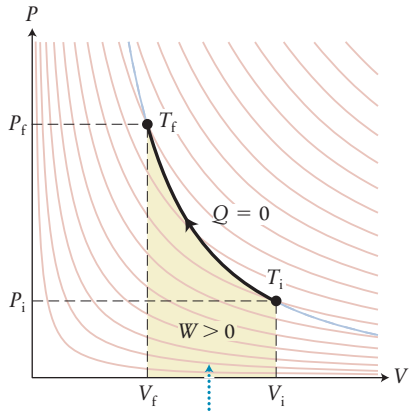


$$\Delta E_{\text{th}} = W = NC_V\Delta T \quad \text{(isentropic process)}. \tag{20.19}$$



20.16 Is the product PV in the final state in Figure 20.33*c* greater than, equal to, or smaller than the product PV in the initial state?

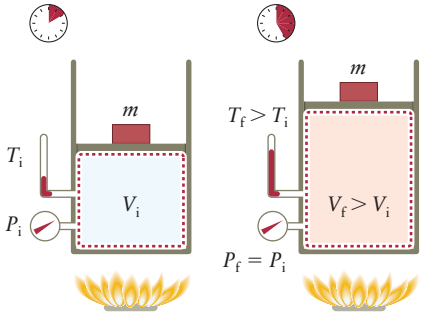
Figure 20.33 An example of an isentropic quasistatic process.



(*a*) Thermally insulated volume of ideal gas is compressed slowly

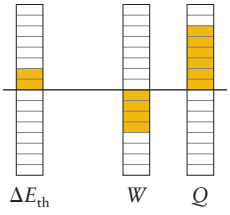
(*b*) Energy diagram for gas

(*c*) PV diagram showing the isentropic process



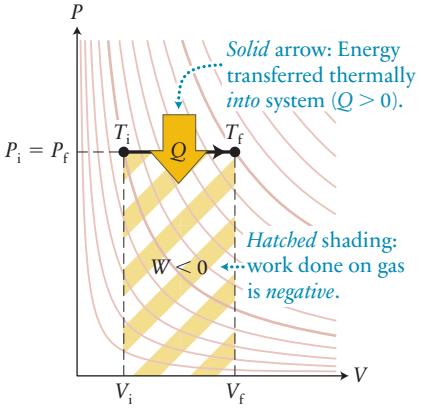
Solid shading: work done on gas is *positive*.

20.7 Isobaric and isothermal ideal gas processes



Next we turn to an isobaric (constant pressure) quasistatic process. An example is shown in **Figure 20.34*a*** on the next page: An ideal gas sample consisting of N particles is heated while it is being held at constant pressure by a piston that exerts a constant force on the gas. If the piston were held in place, the heating would raise the temperature of the gas and, according to the ideal gas law, the pressure would go up. Because the piston is free to move, however, the pressure stays constant and the gas expands instead. Therefore the gas does work on its environment. The energy diagram for the volume of the ideal gas during this process is

Figure 20.34 An example of an isobaric quasistatic process.



(*a*) Ideal gas heated at constant pressure

(*b*) Energy diagram for gas

(*c*) *PV* diagram showing the isobaric process

shown in Figure 20.34*b*. The heating transfers energy to the gas ($Q > 0$), part of which goes into raising the temperature (and therefore the thermal energy of the gas: $\Delta E_{th} > 0$), and part of which is used by the gas to do work on its environment ($W < 0$).

Figure 20.34*c* shows the *PV* diagram for the process. Because the pressure is constant, the path lies on a horizontal line. Because the gas expands, the direction of the path is to the right, toward increasing volume. The shaded area under the path is the negative of the work done on the gas ($W < 0$). (Remember our convention: A hatched area signifies that the work done *on the gas* is negative.) We draw an arrow representing Q with solid shading to represent the fact that we transfer energy thermally to the gas ($Q > 0$).

Because this process is at constant pressure, we can define heat capacity per particle at constant pressure in analogy to Eq. 20.13:

$$C_P \equiv \frac{Q}{N\Delta t} \quad \text{(constant pressure)}, \tag{20.20}$$

and so in an isobaric process the energy transferred thermally is

$$Q = NC_P\Delta T \quad \text{(isobaric process)}. \tag{20.21}$$

From the ideal gas law (Eq. 19.51), $PV = Nk_BT$, we have for the initial and final states $PV_i = Nk_BT_i$ and $PV_f = Nk_BT_f$. The change in volume is therefore $\Delta V = V_f - V_i = Nk_B\Delta T/P$, which means the work done on the gas is, from Eq. 20.9,

$$W = -P\Delta V = -Nk_B\Delta T \quad \text{(isobaric process)}. \tag{20.22}$$

Now we have all three terms in the energy law for an ideal gas, $\Delta E_{th} = W + Q$. Equation 20.15 gives the change in the thermal energy ΔE_{th}, Eq. 20.22 gives the work done on the gas W, and Eq. 20.21 gives the energy Q transferred thermally into the gas. We can use this information to obtain an expression for C_P for ideal gases. Substituting Eqs. 20.15, 20.21, and 20.22 into the energy law for an ideal gas, we obtain

$$NC_V\Delta T = -Nk_B\Delta T + NC_P\Delta T \quad \text{(ideal gas)}. \tag{20.23}$$

Dividing by $N\Delta T$, we see that for an ideal gas, the heat capacities per particle are related by the expression

$$C_P = C_V + k_B \quad \text{(ideal gas)} \tag{20.24}$$

or, substituting from Eq. 20.14 for C_V,

$$C_P = \frac{d}{2}k_B + k_B = \left(\frac{d}{2} + 1\right)k_B \quad \text{(ideal gas)}. \tag{20.25}$$

Using Eqs. 20.14 and 20.25, we can now write the **heat capacity ratio** as

$$\gamma \equiv \frac{C_P}{C_V} = \frac{\left(\frac{d}{2} + 1\right)k_B}{\frac{d}{2}k_B} = 1 + \frac{2}{d} \quad \text{(ideal gas)}. \tag{20.26}$$

For a monatomic ideal gas, for which $d = 3$, the heat capacity ratio is $\gamma = \frac{5}{3}$.

QUANTITATIVE TOOLS

EXAMPLE 20.7 Heat capacity ratio

Experimentally one obtains $C_P = 4.844 \times 10^{-23}$ J/K for nitrogen gas at room temperature. (*a*) Calculate the heat capacity ratio γ for a gas of nitrogen molecules, N_2, at room temperature. (*b*) Which degrees of freedom of the N_2 molecules contribute to the heat capacity?

❶ **GETTING STARTED** I am given the room-temperature C_P value for nitrogen gas and asked to calculate γ and then to determine which of the degrees of freedom of the N_2 molecules contribute to the heat capacity. I assume the gas behaves ideally so that I can apply the results of this section.

❷ **DEVISE PLAN** The heat capacity ratio γ is given by Eq. 20.26. To calculate this ratio I need to know d, the number of degrees of freedom of the N_2 molecules that contribute to storing energy at room temperature. Equation 20.25 relates d to C_P, which is given. Once I determine d using this relationship, I can calculate γ and establish which degrees of freedom contribute to the heat capacity.

❸ **EXECUTE PLAN** (*a*) From Eq. 20.25, I get $\frac{d}{2} + 1 = C_P/k_B$, or $d = 2(C_P/k_B - 1)$. Substituting the value given for C_P, I get

$$d = 2\left(\frac{4.844 \times 10^{-23}\ \text{J/K}}{1.381 \times 10^{-23}\ \text{J/K}} - 1\right) = 5.015.$$

Substituting this value for d into Eq. 20.26, I get $\gamma = 1 + \frac{2}{5.015} = 1.399$. ✔

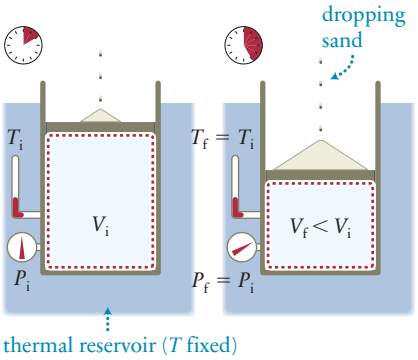
(*b*) Because the nitrogen molecule is diatomic, it has three translational, two rotational, and two vibrational degrees of freedom. I know from Section 20.3 that vibrational motion does not begin to contribute to the heat capacity until the temperature of a gas is about 1000 K. Because my sample is at room temperature, and given that my result for d is very close to 5, I conclude that the translational and rotational degrees of freedom are the ones that contribute to the heat capacity ratio. ✔

❹ **EVALUATE RESULT** I can check the reasonableness of my calculated value $\gamma = 1.399$ by using it in Eq. 20.26 to determine C_V for the nitrogen molecule and then comparing what I get with the value obtained using data from Table 20.3. From Eq. 20.26: $C_V = C_P/\gamma = (4.844 \times 10^{-23}\ \text{J/K})/1.40 = 3.46 \times 10^{-23}$ J/K; from Table 20.3: $C_V = 2.50k_B = 2.50(1.381 \times 10^{-23}\ \text{J/K}) = 3.45 \times 10^{-23}$ J/K. That these two calculations result in about the same value for C_V gives me confidence in the value I obtained for γ.

The nitrogen molecule, N_2, is similar to the hydrogen molecule, H_2. I therefore expect the contribution of the various degrees of freedom to the heat capacity of the two molecules to be similar. I know from Section 20.3 that it is translational and rotational motions that contribute in H_2, which agrees with the motion types I chose in part *b*.

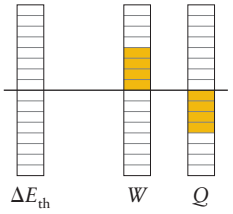
20.17 Suppose the isobaric process in Figure 20.34*c* begins and ends on the same isotherms as the isochoric process in Figure 20.30*c*. Which process requires a greater amount Q of energy transferred thermally?

An example of an isothermal (constant temperature) quasistatic process is shown in **Figure 20.35*a*** on the next page. Sand is dropped onto a piston, which then moves downward, compressing an ideal gas sample. The gas sample consists of N particles and is in thermal contact with a large volume of water. To keep the gas at constant temperature, the water volume must be large enough that adding (or removing) energy thermally to it does not noticeably change the water temperature. Such a body of water is called a thermal reservoir. The thermal reservoir is not part of the system (the gas by itself). The purpose of the thermal reservoir is to keep the temperature of our system constant by thermally exchanging energy with it.



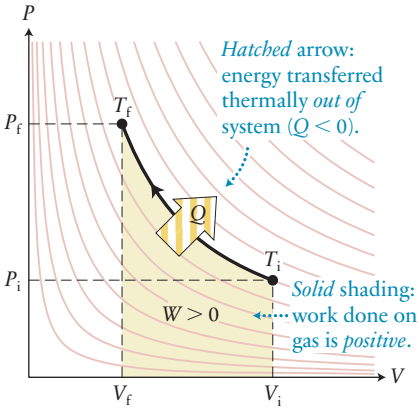
The work done by the piston on the gas is converted to thermal energy. For the process to be isothermal, the work has to be done sufficiently slowly for the gas and the thermal reservoir to remain in thermal equilibrium. A quasistatic isothermal process is thus a slow interplay between work done on the gas and thermal transfer of energy out of the gas.

The temperature of the gas remains constant, and hence the thermal energy does not change:



$$\Delta E_{\text{th}} = 0 \quad \text{(isothermal process)}. \tag{20.27}$$

Figure 20.35 An example of an isothermal quasistatic process.



(*a*) Ideal gas compressed slowly at constant temperature

(*b*) Energy diagram for gas

(*c*) *PV* diagram showing the isothermal process

The energy diagram for the volume of ideal gas during this isothermal process is shown in Figure 20.35*b*. The piston is doing work on the gas ($W > 0$), and energy is transferred thermally from the gas ($Q < 0$). Because the temperature is constant, there is no change in the thermal energy. Hence the energy law for an ideal gas is $0 = W + Q$, which means

$$Q = -W \quad \text{(isothermal process)}. \tag{20.28}$$

The work done on the gas can be found by substituting $P = Nk_BT/V$ from the ideal gas law into Eq. 20.8:

$$W = -\int_{V_i}^{V_f} \frac{Nk_BT}{V}\,dV = -Nk_BT\int_{V_i}^{V_f} \frac{dV}{V} \quad \text{(isothermal process)}, \tag{20.29}$$

where we have pulled the (constant) temperature T out of the integral. Solving the integral, we have

$$W = -Nk_B\mathrm{T}(\ln V_f - \ln V_i) = -Nk_BT\ln\left(\frac{V_f}{V_i}\right) \quad \text{(isothermal process)}. \tag{20.30}$$

The energy transferred thermally to the gas is then, from Eq. 20.28,

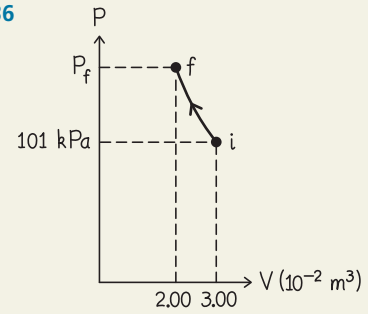
$$Q = -W = Nk_BT\ln\left(\frac{V_f}{V_i}\right) \quad \text{(isothermal process)}. \tag{20.31}$$

Figure 20.35*c* shows the *PV* diagram for the isothermal process. The path lies along an isotherm. The shading for the arrow representing Q is hatched because energy is transferred thermally out of the gas. Note that $V_f < V_i$, and so $Q < 0$, as we concluded earlier (see Checkpoint 20.11).

Table 20.6 summarizes the expressions we have obtained for the various terms in the energy law for an ideal gas for each of the four constrained ideal gas processes.

Table 20.6 Energy law for an ideal gas and constrained ideal gas processes

Process	Constraint	W	Q	ΔE_{th}	Energy law for ideal gas
isochoric	V fixed	0	$NC_V\Delta T$		$\Delta E_{th} = Q$
isentropic	S fixed		0	$NC_V\Delta T$	$W = \Delta E_{th}$
isobaric	P fixed	$-Nk_B\Delta T$	$NC_P\Delta T$	$NC_V\Delta T$	$\Delta E_{th} = W + Q$
isothermal	T fixed	$-Nk_BT\ln\left(\frac{V_f}{V_i}\right)$		0	$Q = -W$



EXAMPLE 20.8 Isothermal compression

An ideal gas sample is compressed quasistatically at constant temperature. The initial pressure and volume are $P_i = 1.01 \times 10^5$ Pa and $V_i = 3.00 \times 10^{-2}$ m^3, and the final volume is $V_f = 2.00 \times 10^{-2}$ m^3. How much work is done on the gas during the compression?

❶ **GETTING STARTED** I begin by making a *PV* diagram of the process (**Figure 20.36**). The process is an isothermal compression, so it is represented by a path going up along an isotherm toward the left.

QUANTITATIVE TOOLS

Figure 20.36

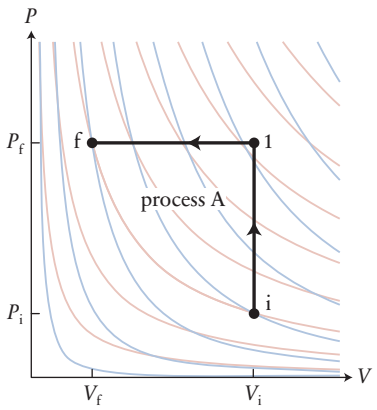
2 DEVISE PLAN The work done on an ideal gas in an isothermal process is given by Eq. 20.30. I know the initial and final volumes, but not the factor Nk_BT. I can determine this factor from the ideal gas law, $PV = Nk_BT$; it does not matter whether I use initial values or final values in my calculation because the temperature is the same in both cases. Because I do not know the final pressure, however, I should use initial values.

3 EXECUTE PLAN From the ideal gas law, I have $Nk_BT = P_iV_i$. From Eq. 20.30, the work done on the gas is

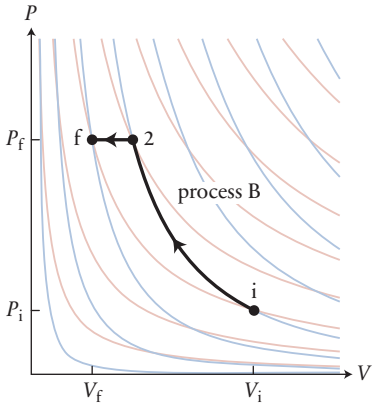
$$W = -Nk_BT\ln\left(\frac{V_f}{V_i}\right) = -P_iV_i\ln\left(\frac{V_f}{V_i}\right).$$

Substituting values for the variables, I get

$$W = -(1.01\times10^5\text{ Pa})(3.00\times10^{-2}\text{ m}^3)\ln\left(\frac{2.00\times10^{-2}\text{ m}^3}{3.00\times10^{-2}\text{ m}^3}\right)$$
$$= 1.23\times10^3\text{ J}. \checkmark$$



4 EVALUATE RESULT My answer is positive, as I expect for the work done on a gas in compressing it. To see whether the magnitude of my answer is in the right ballpark, I assume that the volume change is achieved by moving a piston of surface area 1×10^{-2} m^2 over a distance of 1 m. At a pressure of 1.01×10^5 Pa, the gas exerts on the piston a force of magnitude $(1\times10^{-2}\text{ m}^2)(1.01\times10^5\text{ Pa}) \approx 10^3$ N. The piston exerts a force of equal magnitude on the gas. If this force were constant, the work done on the gas during a force displacement of 1 m would be $W = (10^3\text{ N})(1\text{ m}) = 10^3$ J, which is of the same order of magnitude as the answer I obtained. (This estimate doesn't take into account the increase in pressure and so is a bit lower than the actual value.)



20.18 Consider an ideal gas undergoing the two processes depicted in Figure 20.37 between the same initial and final states that lie on an isotherm. In process A the gas is taken via an isochoric process to an intermediate state 1 and then via an isobaric process to the final state. In process B the gas undergoes an isentropic transformation to an intermediate state 2 and then an isobaric transformation to the final state. Which process has the greater value for (*a*) the work done on the gas and (*b*) the magnitude of the energy transferred thermally to the gas?

Figure 20.37 Checkpoint 20.18.

(*a*) Process A: isochoric step, then isobaric step

(*b*) Process B: isentropic step, then isobaric step

20.8 Entropy change in ideal gas processes

In this section we examine the entropy changes that occur for the four constrained quasistatic processes discussed in the preceding two sections. Recall from Chapter 19 that the entropy of a monatomic ideal gas is determined completely by the volume and the temperature of the gas (Eq. 19.59):

$$S = N\ln V + \tfrac{3}{2}N\ln T + \text{constant} \quad \text{(monatomic ideal gas)}. \qquad (20.32)$$

We obtained this expression for a monatomic ideal gas where each atom has three degrees of freedom (Section 20.3). The factor 3 in the $\frac{3}{2}$ in this expression comes from the three dimensions of the velocity space among which we equipartitioned the energy (Eq. 19.29). In the more general case of an ideal gas with d degrees of freedom, we replace the 3 by d:

$$S = N\ln V + \frac{d}{2}N\ln T + \text{constant} \quad \text{(ideal gas)}. \qquad (20.33)$$

During a process in which the gas undergoes a transformation from an initial equilibrium state (V_i, T_i) to a final equilibrium state (V_f, T_f), the entropy changes by an amount (see Eqs. 19.8 and 19.56)

$$\Delta S = N \ln\left(\frac{V_f}{V_i}\right) + \frac{d}{2} N \ln\left(\frac{T_f}{T_i}\right) \quad \text{(ideal gas)}. \tag{20.34}$$

For an isothermal process, $T_i = T_f$, and so the second term on the right is zero because $\ln(1) = 0$. Equation 20.34 thus becomes

$$\Delta S = N \ln\left(\frac{V_f}{V_i}\right) \quad \text{(isothermal process)}, \tag{20.35}$$

a result we already obtained in Eq. 19.8. Comparing this result with Eq. 20.31, we see that we can express the entropy change for an isothermal process as

$$\Delta S = \frac{Q}{k_B T} \quad \text{(isothermal process)}. \tag{20.36}$$

This expression allows us to calculate the change in entropy directly once we know the amount of energy transferred thermally, allowing us to bypass Eq. 20.34. Equation 20.36 is applicable only when the temperature is constant, however. For any other process, Eq. 20.34 provides the simplest approach for calculating the entropy change.

For an isochoric process, $V_f = V_i$, and so Eq. 20.34 reduces to

$$\Delta S = \frac{d}{2} N \ln\left(\frac{T_f}{T_i}\right) \quad \text{(isochoric process)} \tag{20.37}$$

or, substituting from Eq. 20.14,

$$\Delta S = \frac{N C_V}{k_B} \ln\left(\frac{T_f}{T_i}\right) \quad \text{(isochoric process)}. \tag{20.38}$$

20.19 Can you use Eq. 20.36 to calculate the change in entropy for an isochoric process?

In an isobaric process, both V and T change, but the two are related by the ideal gas law, $PV = Nk_BT$. Because P is constant in any isobaric process, we have $V_i = (Nk_B/P)T_i$ and $V_f = (Nk_B/P)T_f$. Therefore

$$\frac{V_f}{V_i} = \frac{(Nk_B/P)T_f}{(Nk_B/P)T_i} = \frac{T_f}{T_i} \quad \text{(isobaric process)}. \tag{20.39}$$

With this result, Eq. 20.34 becomes

$$\begin{aligned} \Delta S &= N \ln\left(\frac{T_f}{T_i}\right) + \frac{d}{2} N \ln\left(\frac{T_f}{T_i}\right) \\ &= N\left(1 + \frac{d}{2}\right) \ln\left(\frac{T_f}{T_i}\right) \quad \text{(isobaric process)}. \end{aligned} \tag{20.40}$$

Substituting from Eq. 20.25, we can rewrite this expression in the form

$$\Delta S = \frac{N C_P}{k_B} \ln\left(\frac{T_f}{T_i}\right) \quad \text{(isobaric process)}. \tag{20.41}$$

Note the similarity between the expression for the entropy change in an isochoric process (Eq. 20.38) and the expression for the entropy change in an isobaric process (Eq. 20.41). The only difference is the type of heat capacity per particle: For the isochoric process we use C_V; for the isobaric process we use C_P.

As an example, consider the isobaric expansion shown in Figure 20.34. The final temperature is higher than the initial temperature, and so, because $\ln(T_f/T_i) > 0$, Eq. 20.41 tells us that the entropy increases. Indeed, from the PV diagram in Figure 20.34*c* we see that the final state must lie on a higher isentrope than the initial state, indicating that the entropy of the final state is greater than the entropy of the initial state.

In an isentropic process, the entropy doesn't change, and so

$$\Delta S = 0 \quad \text{(isentropic process)}. \tag{20.42}$$

This result implies that during an isentropic process the changes in volume and temperature are such that the two terms in Eq. 20.34 cancel each other. In other words, the volume and temperature changes are correlated in such a way as to keep the entropy of the system constant.

20.20 Suppose two different combinations of constrained quasistatic processes take two identical ideal gases from the same initial equilibrium state to the same final equilibrium state. Is the change in entropy the same or different in the two cases?

Table 20.7 summarizes the entropy changes for the four constrained ideal gas processes. As you saw in Checkpoint 20.20, the value of the entropy change is independent of the process and depends on only the temperatures and volumes of the initial and final equilibrium states. For *any* process, we can use Eq. 20.34 to calculate the entropy change. The expressions summarized in Table 20.7, however, provide a quick way to obtain the entropy changes for the four basic constrained ideal gas processes. Keep in mind that in these processes the system is not closed, and so the entropy change can be positive, negative, or zero.

Equation 20.33 can be rewritten in a form that allows us to derive useful relationships among the pressure, volume, and temperature of any two states, (P_i, V_i, T_i) and (P_f, V_f, T_f), that lie on an isentrope. We begin by combining the first and second terms on the right in Eq. 20.33, which gives us

$$S = N \ln(T^{d/2}V) + \text{constant}. \tag{20.43}$$

Table 20.7 Entropy changes in ideal gas processes

Process	ΔS	Equation
isochoric	$\frac{NC_V}{k_B} \ln\left(\frac{T_f}{T_i}\right)$	20.38
isothermal	$N \ln\left(\frac{V_f}{V_i}\right) = \frac{Q}{k_B T}$	20.35, 20.36
isobaric	$\frac{NC_P}{k_B} \ln\left(\frac{T_f}{T_i}\right)$	20.41
isentropic	0	20.42

Because the entropy is constant, the quantity $T^{d/2}V$ must be constant as well for a sample that consists of a fixed number N of particles: $T_i^{d/2}V_i = T_f^{d/2}V_f$. Raising the constant quantity $T^{d/2}V$ to the power $\frac{2}{d}$, and substituting $\frac{2}{d} = \gamma - 1$ from Eq. 20.26, we see that $(T^{d/2}V)^{2/d} = TV^{\gamma-1}$, or

$$T_iV_i^{\gamma-1} = T_fV_f^{\gamma-1} \quad \text{(isentropic process)}. \tag{20.44}$$

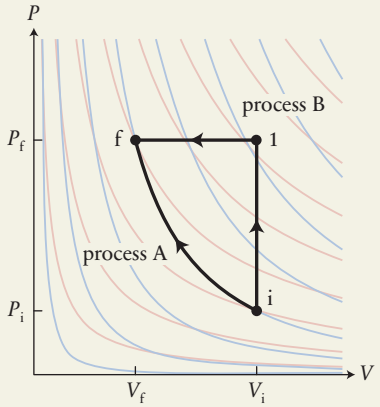
This expression provides the relationship between volume and temperature along an isentrope. Using the ideal gas law, we can obtain expressions relating other quantities along an isentrope. Multiplying the ideal gas law, $PV = Nk_BT$, by $V^{\gamma-1}$, we obtain:

$$PV^{\gamma} = Nk_BTV^{\gamma-1}. \tag{20.45}$$

From Eq. 20.44 we see that the right side of Eq. 20.45 is constant for an isentropic process, and thus the quantity PV^{γ} must also be constant:

$$P_iV_i^{\gamma} = P_fV_f^{\gamma} \quad \text{(isentropic process)}. \tag{20.46}$$

From the ideal gas law, we know that V is proportional to T/P, which means that $PV^{\gamma} \propto P(T/P)^{\gamma} = P^{1-\gamma}T^{\gamma}$ is constant for an isentropic process. Raising this quantity to the power $1/\gamma$, we get $(P^{1-\gamma}T^{\gamma})^{1/\gamma} = P^{(1/\gamma)-1}T$, and so in an isentropic process,



$$P_i^{(1/\gamma)-1}T_i = P_f^{(1/\gamma)-1}T_f \quad \text{(isentropic process)}. \tag{20.47}$$

Equations 20.44, 20.46, and 20.47 relate the pressure, volume, and temperature for the initial and final equilibrium states of an ideal gas sample that consists of N particles undergoing an isentropic process.

EXAMPLE 20.9 Entropy changes

Figure 20.38 shows two quasistatic processes that take a sample of an ideal gas containing N particles from an initial state (P_i, V_i) to a final state (P_f, V_f). Process A is a one-step isentropic compression. Process B has two steps: an isochoric pressure increase to an intermediate state 1 followed by an isobaric decrease in volume. Express the changes in entropy for process A and process B in terms of the given quantities.

Figure 20.38

❶ **GETTING STARTED** The fact that the initial and final states are on different isotherms (red curves) in Figure 20.38 tells me that the two are at different temperatures, which I call T_i and T_f. These temperatures are related to the initial and final volume and pressure by the ideal gas law. For the intermediate state, I can write $(P_1, V_1) = (P_f, V_i)$. I'll denote the temperature of this state by T_1.

❷ **DEVISE PLAN** Table 20.7 gives expressions for the entropy changes in the four constrained processes. I can eliminate the temperature from these expressions by using the ideal gas law, $PV = Nk_BT$, and Eq. 20.39.

❸ **EXECUTE PLAN** Process A is isentropic, which means that its entropy doesn't change: $\Delta S_A = 0$. ✔

I first obtain the entropy change for the isochoric step of process B from Eq. 20.38:

$$\Delta S_{B,\text{isochoric}} = \frac{NC_V}{k_B}\ln\left(\frac{T_1}{T_i}\right).$$

From the ideal gas law, I get for the initial and intermediate states, respectively:

$$P_iV_i = Nk_BT_i \tag{1}$$

$$P_fV_i = Nk_BT_1. \tag{2}$$

Dividing Eq. 2 by Eq. 1 gives me $T_1/T_i = P_f/P_i$, and so for the first step of process B I have

$$\Delta S_{B,\text{isochoric}} = \frac{NC_V}{k_B}\ln\left(\frac{P_f}{P_i}\right). \tag{3}$$

The entropy change for the isobaric step of process B is given by Eq. 20.41:

$$\Delta S_{B,\text{isobaric}} = \frac{NC_P}{k_B}\ln\left(\frac{T_f}{T_1}\right).$$

Equation 20.39 yields $T_f/T_1 = V_f/V_i$, so I can write the entropy change as

$$\Delta S_{B,\text{isobaric}} = \frac{NC_P}{k_B}\ln\left(\frac{V_f}{V_i}\right). \tag{4}$$

The entropy change for process B is the sum of the entropy changes for the two steps, so, adding Eqs. 3 and 4, I get

$$\Delta S_B = \frac{NC_V}{k_B}\ln\left(\frac{P_f}{P_i}\right) + \frac{NC_P}{k_B}\ln\left(\frac{V_f}{V_i}\right). \checkmark$$

4 EVALUATE RESULT The two processes connect the same initial and final states, so the entropy change should be the same for the two processes. Therefore the expression I obtained for process B should be zero: $\Delta S_B = 0$. Because the process that takes the gas from the initial to the final state is isentropic, Eq. 20.46 tells me that $P_f/P_i = (V_i/V_f)^\gamma$. Summing my expressions for $\Delta S_{B,\text{isochoric}}$ and $\Delta S_{B,\text{isobaric}}$ and making this substitution for P_f/P_i yield

$$\Delta S_B = \frac{NC_V}{k_B}\ln\left(\frac{V_i}{V_f}\right)^\gamma + \frac{NC_P}{k_B}\ln\left(\frac{V_f}{V_i}\right)$$

$$= \frac{NC_V}{k_B}\gamma\ln\left(\frac{V_i}{V_f}\right) + \frac{NC_P}{k_B}\ln\left(\frac{V_f}{V_i}\right).$$

Because $\gamma \equiv C_P/C_V$ (Eq. 20.26), I obtain, as expected

$$\Delta S_B = \frac{NC_P}{k_B}\ln\left(\frac{V_i}{V_f}\right) + \frac{NC_P}{k_B}\ln\left(\frac{V_f}{V_i}\right)$$

$$= \frac{NC_P}{k_B}\ln\left(\frac{V_i}{V_f}\right) - \frac{NC_P}{k_B}\ln\left(\frac{V_i}{V_f}\right) = 0.$$

20.21 For a quasistatic ideal gas process that ends on a higher isentrope, are W, Q, ΔE_{th}, and ΔS positive, negative, or zero when the gas is (*a*) expanded and (*b*) compressed?

20.9 Entropy change in nonideal gas processes

Let us now briefly consider what happens to the energy and entropy when the temperature of a liquid or gas changes. When we deal with a solid or liquid of given mass and constant volume, it is more convenient to work with specific heat capacity (see Section 20.3 and Table 20.2) rather than heat capacity per particle. The specific heat capacity is obtained by dividing the energy transferred thermally by the mass of the object or system and by the temperature change:*

$$c_V \equiv \frac{Q}{m\Delta T}. \tag{20.48}$$

And so for a given change in temperature, the energy transferred thermally is

$$Q = mc_V\Delta T. \tag{20.49}$$

Because the volume is constant, no work is done and the energy law reduces to $\Delta E_{th} = Q$, so the system's thermal energy change is

$$\Delta E_{th} = mc_V\Delta T. \tag{20.50}$$

*We are assuming here that the specific heat capacity does not depend on temperature. As Figure 20.15 shows, however, this is only approximately true over limited temperature ranges.

To calculate the corresponding entropy change, we rewrite the definition of absolute temperature (Eq. 19.38), which gives the relationship between changes in thermal energy and entropy, as follows:

$$dS = \frac{dE_{\text{th}}}{k_{\text{B}}T}. \tag{20.51}$$

For an infinitesimally small change in temperature, Eq. 20.50 becomes $dE_{\text{th}} = mc_V dT$, and so Eq. 20.51 becomes

$$dS = \frac{mc_V}{k_{\text{B}}}\frac{dT}{T}. \tag{20.52}$$

To determine the entropy change for a finite temperature change, we integrate this expression for a temperature change $\Delta T = T_{\text{f}} - T_{\text{i}}$:

$$\Delta S = \frac{mc_V}{k_{\text{B}}}\int_{T_{\text{i}}}^{T_{\text{f}}}\frac{dT}{T} = \frac{mc_V}{k_{\text{B}}}\ln\left(\frac{T_{\text{f}}}{T_{\text{i}}}\right). \tag{20.53}$$

We can also use Eq. 20.51 to obtain a more general expression for the entropy change in an isothermal process. Let the energy thermally transferred be Q. At constant temperature the entropy change is then

$$\Delta S = \frac{Q}{k_{\text{B}}T} \quad \text{(isothermal process)}. \tag{20.54}$$

Note that this expression is identical to the one we obtained earlier for an ideal gas (Eq. 20.36).

Let us next determine what happens to the energy and entropy of a system during a phase transition. In Section 20.3 we defined the **specific transformation energy** as the energy transferred thermally to a substance undergoing a phase transition divided by the mass of the substance:

$$L \equiv \frac{Q}{m} \quad \text{(phase transition with } Q > 0\text{)}. \tag{20.55}$$

Because the quantity L is always positive and Q can be negative or positive, Eq. 20.55 holds only for melting and vaporization. For solidification and condensation, Q is negative and so we have

$$L \equiv \frac{-Q}{m} \quad \text{(phase transition with } Q < 0\text{)}. \tag{20.56}$$

Because the temperature is constant, we can use Eq. 20.54 to calculate the corresponding entropy change

$$\Delta S = \frac{Q}{k_{\text{B}}T} = \frac{mL}{k_{\text{B}}T} \quad \text{(melting or vaporization)}. \tag{20.57}$$

For solidification and condensation the entropy change is of the opposite sign:

$$\Delta S = -\frac{mL}{k_{\text{B}}T} \quad \text{(solidification or condensation)}. \tag{20.58}$$

QUANTITATIVE TOOLS

20.22 An amount of water with a mass of 0.010 kg at a temperature of 20 °C is placed in a freezer and turns into an ice cube at 0.0 °C. What is the corresponding entropy change? Ignore any volume changes.

Chapter Summary

Thermal interactions and temperature (Sections 20.1, 20.2, 20.5)

Concepts During a **thermal interaction,** thermal energy is transferred from an object at a higher temperature to an object at a lower temperature. The energy Q transferred is called **energy transferred thermally.**

During an **adiabatic process,** only mechanical energy is transferred (work is done on the system); no energy is transferred thermally, so $Q = 0$.

When a gas volume decreases, positive work is done on the gas ($W > 0$); when the volume increases, negative work is done on the gas ($W < 0$).

During a **quasistatic process,** the system always remains close to equilibrium. If a quasistatic process is carried out adiabatically ($Q = 0$), the entropy of the system does not change ($\Delta S = 0$).

At the **triple point of water,** the solid, liquid, and gas phases coexist in thermal equilibrium. This point occurs at 273.16 K and 610 Pa.

Quantitative Tools When the kinetic, potential, and source energies of an ideal gas are constant, only a change in the thermal energy can change the energy of the gas, and this change is given by

$$\Delta E_{\text{th}} = W + Q. \tag{20.2}$$

The work done on a gas during a quasistatic process is

$$W = -\int_{V_i}^{V_f} P\, dV. \tag{20.8}$$

Conversions between the Celsius, Kelvin, and Fahrenheit temperature scales:

$$T_C = \frac{1\ ^\circ\text{C}}{1\ \text{K}}\, T - 273.15\ ^\circ\text{C}$$

$$T_C = \frac{5\ ^\circ\text{C}}{9\ ^\circ\text{F}}(T_F - 32\ ^\circ\text{F}).$$

Thermodynamic processes (Sections 20.3–20.7)

Concepts The **heat capacity** (J/K) of an *object* is a scalar defined as the amount of energy transferred thermally to an object divided by the resulting change in temperature of the object.

The **specific heat capacity** (J/K · kg) is a scalar equal to the heat capacity of an object divided by the mass of the object.

A **degree of freedom** is any independent way of storing energy in a particle.

In an ideal gas in thermal equilibrium, each particle's **equipartition energy share** of the energy of the gas is $dk_BT/2$, where d is the number of degrees of freedom available to the particles.

A PV diagram is a graph of the pressure in a gas as a function of the gas volume. Any point on a PV diagram represents an equilibrium state in which the gas has a well-defined temperature, thermal energy, and entropy. Any continuous path on a PV diagram represents a quasistatic process.

A **thermal reservoir** is a body of material large enough that its temperature does not change in a thermal interaction.

An **isothermal process** is one that occurs at constant temperature. An **isobaric process** is one that occurs at constant pressure. An **isochoric process** is one that occurs at constant volume. An **isentropic process** is one in which the entropy does not change.

Quantitative Tools At temperature T, the thermal energy of a sample of an ideal gas that contains N particles, each having d degrees of freedom, is

$$E_{\text{th}} = \frac{d}{2} N k_B T, \tag{20.4}$$

where $k_B = 1.381 \times 10^{-23}$ J/K is the Boltzmann constant.

At constant volume, the **heat capacity per particle** of a gas that contains N particles, each having d degrees of freedom, is

$$C_V \equiv \frac{Q}{N\Delta T} = \frac{d}{2} k_B. \tag{20.13) (20.14}$$

At constant pressure, the **heat capacity per particle** is

$$C_P \equiv \frac{Q}{N\Delta T} = C_V + k_B = \left(\frac{d}{2} + 1\right) k_B. \tag{20.20) (20.24) (20.25}$$

For any ideal gas process,

$$\Delta E_{\text{th}} = N C_V \Delta T. \tag{20.15}$$

The unitless **heat capacity ratio** γ is

$$\gamma \equiv \frac{C_P}{C_V} = 1 + \frac{2}{d}. \tag{20.26}$$

Table 20.4 Phase transition temperatures and specific transformation energies for melting (m) and vaporization (v)

Substance	T_m (K)	L_m (10^3 J/kg)	T_v (K)	L_v (10^3 J/kg)
Helium	–	–	4.230	20.8
Hydrogen	13.84	58.6	20.37	449
Nitrogen	63.18	25.5	77.36	199
Oxygen	54.36	13.8	90.19	213
Ammonia	195	331	239.8	1369
Carbon tetrachloride	250.3	16	349.8	194
Ethanol	159	100.7	351	837
Water	273.15	334	373.12	2256
Mercury	234	11.8	630	272
Aluminum	933.6	395	2740	10,500
Lead	600.5	24.5	2023	871
Sulfur	392	38.1	717.75	326
Gold	1336.15	64.5	2933	1578
Copper	1356	134	2840	5069

Entropy in ideal gas processes (Sections 20.2, 20.8)

Concepts At **absolute zero** ($T = 0$), the thermal energy of a system is a minimum and its entropy is zero because it has only one basic state available to it.

Quantitative Tools The entropy of an ideal gas that has d degrees of freedom is

$$S = N \ln V + \frac{d}{2} N \ln T + \text{constant}, \tag{20.33}$$

and the change in its entropy during a process is

$$\Delta S = N \ln\left(\frac{V_f}{V_i}\right) + \frac{d}{2} N \ln\left(\frac{T_f}{T_i}\right). \tag{20.34}$$

Table 20.6 Energy law for an ideal gas and constrained ideal gas processes

Process	Constraint	W	Q	ΔE_{th}	Energy law for ideal gas
isochoric	V fixed	0	$NC_V\Delta T$		$\Delta E_{th} = Q$
isentropic	S fixed		0	$NC_V\Delta T$	$W = \Delta E_{th}$
isobaric	P fixed	$-Nk_B\Delta T$	$NC_P\Delta T$	$NC_V\Delta T$	$\Delta E_{th} = W + Q$
isothermal	T fixed	$-Nk_BT \ln\left(\frac{V_f}{V_i}\right)$		0	$Q = -W$

For any isentropic process:

$$T_i V_i^{\gamma-1} = T_f V_f^{\gamma-1} \tag{20.44}$$

$$P_i V_i^{\gamma} = P_f V_f^{\gamma} \tag{20.46}$$

$$P_i^{\frac{1}{\gamma}-1} T_i = P_f^{\frac{1}{\gamma}-1} T_f. \tag{20.47}$$

Entropy in nonideal gas processes (Section 20.9)

Quantitative Tools For a solid or liquid that has a specific heat capacity c_V, the entropy change when a sample of mass m undergoes a temperature change is

$$\Delta S = \frac{mc_V}{k_B} \ln\left(\frac{T_f}{T_i}\right). \quad (20.53)$$

The entropy change during a melting or vaporization phase transition at temperature T is

$$\Delta S = \frac{mL}{k_B T}. \quad (20.57)$$

The entropy change during a solidification or condensation phase transition at temperature T is

$$\Delta S = -\frac{mL}{k_B T}. \quad (20.58)$$

Questions and Problems

For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

Unless you are told otherwise, assume that all processes in these problems are quasistatic and that all gases are monatomic and ideal.

20.1 Thermal interactions

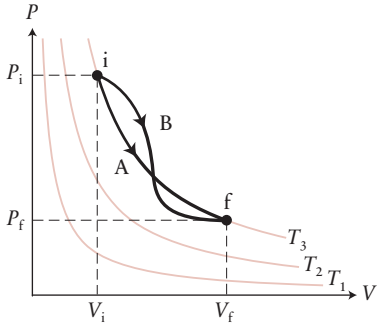
1. When the volume of a gas increases, is the work done by the gas on its surroundings positive, negative, or zero? •
2. A thermally insulated chamber fitted with a piston as its bottom surface contains an ideal gas. The piston slowly moves upward and compresses the gas into a smaller volume. Draw an energy diagram for this process, taking the gas as your system. •
3. State whether each process is quasistatic, adiabatic, both, or neither for the defined system: (*a*) Water boils in a pot. System: water. (*b*) A balloon filled with air is slowly compressed and cooled. System: balloon and air. (*c*) An initially sealed vial of air is opened in an air-filled room that is isolated from its outside environment, where the temperature and number density of air particles are the same inside and outside the vial. System: vial, room, and air. •
4. A sample that contains 5.60×10^{21} particles of a monatomic ideal gas expands adiabatically and quasistatically from 1.00 L to 2.00 L. If the initial gas pressure is 30.5 kPa, what is the final temperature of the gas? ••
5. You are designing an engine that contains several pistons that each move 150 mm per stroke. You believe the engine may consume less energy than a traditional engine if many of the processes in the engine are reversible. The gas is a mixture of several substances, but the particles have an average mass of 7.548×10^{-26} kg per particle, and the gas temperature can reach 300 °F. Determine an upper limit on the number of cycles a piston can go through each second, and satisfy the reversibility constraint. How could this upper limit be increased? Is the reversibility constraint sensible? •••

20.2 Temperature measurement

6. A Kelvin thermometer and a Fahrenheit thermometer both give the same reading for a certain sample at what numerical value? •
7. You poured freshly brewed hot tea into a cup. A thermometer indicates that its temperature is 96.8 °C. Convert this temperature into the Fahrenheit and Kelvin scales. •
8. You are monitoring the temperature of a solution in the laboratory. Using a thermometer, you recorded a temperature of 40.5 °C. Two hours later, about to do the same measurement, you accidentally dropped the thermometer you previously used and broke it. Instead, you used a differently scaled thermometer for the measurement and recorded a reading of 144 °F. Express the difference between the two temperature readings in (*a*) degrees Celsius, (*b*) kelvin, and (*c*) degrees Fahrenheit. ••
9. While converting a list of degrees Celsius temperatures to degree Fahrenheit, you notice that both scales have the same numerical value at a certain reading. What is this number? •
10. When a certain ideal gas thermometer is placed in water at the freezing point, the mercury level in the right arm is 869 mm above the reference mark. How far is the mercury level above the reference mark when this thermometer is placed at room temperature where the atmospheric pressure is 1.00 atm (See Table 20.1 for temperature values.)? ••
11. When a certain ideal glass thermometer is at room with a temperature of 25 °C, the mercury level in the right arm is 245 mm above the reference mark. When the thermometer is then dipped into a saline solution, the mercury level drops by 25 mm. (*a*) What is the temperature of saline solution? (*b*) Is your answer to part *a* sufficient enough to solidify a certain type of oil with a freezing point of 2.77 °C? ••
12. When a certain ideal gas thermometer is immersed in water at the triple point, the mercury level in the right arm is 124 mm above the reference mark. When this thermometer is then immersed in a liquid of unknown temperature, the mercury level drops by 68.0%. (*a*) What is

the temperature of the liquid? (*b*) What is a potential source of error in this measurement? ●●

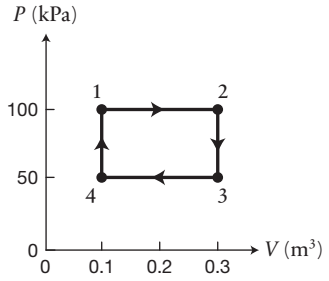
13. An engineer planning a weld from manufacturer specifications realizes that the units for temperature have been accidentally omitted. The specifications say, "The temperature of the weld should be no lower than 95% of 1960 but can be safely welded at a much higher temperature." The engineer is not sure whether the 1960 is 1960 K or 1960 °C. To what temperature (in degrees Celsius) should she specify the weld to be sure it is not done at too low a temperature? ●●
14. For an environmental study, you need to collect temperature data for a year in a North American desert, where the temperature ranges from 255 K in winter to 320 K in summer. You have a single thermal sensor that can be calibrated in degrees Celsius or degrees Fahrenheit, but the readout is fixed to one decimal place. (*a*) Which scale, Fahrenheit or Celsius, will give you greater precision? (*b*) Your research group doubts your choice, so you must provide numerical evidence to support it. What is the ratio of the number of readings possible on the scale you chose to the number of readings possible on the scale you didn't choose? ●●●



20.3 Heat capacity

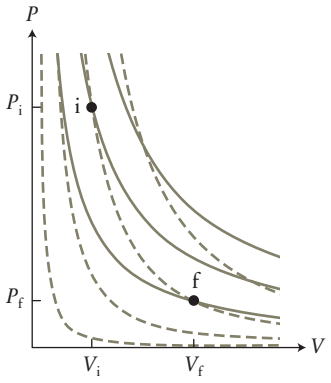
15. How much energy is needed to boil 750 g of water at freezing point? ●
16. A 250-g piece of an unknown metal has been in boiling water for several minutes. To bring this metal at room temperature (20 °C), 89.8 kJ of heat must be removed. (*a*) Calculate the specific heat of the metal. (*b*) Determine what type of metal is the sample using your answer in part *a*. ●
17. According to the Can Manufacturers Institute, the energy used to make an aluminum can from recycled aluminum is 5% of the energy used to make an aluminum can from virgin ore. In a typical year, 1.7 billion pounds of aluminum cans are recycled. How much energy is thermally transferred to get this mass of aluminum from 20 °C to its melting point, 660 °C? ●●
18. Three diatomic molecules from different gas samples—one at 3 K, one at 298 K, and one at 1000 K—are in thermal equilibrium with their respective surroundings. (*a*) Rank the molecules according to heat capacity per molecule at constant volume, highest first. (*b*) What is the thermal energy of each molecule, expressed in terms of T and k_B? ●●
19. How much heat energy is needed to convert a mixture of 20.0 g of ice and 35.0 g of water at thermal equilibrium to steam at 100.0 °C? If this energy were used to lift a truck, to what height could a 1.00×10^4-kg truck be lifted? ●●
20. A 0.350-kg aluminum calorimeter contains 0.110 kg of water, and both are at room temperature (20.0°C). A 0.280-kg block of lead at 90.0°C is then dropped into the container. Assuming no heat loss to the surroundings, find the final temperature of the system. ●●
21. Devil's Throat, the longest drop in Iguazu Falls on the Brazil-Argentina border, has a height of 82 m. If all the kinetic energy a given volume of water acquires in dropping through Devil's Throat could go into heating the water, how much would the water temperature rise? ●●
22. You pour 5.0 L of water at 20 °C into a large pot to make spaghetti. If the heating element on your stove is rated at 1250 W, how many minutes does it take for the water to start boiling? Ignore any energy thermally transferred to the environment. ●●
23. A helium atom is in a nanowire (a wire with a diameter on the scale of molecules) in thermal equilibrium at 77 K. (*a*) The atom is constrained in the nanowire and so can move in only one dimension, along the wire length. What is the atom's thermal energy? (*b*) The atom is boiled off the nanowire and allowed to float free at 295 K. What is its thermal energy now? ●●●
24. A diatomic molecule in thermal equilibrium at 120 K is constrained to move freely only on a two-dimensional surface. (*a*) What is the molecule's thermal energy? (*b*) The molecule is boiled off the surface and allowed to float freely in a gas at thermal equilibrium at 298 K. What is the molecule's thermal energy now? (*c*) What is its thermal energy if it is heated to 3000 K? ●●
25. A cryogenic substance is found to have a specific heat capacity c that varies with temperature according to $c = \beta T^2$, where β is an empirically derived constant with units $\text{J/K}^3 \cdot \text{kg}$. If 231 J of energy must be transferred thermally to an 8000-mg sample of this substance to raise the temperature of the sample from 1.00 to 6.00 K, what is the value of β? ●●●

20.4 *PV* diagrams and processes



26. An ideal gas expands adiabatically and quasistatically in a chamber fitted with a piston. Is this process isothermal, isentropic, isobaric, isochoric, or none of these? ●
27. Figure P20.27 shows two processes, A and B, carried out on an ideal gas. In which process was the amount of work done by the gas greater? ●

Figure P20.27



28. Figure P20.28 is the *PV* diagram for a process carried out on 10 mol of an ideal gas in thermal equilibrium that begins and ends on the same state (the initial state i and the final state f for the gas are at 1). (*a*) Characterize each leg of the process—$1 \rightarrow 2$, $2 \rightarrow 3$, $3 \rightarrow 4$, $4 \rightarrow 1$—as being isothermal, isobaric, isochoric, or isentropic. (*b*) Determine the temperature at state 1 and at state 3. ●●

Figure P20.28

29. The curves in Figure P20.29 are isochors, isobars, isotherms, or isentropes. If a system is taken from initial state i to final state f, with $V_i = 0.15\ m^3$ and $P_f = 1.00$ atm, what is the change in the entropy of the system? ●●

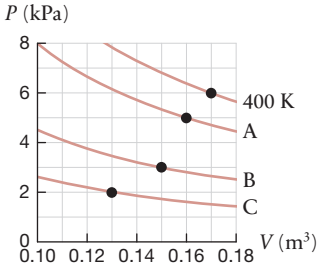


Figure P20.29

30. A 0.300-kg sample of nitrogen gas (diatomic molecules, $m_{N_2} = 4.652 \times 10^{-26}$ kg) in a chamber fitted with a piston undergoes an isothermal expansion from 0.0500 m^3 to 0.150 m^3. If the final pressure is 150 kPa, what is the final temperature? ●●

31. Figure P20.31 shows four isotherms on the *PV* diagram for an ideal gas. What are the temperatures of isotherms A, B, and C? ●●

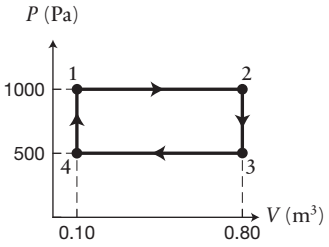

Figure P20.31

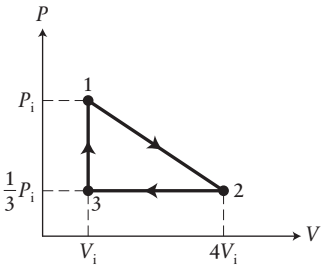
20.5 Change in energy and work



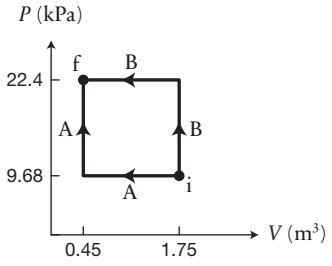
32. An ideal gas undergoes the process represented in Figure P20.32, where the gas is in state 1 when the process begins and again in state 1 at the finish. (*a*) Determine the work done by the gas during each of the four legs—$1 \rightarrow 2$, $2 \rightarrow 3$, $3 \rightarrow 4$, $4 \rightarrow 1$. (*b*) Determine the work done by the gas for the process. ●

Figure P20.32

33. An ideal gas undergoes the process represented by the *PV* diagram of Figure P20.33, where the gas is in state 1 when the process begins and again in state 1 at the end of the process. Calculate the work done on the gas as a function of the initial pressure and volume. ●

Figure P20.33

34. If 1.00 mol of an ideal monatomic gas initially at 72 K absorbs 100 J of thermal energy, what is the final temperature? Assume the volume does not change. ●



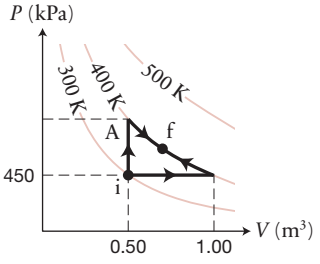
35. An ideal gas is inside a cylinder fitted with a piston of cross-sectional area 0.10 m^2, and initially the gas pressure is 5.0×10^4 Pa. A quantity $Q = 5.0$ kJ of thermal energy is transferred slowly to the gas while the piston moves 0.10 m and the gas expands. If the expansion is isobaric, how much work is done on the gas? ●●

36. What is the thermal energy associated with 5.6×10^{18} nitrogen molecules, N_2, at 100 °F? Assume the nitrogen can be treated as an ideal gas. ●●

37. In a cylindrical chamber fitted with a piston, the piston compresses 10.0 mol of ideal gas from 1.00 m^3 to 0.100 m^3 at a constant temperature of 300 K. Suppose this compression was done by placing a 100-kg block on top of the piston. What is the piston radius? Assume the air pressure outside the piston is 1.00 atm, and ignore the piston mass. ●●

38. Figure P20.38 shows two processes, A and B, for moving 3.45×10^{22} particles of a monatomic ideal gas from state i to state f. (*a*) Which process requires less work done on the gas? (*b*) Which process requires a smaller quantity Q of energy transferred thermally to the gas? (*c*) By how much does the work done on the gas in process A differ from the work done on the gas in process B? ••

Figure P20.38



39. A 1.00-mol sample of an ideal diatomic gas in which the gas particles both translate and rotate is initially at 600 K. Energy is then added thermally to the sample until its temperature is 1000 K. At this temperature, the particles also vibrate. The sample is then heated to 1200 K. How much thermal energy does the sample absorb? ••
40. You have a sample that contains 9.70×10^{21} particles of an unknown gas in a chamber that has a volume of 0.0100 m^3. The initial pressure in the chamber is 1.84×10^4 Pa, and you determine that 378 J of energy must be added to the sample to increase the pressure to 2.68×10^4 Pa. (*a*) What can you say about the structure of the particles? (*b*) If your choices for the identity of the gas are helium, hydrogen, ammonia, and nitrogen, which do you choose, and why? •••

20.6 Isochoric and isentropic ideal gas processes

41. The PV diagram in Figure P20.41 shows two processes for taking an ideal gas from an initial state i to a final state f. How much work is done on the gas in the isochoric leg labeled A? •

Figure P20.41

42. You park your car in the sun with the windows rolled up, and the interior temperature rises from 35 °C at 100 kPa to 48 °C. The interior volume of your car is roughly 1.5 m × 2.0 m × 1.0 m. (*a*) What is the mass of the air in the car, assuming a mass density of 1.13 kg/m^3 for air at 35 °C? (*b*) How much energy was delivered from the Sun to the interior to raise the temperature as indicated if all the energy went into the air? Use 720 J/K · kg for the specific heat capacity of air. ••
43. Your one-story house has a floor area of 2.0×10^2 m^2 and 3.0-m-high ceilings. (*a*) On a hot day, you leave home with all the windows closed and the air-conditioning on. A power failure causes the air-conditioning to stop, and by the time you return home, the quantity of thermal energy you calculated in Problem 42 has been added to the inside air. By how many kelvins has the inside air temperature increased? (*b*) How much thermal energy from the Sun would be required to raise the temperature in your house from 24 °C to 25 °C? ••
44. Steam at 120 °C and 101.3 kPa is added to a hollow steel can that is then sealed and allowed to cool. (*a*) What is the pressure inside the can at 101 °C? (*b*) The can is 0.20 m tall and 0.10 m in diameter. What is the magnitude of the force exerted by the atmosphere on the curved and flat portions of the can exterior? (*c*) Once the steam cools sufficiently, it begins to condense into liquid water and the can collapses inward. Why does the can retain its shape for much, but not all, of this process? (Hint: Search "collapsing soda can" on your favorite Internet video site.)
45. A sample of helium gas is allowed to expand in a process that is adiabatic and quasistatic. As the gas cools from 105 °C to 101 °C, it does 9.05 J of work on a piston. How many helium atoms are there in the sample? ••

20.7 Isobaric and isothermal ideal gas processes

46. A 2.00-L sample of an ideal gas initially at 1.00 atm and 273 K undergoes an isobaric process that cools the sample to 265 K. (*a*) What is the final pressure in the gas? (*b*) What is the final volume of the gas? •
47. A cylinder fitted with a piston contains 1.00 mol of air at room temperature, 20.0 °C. The air is slowly compressed by the piston while the temperature is kept constant. What is the work done on the air if the final volume is one-third the initial volume? •
48. A chamber fitted with a piston can be controlled to keep the pressure in the chamber constant as the piston moves up and down to increase or decrease the chamber volume. If the chamber contains an ideal gas at 296 K and 1.00 atm, what is the work done on the gas as the piston compresses it from 1.00 L to 0.333 L? •
49. Your lab mate is measuring the heat capacity ratio of an unknown diatomic gas at room temperature and standard atmospheric pressure. She obtains values for C_P and C_V and tells you the ratio is 6/9. Give the reason you need to check your lab mate's work. ••
50. A spherical air bubble in a lake expands as it rises slowly to the surface. At the point it starts to rise, the pressure is 2.00 atm, the temperature of the water is 10.0 °C, and the radius of the bubble is 5.00×10^{-3} m. At the surface, the pressure is 1.00 atm and the temperature of the water is 20.0 °C. (*a*) What is the final-to-initial volume ratio for the expanding bubble? (*b*) What is the change in thermal energy of the bubble? ••
51. A chamber fitted with a piston contains 1.00 mol of an ideal gas. (*a*) The piston is slowly moved to decrease the

chamber volume while the gas temperature is held constant at 296 K. How much work is done *by* the gas if the final chamber volume is one-third the initial volume? (*b*) If, instead of moving in the direction that decreases the chamber volume, the piston slowly moves in the direction that increases that volume, how much work is done *by* the gas if the final chamber volume is three times the initial volume? ●●

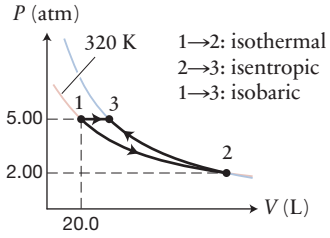
52. To change the volume of a gas isothermally by a factor f_1 of its initial value, it is necessary to do work W_1 on the gas. What work W_2 is needed to change the volume by a factor f_2 of the initial gas volume at the same temperature? Express your answer in terms of f_1, f_2, and W_1. ●●

53. An ideal gas initially at volume V_1, pressure P_1, and temperature T_1 undergoes an isobaric process that changes its temperature to T_2. The gas immediately undergoes an isothermal process that changes its volume to V_3. What is the final pressure in the gas in terms of these variables? ●●

54. At temperature T, a balloon is partly inflated with an ideal gas to a volume of 1.0 L. The balloon is then put in a low-pressure container at the same temperature T and its volume is increased to 2.0 L. If 26 J of work was done by the gas to accomplish this expansion, what is the final pressure inside the balloon in the low-pressure container? ●●

55. A 1.00-mol sample of an ideal gas expands such that its entropy doubles to 1.345×10^{24}. The temperature is held constant at 100 K during the expansion. (*a*) How much work is done by the gas on its surroundings? (*b*) What quantity Q of energy is transferred thermally to the gas? ●●

56. A 0.320-kg piston seals a chamber that contains 7.55×10^{24} helium atoms initially at 2.00 °C. The piston is free to move vertically, but it is originally held fixed in place with the chamber volume at 0.250 m^3. When the piston is released, the chamber volume immediately increases as the piston moves upward. At the instant when the piston has moved 0.320 m from its initial position, its velocity is 43.5 mm/s upward. The air pressure in the room is 1.00 atm, and the piston has a circular cross-section and a radius of 0.200 m. What is the final temperature of the gas if the expansion is (*a*) isentropic and (*b*) isothermal? ●●●



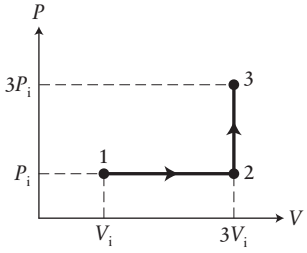
57. The ideal gas law is valid for a gas when, among other things, any interactions between particles are ignored. A more realistic model was proposed by Johannes Diderik van der Waals in 1873, for which he received a Nobel Prize in 1910. The van der Waals equation of state is

$$\left(P + \frac{an^2}{V^2}\right)(V - nb) = Nk_B T,$$

where a and b are constants, and n is the number of moles of the gas particles. Use this equation to determine the work done on a gas undergoing an isothermal process. Verify that your result reduces to the ideal gas case when $a = b = 0$. ●●●

58. A sample of diatomic ideal gas ($\gamma = 1.4$) initially has a volume of 20.0 L and is at 5.00 atm and 320 K. The gas undergoes the process shown in Figure P20.58. First it expands isothermally ($1 \rightarrow 2$) until the pressure is 2.00 atm, and then it is compressed isentropically ($2 \rightarrow 3$) until the pressure is 5.00 atm again. (*a*) Determine the volume of the gas after the isothermal expansion and the work done by the gas during the expansion. (*b*) Determine the volume and temperature of the gas after the isentropic compression, and the work done on the gas during the compression. (*c*) Determine the change in entropy of the gas by determining ΔS for $1 \rightarrow 2$ plus ΔS for $2 \rightarrow 3$. (*d*) Show that the entropy change is the same when the gas undergoes the isobaric process $1 \rightarrow 3$. ●●●

Figure P20.58



20.8 Entropy change in ideal gas processes

59. A sample of nitrogen gas ($\gamma = 1.4$) initially has a volume of 0.61 m^3 and a pressure of 1.00 atm. If the sample expands isentropically to a volume of 1.00 m^3, what is the final pressure? ●

60. A sample of an ideal gas for which $\gamma = \frac{7}{5}$ initially has a volume of 1.00 L and a pressure of 100 Pa. If the gas expands isentropically to 1.20 L, what is the final pressure? ●

61. Figure P20.61 shows the PV diagram for a monatomic ideal gas undergoing an isobaric expansion $1 \rightarrow 2$ followed by an isochoric pressure increase $2 \rightarrow 3$. If the sample contains N gas particles, what is the net change in entropy? ●●

Figure P20.61

62. An ideal gas for which $\gamma = 1.4$ initially has a volume of 1.5 m^3 and a pressure of 15 MPa. The gas is then slowly compressed isentropically to a volume of 0.50 m^3. (*a*) What is the final pressure in the gas? (*b*) By how much did the entropy of the gas change? ●●

63. A $\frac{1}{3}$-mol sample of an ideal gas is sealed in a container and heated from 273 K to 500 K. For this gas, what is the value of C_P in units of k_B if the temperature increase causes an entropy change of 1.8215×10^{23}? ●●

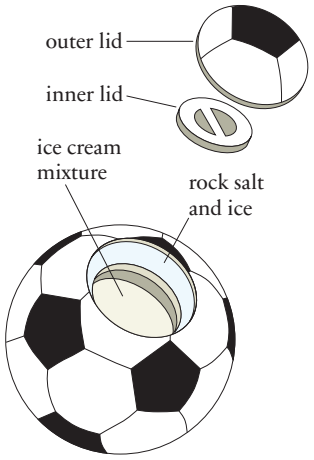
64. Two identical thermally insulated spherical tanks, A and B, are connected by a valve. Initially tank A contains 10 mol of an ideal diatomic gas, tank B is evacuated, and the valve is closed. If the valve is opened and the gas expands isothermally from A to B, what is the change in the entropy of the gas? ••

65. As part of a physics experiment, air under high pressure is allowed to expand isentropically out of a metal can and into an empty plastic bag. When the expansion is complete, the bag and contents are at atmospheric pressure. The air inside the can is initially at 5.0 atm and 25 °C. What is the air's temperature once it is in the plastic bag? ••

66. A gas is inside a cylinder fitted with a piston. The gas and its surroundings are both at 20 °C, and the gas is compressed as the piston moves and decreases the cylinder volume. The compression takes place slowly enough to allow the gas temperature to stay at 20 °C, and the work done on the gas by the compression is 2.0×10^3 J. What is the change in entropy of the gas? ••

67. An ideal gas that initially has a volume of 1.00 mL and is at 1.00 atm expands isentropically to 10.0 mL and 0.0215 atm. (*a*) How many degrees of freedom do the gas particles have? (*b*) What does this tell you about the structure of the particles? ••

68. A chamber fitted with a piston contains 1.00 mol of a monatomic ideal gas that is taken from an initial state i to a final state f via states 1 and 2. The chamber volume is initially $V_i = 0.100\ \text{m}^3$, and the temperature is $T_i = 273$ °C. To take the gas to state 1, it is heated isochorically to $T_1 = 373$ °C. To take it to state 2, it is heated isobarically to $T_2 = 473$ °C. Finally, the gas is allowed to expand isothermally until its volume is $V_f = 2V_2$. What is the change in entropy of the gas? ••



69. An ideal monatomic gas expands isentropically from an initial pressure P_i and initial volume V_i to a final pressure $P_f = P_i/20$ and final volume $V_f = 6V_i$. What is the work done by the gas, expressed in terms of P_i and V_i? [Hint: Use Eq. 20.8 (but remember that you want work done *by* the gas, so watch your signs) and the fact that $PV^\gamma =$ constant for an isentropic expansion (Eq. 20.46), with $\gamma = \frac{5}{3}$ for a monatomic ideal gas.] •••

20.9 Entropy change in nonideal gas processes

70. A thermodynamic process raises the temperature of 1.00 mol of water from 59.0 °C to 61.0 °C. What is the change in thermal energy of the water? •

71. An ice cream maker is in the form of a soccer ball (Figure P20.71). You fill the inner container with a mixture of cream and sugar at 32.0 °C and add rock salt and ice to the sleeve encircling the inner container. You then put both lids on and kick the ice cream maker around like a regular soccer ball until the internal temperature is low enough (−3.00 °C) to freeze the cream-sugar mixture into ice cream. (*a*) If the specific heat capacity of the mixture is $2900\,\text{J/K}\cdot\text{kg}$, what quantity of thermal energy must be removed from the inner container to bring 0.500 kg of the mixture to the temperature required for freezing? (*b*) If the mass of the maker plus its contents is 3.80 kg, how high above ground level would you need to lift the unit in order for the gravitational potential energy of the ice cream maker–Earth system to be equal to the quantity of energy you found in part *a*? ••

Figure P20.71

72. 2.00×10^4 J of energy is transferred thermally into a huge tank filled with liquid water. The water temperature remains constant at 10.0 °C during the process. By how much does the entropy of the water change? ••

73. An iceberg initially at 273 K is stopped in its motion by a small island. During the first few seconds of contact, 10 kJ of energy is transferred thermally from the island to the iceberg without the temperature of either object changing significantly. If the island temperature before the collision is 300 K, what is the change in entropy of the iceberg-island system as a result of the energy transfer? ••

Additional Problems

74. The average normal temperature of the human body is 98.6 °F. What is this temperature on the Celsius scale? •

75. Which are the most likely units for a measured temperature with a numerical value of (*a*) −322 and (*b*) 0? •

76. An ideal gas undergoes an isentropic process that changes its pressure from P_i to P_f and its volume from V_i to V_f. What is the work done on the gas? ••

77. A 22.7-g sample of diatomic oxygen gas molecules is in a sealed rigid container that has a volume of $0.0240\ \text{m}^3$. If the gas is initially at −1.50 °C, by how much does the pressure in the container change when the gas is cooled to −23.00 °C? ••

78. It is sometimes said, erroneously, that biological organisms violate the second law of thermodynamics because the biochemical reactions they carry out reduce their entropy by converting incoherent raw materials to coherent substances. To show that this is not so, consider your body at 37.0 °C transferring energy thermally into its immediate environment, where the temperature is 20 °C. For the system made up of your body and its environment, determine whether the entropy of the system increases or decreases over time, and at what rate. Assume your body transfers energy thermally at a rate of 100 W. ••

79. Two identical samples of a monatomic ideal gas start out at the triple point of water. Sample A is heated isochorically to five times its original temperature. Sample B is compressed isentropically and quasistatically to one-fifth of its original volume. In which process is the quantity of energy transferred thermally to the sample greater, and by how much? ●●●

80. You are working in a factory that uses water in its cooling systems and consequently has a lot of steam reservoirs. Due to carelessness, a 70.0-kg metal plate has been left on top of the only steam vent for a certain steam reservoir, and as a result the pressure in the reservoir builds up sufficiently to lift the plate a small distance. With the plate raised, the reservoir pressure drops slightly, and the plate lowers slowly back down and gently comes to rest on top of the vent. The vent is circular and has a diameter of 100 mm, and the plate is a square, 450 mm on a side. No steam is seen seeping out after this incident, and so you assume the plate has made a good seal such that only the circular section of plate directly above the vent is in contact with the steam. A flow meter attached to the reservoir tells you that 108 kg of liquid water was piped into that reservoir, and you know that this reservoir has a volume of 100 m^3. A coworker sees a few drops of water that have condensed on a glass portal located in the reservoir wall and thinks that the steam in the reservoir must have cooled enough to begin condensing to water (most of what's in the reservoir is still steam, though). Your coworker is about to grab the plate with his hands in order to uncover the vent and allow the steam to escape as it is designed to do when you suddenly realize that touching the plate might not be a good idea. ●●● CR

81. You are the founder of a start-up company that extracts electrical energy from ocean waves, a process called WaveGen. Your basic technology is a tube anchored vertically to the ocean floor. The unit is installed close to shore so that the bottom is anchored to the seabed and the top is above the water surface. At the top of the unit is a turbine generator for creating electricity. Waves rise and fall in the tube like a piston going up and down. As a wave rises in the tube, it pushes the air above it up into the generator. As the wave falls, air from the atmosphere flows into the tube through holes drilled in the part of the tube that is not under water. The average change in vertical wave height is 2.00 m, and the waves repeat on average every 5.00 s. A nearby seaside town requires 0.500 MW, and your goal is to supply all this electrical power. You know that the WaveGen tubes can be made economically up to a diameter of 2.00 m and that the efficiency of the generator in converting wave power to electricity is 68.0%, and you can produce a few tubes per day. ●●● CR

21.8 Brayton cycle

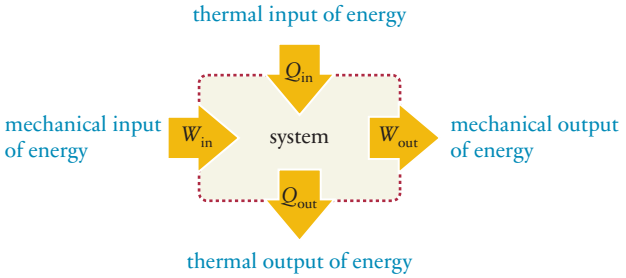
Some textbooks define energy as the *capacity to do work*. In the two preceding chapters, however, we saw that energy can do more than that. It can also be used to heat objects, and in this chapter we ask (and answer) two important questions about energy: To what extent can we use mechanical energy for heating and thermal energy for doing work? And, more specifically, to what extent can we convert energy from forms provided by nature to forms useful for technology and society?

The oceans of the world, for example, contain a very large amount of thermal energy. If we could convert just a small fraction of that energy to useful forms, we could satisfy the world's energy needs for thousands of years. Why can't a ship take in some of the thermal energy in the ocean and use it for propulsion? Such a scheme does not violate the energy law: Thermal energy would simply be converted to an equal amount of mechanical energy. As we see in this chapter, however, the entropy law imposes constraints on conversions of energy.

21.1 Converting energy

In Chapter 5 we saw that energy is a quantitative measure of the state of an object and that the law of conservation of energy implies that any change of state must be accompanied by a compensating change of state (or by a set of compensating changes of state). Whenever a pair of complementary changes of different types take place, energy is converted from one form to another. For example, burning propane gas involves two changes of state: a change in the molecular chemical bonds of the reagents (which we associate with chemical energy) and a change in the temperature of the gases (which we associate with thermal energy). The combustion is irreversible: It would be pretty startling if the hot gases would suddenly "unburn," cooling down and reconstituting the original propane and oxygen. Because the process is irreversible, we can conclude that the entropy of the gas increases in the process of burning (see Section 19.4).

A ball accelerating in free fall is another example of a complementary pair of changes of state: a change in the state of motion of the ball (which we associate with kinetic energy) and a change in the configuration of the Earth-ball system (which we associate with gravitational potential energy). This process is reversible: A movie clip of the falling ball played backward shows an upward moving ball slowing down as if it had been thrown upward (which *can* happen). We can thus conclude that the entropy of the Earth-ball system does not change.



21.1 For each system, identify the complementary changes of state and associated energies, and determine whether or not the entropy of the system increases. (*a*) A puck slides to a stop on a surface. System: puck and surface. (*b*) A compressed spring is released and accelerates a cart on a low-friction track. System: spring and cart. (*c*) A projectile is fired from a cannon. System: projectile, cannon, and explosive chemicals. (*d*) A hot object and a cold object are placed in contact and reach thermal equilibrium. System: both objects.

To analyze the energy conversions that occur in a process, such as the ones in Checkpoint 21.1, we must choose a system and separately analyze all the energy transfers into and out of the system. As we saw in Chapter 20, energy can be transferred in two ways: mechanically and thermally. **Figure 21.1** shows for each of these two types of transfers an arrow representing the transfer of energy *into* the system (called *energy input*) and an arrow representing the transfer of energy *out of* the system (called *energy output*). Diagrams that show the energy inputs and energy outputs of a system are called **energy input-output diagrams.**

Energy inputs and energy outputs are always taken to be positive. The work done on a system is thus the difference between the **mechanical input of energy** and the **mechanical output of energy:** $W = W_{\text{in}} - W_{\text{out}}$. Likewise, the energy transferred thermally into a system is the difference between the **thermal input of energy** and the **thermal output of energy:** $Q = Q_{\text{in}} - Q_{\text{out}}$.

Figure 21.1 can represent the functioning of any device or industrial process. **Figure 21.2** on the next page shows the energy input-output diagrams for two devices: a car's internal combustion engine and a refrigerator. In a non-electric car, the combustion of gasoline provides a thermal input of energy to the engine (the system). The engine has two energy outputs: a mechanical output of energy to the wheels (and other parts) of the car and a thermal output of energy to the environment (Figure 21.2*a*). In a refrigerator there are two energy inputs (Figure 21.2*b*): a thermal input of energy from the refrigerator contents (which are part

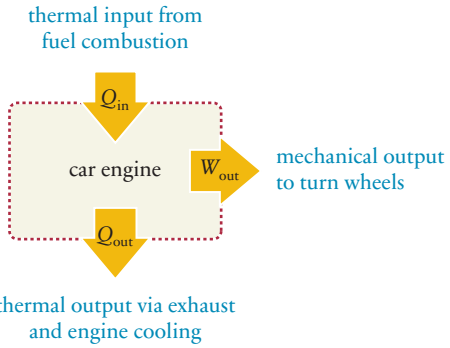


Figure 21.1 Energy input-output diagram.

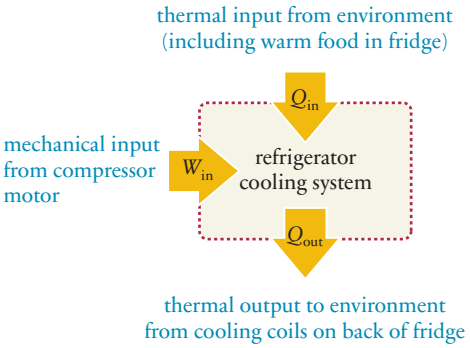


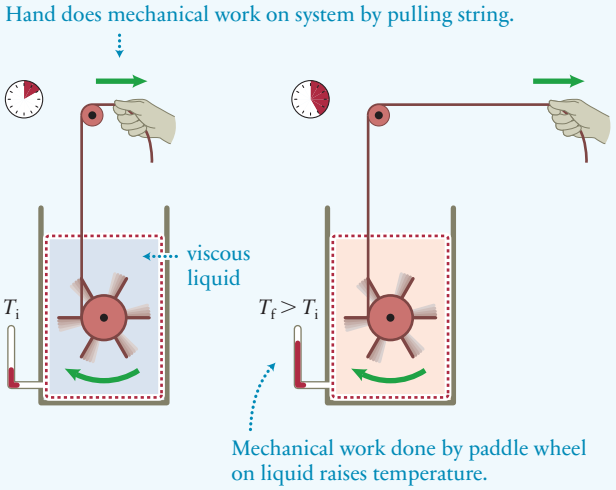
CONCEPTS

Figure 21.2 Examples of energy input-output diagrams.

(*a*) Energy input-output diagram for car engine

(*b*) Energy input-output diagram for refrigerator

of the environment) and a mechanical input of energy from the compressor motor to the rest of the refrigerator (the system). The refrigerator also has a thermal output of energy to the environment. (You may have noticed that the back of a refrigerator gets hot.)



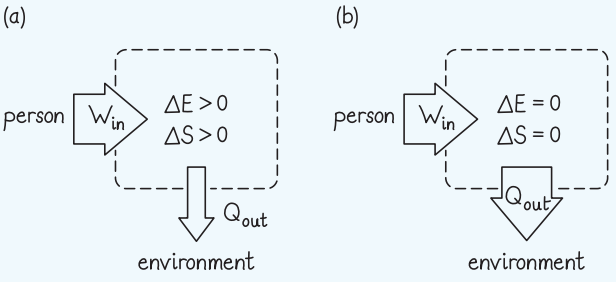
Each energy input or energy output in Figures 21.1 and 21.2 is accompanied by changes in entropy in the environment and in the system. To gain some practice determining energy and entropy changes, let us analyze a few specific situations.

CONCEPTS

EXERCISE 21.1 Converting mechanical energy to thermal energy

Consider the device illustrated in **Figure 21.3**. A string is attached to a paddle wheel that is immersed in a viscous liquid in a container. As the string is pulled, the paddle wheel rotates at constant speed, increasing the temperature of the liquid from T_i to T_f. (*a*) Draw an energy input-output diagram for the system comprising the paddle wheel and the liquid. Do the energy and entropy of the system comprising the paddle wheel and the liquid increase, decrease, or stay the same? (*b*) Assume the paddle wheel stops turning at the instant shown on the right in Figure 21.3, and we now wait until the liquid cools back

Figure 21.3



down to its initial temperature T_i. Draw an energy input-output diagram for the system, but this time over the time interval from the instant the wheel begins turning to the instant the liquid temperature is again T_i. Do the energy and entropy of the system increase, decrease, or stay the same over this new time interval?

SOLUTION (*a*) The work done on the system by pulling the string corresponds to an energy input. Because the system is not thermally insulated, energy is transferred thermally to the environment as the temperature of the system increases. My energy input-diagram therefore has one input and one output (**Figure 21.4*a***). Because the temperature of the system increases, I know that the energy of the system increases and so the energy input must be greater than the energy output. The increase in thermal energy increases the entropy of the system. ✔

(*b*) If the liquid cools back to its initial temperature, the initial and final states of the system are the same, so the energy change and the entropy change are both zero. The input of energy is the same as in part *a*, but because the energy of the system is not changing, the thermal output of energy must now be equal in magnitude to the mechanical input (Figure 21.4*b*). ✔

Figure 21.4

Note that the energy law imposes no restrictions on energy conversions: The energy law permits any form of energy to be converted entirely to any other form of energy. The device in Exercise 21.1, for example, converts mechanical energy entirely to thermal energy. Let us now look at the conversion of thermal energy to mechanical energy.

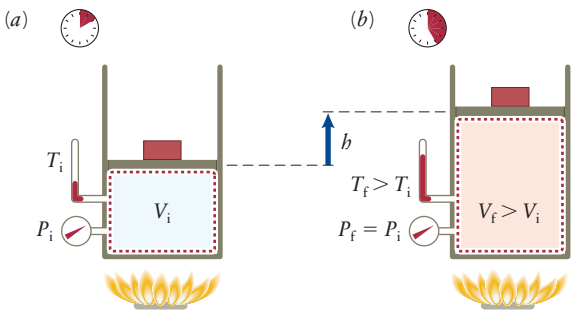
21.2 (*a*) For the situation illustrated in **Figure 21.5**, draw an energy input-output diagram for the gas. (*b*) Do the energy and entropy of the gas change? Ignore any friction in the piston and any energy transferred thermally out of the gas.

As you saw in Checkpoint 21.2, energy transferred thermally to the gas does work on the piston, and so the device converts thermal energy to mechanical energy. Because the temperature of the gas goes up, however, the thermal energy of the gas increases. Thus not all thermal energy is converted to mechanical energy in this device.

To prevent the thermal energy of the gas from increasing, we could immerse the setup in a thermal reservoir held at some fixed temperature T_R, as illustrated in **Figure 21.6**. If we then slowly remove grains of sand lying on top of the piston, the upward force exerted by the gas on the piston is a tiny bit greater than the downward force exerted by the remaining sand on the piston, and so the piston moves up. As the gas expands, it does work on the piston. Because the temperature of the gas remains constant, its thermal energy doesn't change, and so the energy required to raise the piston must be transferred thermally from the reservoir. Here is a situation where thermal energy is converted entirely to mechanical energy.

As a device, the setup of Figure 21.6 is not very practical because to maintain a constant gas temperature, the expansion would have to proceed *very* slowly. Moreover, in order for the gas to continue to do work on the piston, its volume would have to keep expanding.

Figure 21.5 When a volume of gas is heated at constant pressure in a cylinder fitted with a movable piston, both its temperature and its volume increase.



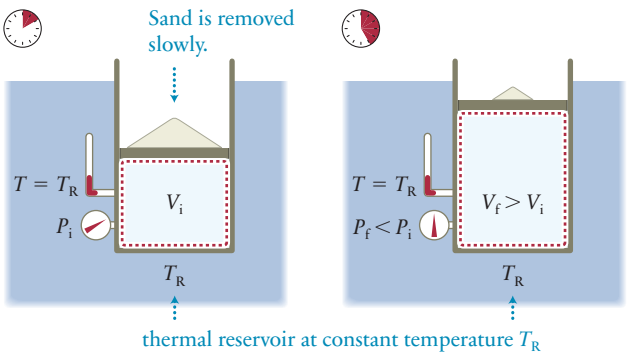


Figure 21.6 A gas held at constant temperature in a cylinder fitted with a movable piston expands slowly as the load on the piston is diminished.

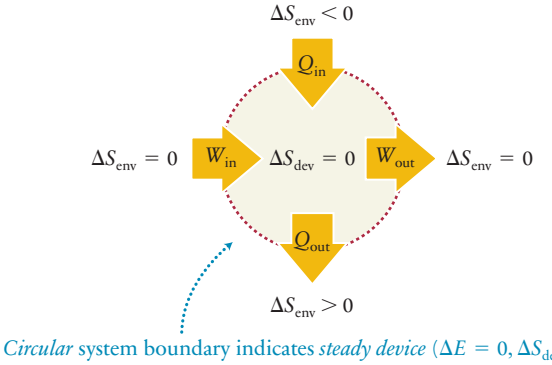
When designing practical devices for converting energy, we usually want them to be able to operate indefinitely. If the device were to keep expanding in volume as in Figure 21.6 or keep getting hotter or building up pressure over time, it could not be operated for very long. For this reason we want the state of the device that converts energy to remain the same or to return to the same state over some repeating time interval. Such a device is called a **steady device.** When a steady device evolves from an initial state through a series of processes back to its initial state, the series of processes is called a *cycle*. During the operation of the device, this cycle is repeated continuously. For simplicity, we shall assume that all steady devices involve only quasistatic processes and that no energy is dissipated due to friction.



Because the initial and final states of a steady device are the same over one cycle, there is no change in the energy of the system: $\Delta E = 0$. Over one cycle, therefore, the energy input must be equal to the energy output: $W_{in} + Q_{in} = W_{out} + Q_{out}$.

To see what constraints are imposed by the entropy law (Eq. 19.5; $\Delta S > 0$ for a closed system moving toward equilibrium) on the energy inputs and outputs of a steady device, we examine the entropy changes associated with these energy inputs and outputs. The device is not a closed system and so we cannot apply the entropy law to it. The device and its environment constitute a closed system, however, so we can write $\Delta S = \Delta S_{dev} + \Delta S_{env} \geq 0$ (Eqs. 19.5, 19.6). Because the initial and final states of the cycle are the same, we know that there cannot be any change in the entropy of the device: $\Delta S_{dev} = 0$ for one cycle. Therefore, we need to consider only entropy changes in the environment when we deal with steady devices and make sure these changes satisfy $\Delta S_{env} \geq 0$.

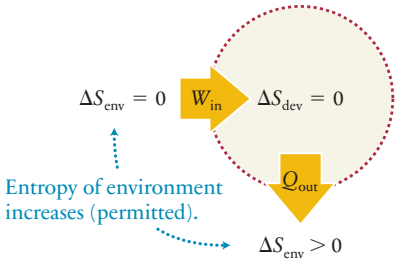
As we saw in Section 20.1, no entropy change is associated with a quasistatic adiabatic process. Because $Q = 0$ for mechanical inputs and outputs of energy and because we assume that the processes in a steady device

CONCEPTS

Figure 21.7 Energy and entropy changes associated with energy inputs and energy outputs for a steady device.

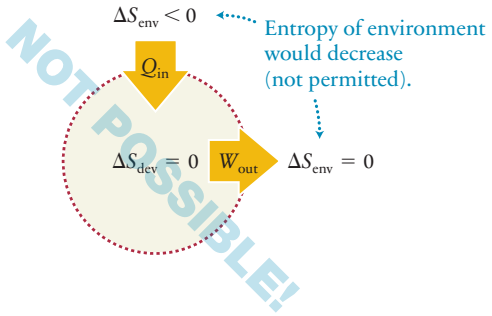
are quasistatic, we have $\Delta S_{env} = 0$ for W_{in} and W_{out}. Therefore the only changes in the entropy of the environment we need to consider are those caused by thermal inputs and outputs of energy:

> **Steady devices operate under two constraints: (1) The energy input must be equal to the energy output. (2) The device's thermal inputs and outputs must increase the entropy of the environment (or leave it unaltered).**



In Chapter 20, we saw that the entropy change associated with energy transferred thermally has the same sign as Q (Eq. 20.54). Therefore, a thermal output of energy increases the entropy of the environment. Conversely, a thermal input of energy decreases the entropy of the environment. **Figure 21.7** summarizes these entropy changes due to the various kinds of energy inputs and energy outputs for a steady device. We use a circular system boundary to indicate that the system is a steady device. The diagram represents the energy inputs and outputs during one complete cycle.

We are now in a position to analyze steady devices that convert energy. First consider a steady device that converts mechanical energy to thermal energy. Such a device has a mechanical input of energy and a thermal output of energy (**Figure 21.8a**). The mechanical input of energy involves no change in the entropy of the environment; the thermal output of energy causes an increase in the entropy of the environment. The entropy of the environment therefore increases, which is permitted by the entropy law. This means that a steady device can convert mechanical energy entirely to thermal energy.

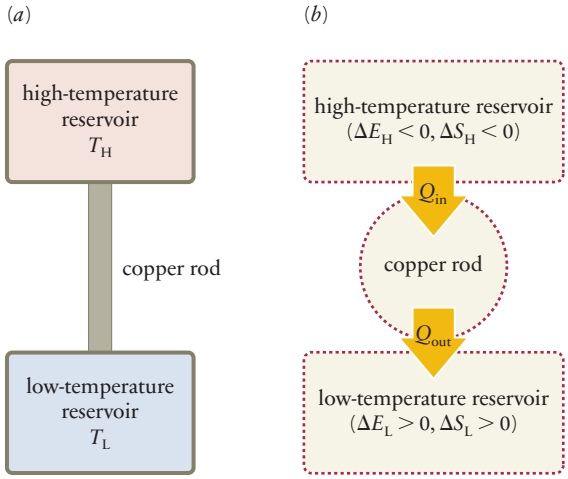


Next consider a steady device that converts thermal energy to mechanical energy (Figure 21.8*b*). The thermal input of energy causes a decrease in the entropy of the environment; the mechanical output of energy involves no change in the entropy of the environment. The entropy of the environment therefore decreases, which is not permitted by the entropy law for a steady device. Therefore no steady device can convert thermal energy entirely to mechanical energy.

Figure 21.8 Energy input-output diagrams for two types of steady device.

(*a*) Device that converts mechanical energy to thermal energy

(*b*) Attempt to convert thermal energy entirely to mechanical energy



21.3 Suppose we slowly push the piston back to its original position in Figure 21.6, all the while maintaining a constant temperature in the gas. (*a*) Over the time interval that includes the expansion and the compression of the gas, has any energy been converted? (*b*) Does the entropy of the gas increase, stay the same, or decrease over that time interval? (*c*) If we keep repeating the expansion and compression, is this device a steady device?

21.2 Quality of energy

In this section we develop a graphical approach to keep track of entropy changes in the environment caused by steady devices that convert energy. Let us begin by considering the very simple situation illustrated in **Figure 21.9a**: A copper rod is in thermal contact with a high-temperature thermal reservoir on one end and a low-temperature thermal reservoir on the other end. Apart from its ends, the rod is thermally isolated from its environment. Because the temperatures of the thermal reservoirs are fixed, the rod remains in a steady state: One end remains at the temperature T_H of the high-temperature reservoir, and the other end remains at the temperature T_L of the low-temperature reservoir. (Remember that thermal reservoirs are large enough so that any energy transferred thermally to them does not change their temperature; see Section 20.7.) As a result of the temperature difference, energy is

CONCEPTS

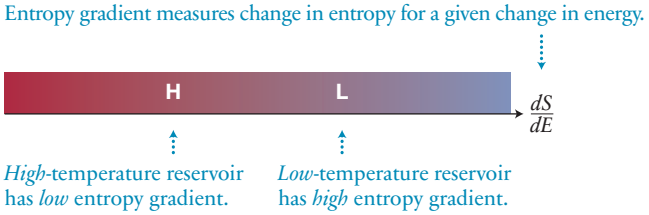
Figure 21.9 (*a*) A copper rod in thermal contact with a high-temperature reservoir and a low-temperature reservoir. (*b*) Energy input-output diagrams for the rod and the reservoirs.

transferred thermally through the rod from the high-temperature reservoir to the low-temperature reservoir. Although the rod hardly qualifies as a device, its state doesn't change and so it satisfies the requirements that the entropy and energy of a steady device do not change over time. (The cycle for this device can be taken to be any arbitrary time interval.)

Figure 21.9*b* shows the energy input-output diagrams for the rod and for the two thermal reservoirs. The change in the energy of the high-temperature reservoir is equal to the thermal input of energy of the rod, $\Delta E_H = -Q_{in}$, while the change in the energy of the low-temperature reservoir is equal to the thermal output of energy of the rod, $\Delta E_L = Q_{out}$. Because the state of the rod is not changing, we know that $\Delta E_{rod} = Q_{in} - Q_{out} = 0$, so $Q_{in} = Q_{out}$ and therefore $\Delta E_H = -\Delta E_L$. The amount of energy transferred out of the high-temperature reservoir is equal to the amount of energy transferred into the low-temperature reservoir.

The thermal transfer of energy through the rod causes entropy changes in the two reservoirs (both part of the rod's environment) even though their temperatures remain unchanged. Because energy is transferred out of the high-temperature reservoir, its energy decreases, and so its entropy decreases too: $\Delta S_H < 0$. The increase of energy in the low-temperature reservoir causes its entropy to increase: $\Delta S_L > 0$. Because the transfer of energy is irreversible, we know that the entropy of the environment must increase, so that $\Delta S_H + \Delta S_L > 0$.

The reason entropy increases can be understood by looking at the way we defined temperature in Chapter 19: $dS/dE \equiv 1/(k_B T)$ (Eq. 19.38).* The quantity dS/dE, called the **entropy gradient**, is a measure of the change in entropy caused by a given change in energy. Equation 19.38 tells us that the magnitude of the change in entropy caused by transferring a given amount of energy to or from a reservoir is inversely proportional to the temperature of the reservoir. The entropy change ΔS caused by a given change in energy ΔE is therefore greater in magnitude for the low-temperature reservoir than for the high-temperature reservoir. Because ΔS_L is positive and ΔS_H is negative, it follows that $\Delta S_H + \Delta S_L > 0$.



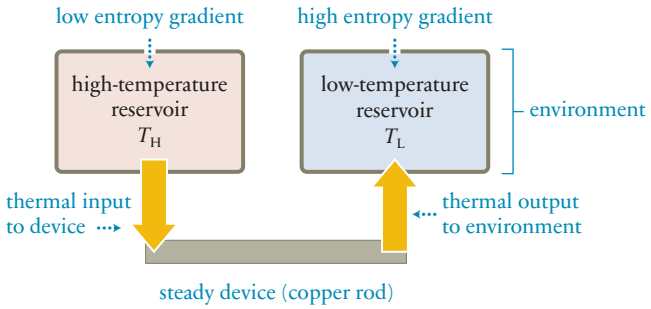
21.4 What are the signs of ΔE_R, ΔS_R, and $\Delta S_R/\Delta E_R$ for a thermal transfer of energy (*a*) to and (*b*) from a thermal reservoir?

You can view the entropy gradient as the "entropy cost of an energy change." The greater the entropy gradient (or the lower the temperature), the greater the change in entropy caused by a given energy change. As you saw in Checkpoint 21.4, the entropy gradient is always positive, regardless of the direction of the energy transfer, because ΔS and ΔE always have the same algebraic sign.

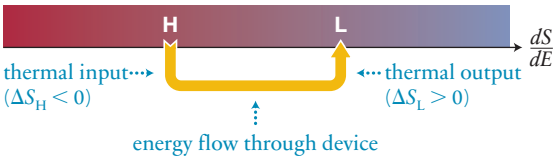
We can arrange the rod's environment by its entropy gradient. Because the high-temperature reservoir has the smaller entropy gradient, we place it to the left of the low-temperature reservoir on the entropy-gradient scale in **Figure 21.10**. If we represent the thermal transfer of energy through the rod in **Figure 21.11a** on the next page, by a curved arrow, we obtain the diagram shown in Figure 21.11*b*. The tail of the arrow represents the thermal input of energy from the high-temperature reservoir, and the head represents the thermal output of energy to the low-temperature reservoir.

Note that we can associate the sign of the entropy changes in the reservoirs with the direction of the arrow. The tail of the arrow (the energy input) points down and $\Delta S_H < 0$; the head (the energy output) points up and $\Delta S_L > 0$. The diagram in Figure 21.11*b* therefore allows us to see that the transfer of energy through the rod increases the entropy of the environment: The rod takes a certain amount of energy out of the environment at low entropy cost (small dS/dE) and returns the same

Figure 21.10 Entropy gradient. The shaded bar represents the rod's environment, which consists of the high-temperature reservoir (H) and the low-temperature reservoir (L).



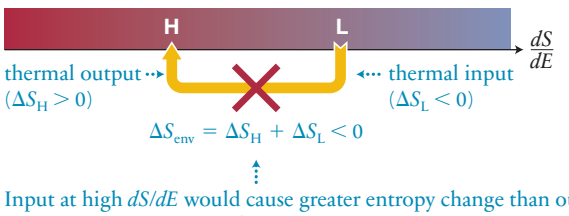
*As we did in Chapter 20, we assume that the kinetic, potential, and source energies of the reservoirs remain constant, so that $\Delta E = \Delta E_{th}$.



CONCEPTS

Figure 21.11 (*a*) We rearrange the device of Figure 21.9 to separate the system (the steady device) from its environment (the thermal reservoirs). (*b*) Using this geometry, we construct an entropy diagram showing the energy conversions and transfers in the steady device. The thermal input at low dS/dE causes entropy change in the environment of smaller magnitude than thermal output at high dS/dE, so the entropy of the environment increases: $\Delta S_H + \Delta S_L > 0$.

(*a*) We separate the device (the system) from its environment



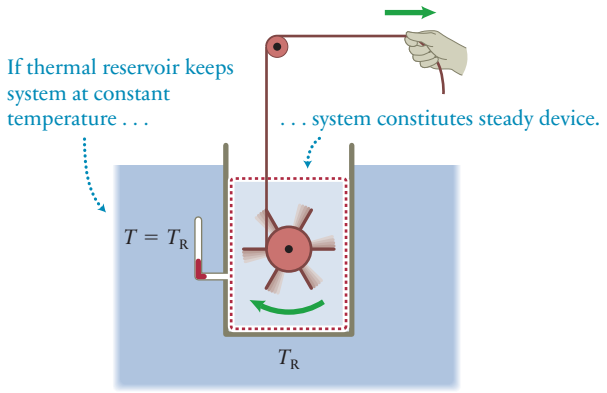
(*b*) Entropy diagram

amount of energy to the environment at a greater entropy cost (large dS/dE). The magnitude of the entropy change caused by the output is therefore greater than the magnitude of the entropy change caused by the input. Because the input causes a decrease in entropy and the output causes an increase in entropy, the combined effect is an increase in the entropy of the environment.

Now suppose the copper rod somehow transfers energy from the low-temperature reservoir to the high-temperature reservoir, as illustrated in **Figure 21.12**. The curved arrow representing the energy transfer now points from the low-temperature reservoir to the high-temperature reservoir and, as you can readily verify, the signs of the entropy changes are the opposite of the signs in Figure 21.11. The rod takes a certain amount of energy out of the environment at large dS/dE and returns the same amount of energy to the environment at a smaller dS/dE. The entropy change of the environment in this process is thus negative, which is not allowed by the entropy law. Indeed, no one has ever observed energy being transferred thermally from a cold object to a hot object with no other changes in the system or the environment (that is, the cold object spontaneously getting colder and the hot object getting hotter).

Figure 21.12 Entropy diagram for a thermal transfer of energy from a low-temperature reservoir (L) to a high-temperature reservoir (H), a process forbidden by the entropy law.

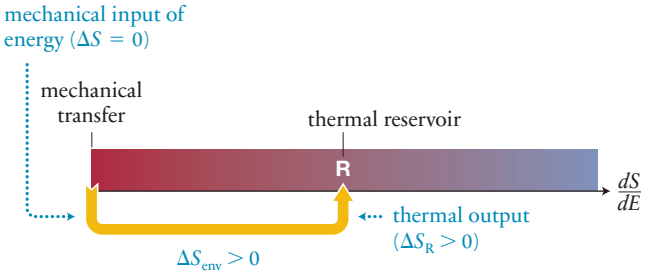
The diagrams in Figures 21.11 and 21.12 are called **entropy diagrams.** An entropy diagram shows the energy conversions and transfers that take place in a steady device with the environment arranged according to an entropy gradient, as shown in Figure 21.10. Arrows in the diagram represent the energy transfers through the device during one complete cycle. The tails of the arrows represent energy inputs to the device, and the heads represent energy outputs. Thermal inputs of energy (tails) cause the entropy of the environment to decrease, while thermal outputs of energy (arrowheads) cause the entropy of the environment to increase.



Entropy diagrams permit us to keep track of entropy changes that result from the energy conversions by a steady device. In particular:

> **A transfer of energy that points to the right in an entropy diagram causes an increase in the entropy of the environment; a transfer that points to the left causes a decrease in the entropy of the environment.**

As we shall see in Section 21.5, entropy diagrams can be used to derive quantitative information about entropy changes in the environment.



Let's now return to the example of a paddle wheel in a viscous liquid. This time, however, we immerse the container of viscous liquid in a large thermal reservoir that keeps the viscous liquid at a constant temperature T_R (**Figure 21.13**). The moving parts and the viscous liquid now constitute a steady device. A person does work on the device by pulling on the string and then the device transfers energy to the reservoir. The device thus converts mechanical energy to thermal energy.

Figure 21.13 Paddle-wheel device from Exercise 21.1 is held at a constant temperature T_R by a large thermal reservoir of water.

CONCEPTS

Figure 21.14 Entropy diagram for the process depicted in Figure 21.13.

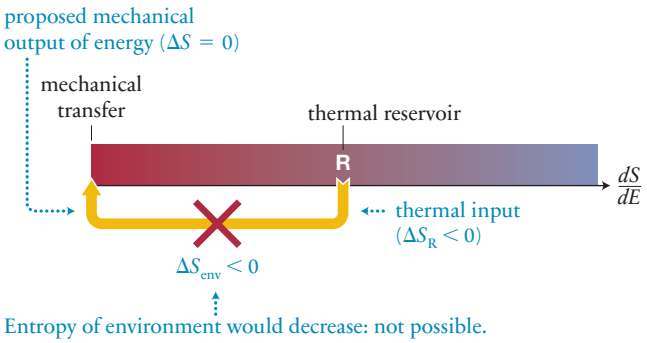
To draw an entropy diagram for this energy conversion process, we must first determine where to put mechanical energy on the entropy-gradient scale. Remember that doing work—in other words, transferring energy mechanically—does not cause any change in entropy. Therefore $\Delta S = 0$ and so $\Delta S/\Delta E = 0$. The entropy gradient associated with mechanical energy is thus zero. Mechanical energy transfers therefore always appear on the far left at the origin of the dS/dE scale (**Figure 21.14**).

The only entropy change in Figure 21.14 is thus caused by the thermal output of energy. This entropy change is positive (arrow points up), and so the entropy of the environment increases.

The inverse of the process in Figure 21.14, illustrated in **Figure 21.15**—conversion of thermal energy entirely to mechanical energy by a steady device—cannot occur. In this process, the device would transfer energy thermally from the environment and mechanically to the environment. The curved arrow now points to the left, causing a decrease in the entropy of the environment, which is impossible. This process would mean that the paddle wheel in Figure 21.13 could rewind the string and pull the hand to the left by transferring energy thermally from the reservoir. The entropy law prevents this from happening.

Summarizing, we see that converting energy with a low entropy gradient to energy with a high entropy gradient with a steady device (arrow points right in entropy diagram) increases the entropy of the environment and is permitted by the entropy law. Conversely, converting

Figure 21.15 Entropy diagram for the conversion of thermal energy entirely to mechanical energy by a steady device.



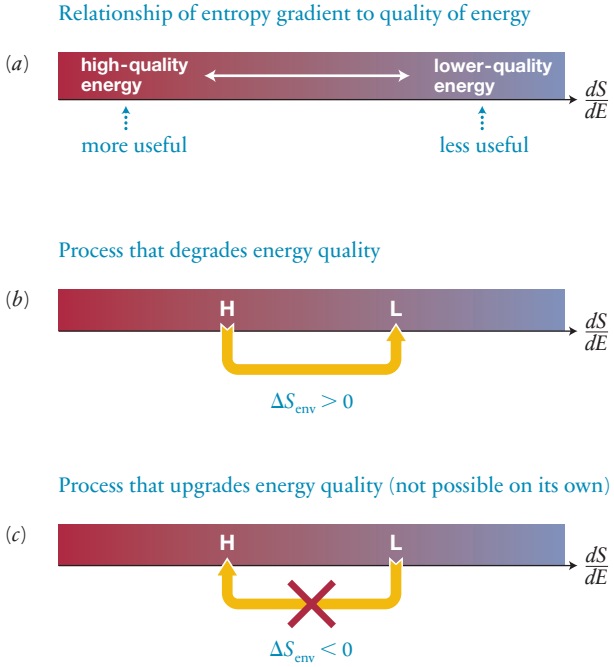


Figure 21.16 Energy with a large entropy gradient is less useful and therefore of lower quality than energy with a small entropy gradient.

energy with a high entropy gradient to energy with a low entropy gradient with a steady device (arrow points left in entropy diagram) decreases the entropy of the environment and is not permitted by the entropy law.

As energy shifts toward the right in an entropy diagram, the energy becomes less useful for, say, heating things or powering machines. You can do less with a tub of lukewarm water than with a bucket of boiling hot water that contains the same amount of thermal energy as the tub. We can therefore associate the entropy gradient with the **quality of the energy:** The smaller dS/dE, the lower the entropy cost and the higher the quality of energy (**Figure 21.16a**). The tendency of the entropy of the environment to increase and energy to shift from higher quality to lower quality (that is, to the right in the entropy diagram) corresponds to a *degradation* of energy quality (Figure 21.16*b*). In the device of Figure 21.13, for instance, high-quality mechanical energy (which allows us to do useful work, such as lifting or accelerating things) is irreversibly turned into less useful, lower-quality thermal energy.

A conversion of lower-quality energy to higher-quality energy (an *upgrade* in energy quality) corresponds to a left-pointing curved arrow in entropy diagrams and produces a decrease in the entropy of the environment (Figure 21.16*c*). Such upgrades cannot occur in steady devices that have a single energy input and a single energy output. For example, it's impossible to convert low-quality thermal energy entirely to high-quality mechanical energy. This is why ships can't be powered by converting thermal energy from the ocean entirely to mechanical energy.

21.5 For a steady device that has a single input of energy and a single output of energy, does the quality of the energy increase, decrease, or stay the same when the entropy change in the environment is (*a*) positive and (*b*) zero?

EXAMPLE 21.2 Energy and entropy changes in a thermal reservoir

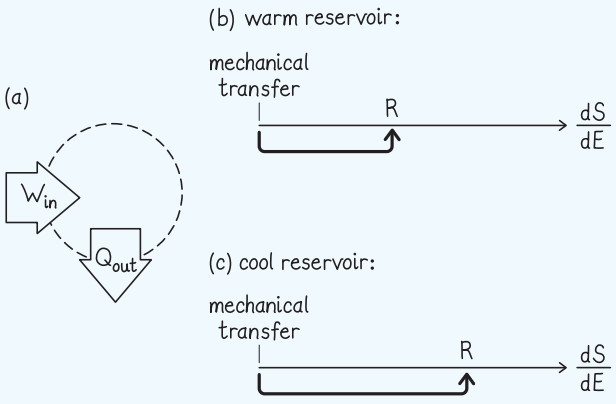
Suppose the person pulling the string in Figure 21.13 does work W on the device immersed in a thermal reservoir R at temperature T_R. (*a*) Do the energy and entropy of the reservoir increase, decrease, or stay the same? (*b*) If the same experiment is repeated with the reservoir at a lower temperature, are the changes in the energy and entropy of the reservoir greater than, the same as, or smaller than in part *a*?

1 GETTING STARTED Because the device is immersed in a thermal reservoir, the state of the device doesn't change. The device is therefore a steady device, and its energy and entropy don't change. Because the reservoir temperature is lower in part *b*, the states of the device and reservoir are different from those in part *a*. In particular, a lower reservoir temperature means that the reservoir's thermal energy is smaller.

2 DEVISE PLAN I can draw an energy input-output diagram for the device and determine its energy inputs and outputs. From the diagram, I can deduce whether there is any thermal transfer of energy to (or from) the reservoir. To evaluate any entropy changes in the reservoir, I draw an entropy diagram for each part of the problem.

3 EXECUTE PLAN (*a*) I know that the person does work on the device and so $W_{in} = W > 0$. Because the energy of the device doesn't change, the energy law tells me that $\Delta E = W + Q = 0$, so $Q = -W < 0$, which means that energy must be transferred thermally out of the device: $Q_{out} = -Q = W$. My energy input-output diagram is shown in **Figure 21.17*a***.

The energy transferred thermally out of the device goes into the reservoir, which tells me that the energy of the reservoir increases by an amount W. ✔



To see what happens to the reservoir entropy, I need an entropy diagram. Mechanical energy initially in the device is converted to thermal energy. I represent this conversion by drawing a right-pointing arrow in my entropy diagram, running from the origin ($dS/dE = 0$ for mechanical energy) to the R representing the reservoir (Figure 21.17*b*). That the arrow points to the right tells me that the entropy of the reservoir increases. ✔

(*b*) Even though the temperature of the reservoir is lowered, the amount of work done on the device by the person is still W, so the temperature change does not affect my energy input-output diagram. This tells me that the energy of the reservoir increases by the same amount W as in part *a*. ✔

Because the reservoir temperature is lower than in part *a*, however, on my entropy diagram for this situation (Figure 21.17*c*), I show R farther to the right than in Figure 21.17*b*. The right-pointing arrow representing the conversion is longer, meaning a greater dS/dE value at this temperature. A greater entropy gradient means a higher entropy cost of energy change, and so the entropy change associated with the energy change W must be greater than the entropy change of part *a*. ✔

4 EVALUATE RESULT I can also evaluate the entropy changes using Eq. 20.54, $\Delta S_R = Q_R/k_B T_R$. The quantity of energy transferred thermally to the reservoir is the same for both parts of the problem: $Q_R = W$. Because the reservoir temperature T_R is lower in part *b*, the entropy change must be greater here than in part *a*.

Figure 21.17

21.6 In an entropy diagram, which of these statements are true? (*a*) The quality of the energy is proportional to the entropy gradient. (*b*) The quality of the energy is inversely proportional to the entropy gradient. (*c*) High-temperature energy is of high quality. (*d*) High-temperature energy is of low quality. (*e*) Low-temperature energy has a small entropy gradient. (*f*) Low-temperature energy has a large entropy gradient.

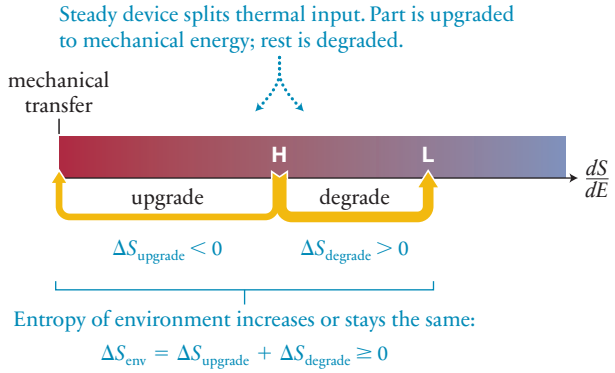
21.3 Heat engines and heat pumps

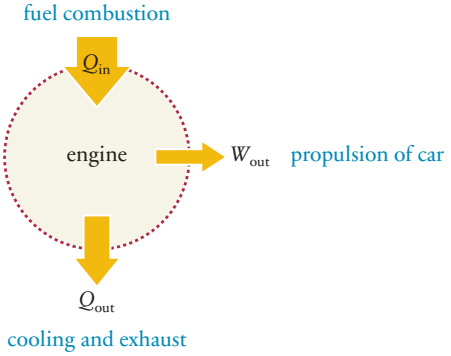
As we just saw, it is not possible for a steady device that has a single energy input and a single energy output to upgrade energy quality. The only way for a steady device to upgrade energy quality is to also degrade energy quality in such a way that the change in entropy of the environment that results from both processes is either positive or zero: $\Delta S_{env} = \Delta S_{upgrade} + \Delta S_{degrade} \geq 0$.

The process illustrated in **Figure 21.18** is one way to combine two compensating processes. A steady device takes in energy from a high-temperature reservoir, converts part of this energy to mechanical energy, and thermally transfers the rest to a low-temperature reservoir. This process is allowed as long as the increase in entropy associated with the degradation of the energy (the thermal output) equals or exceeds the decrease in entropy associated with the upgrade (the mechanical output). A steady device of this type is called a **heat engine.**

CONCEPTS

Figure 21.18 Entropy diagram for a process that upgrades and degrades energy.





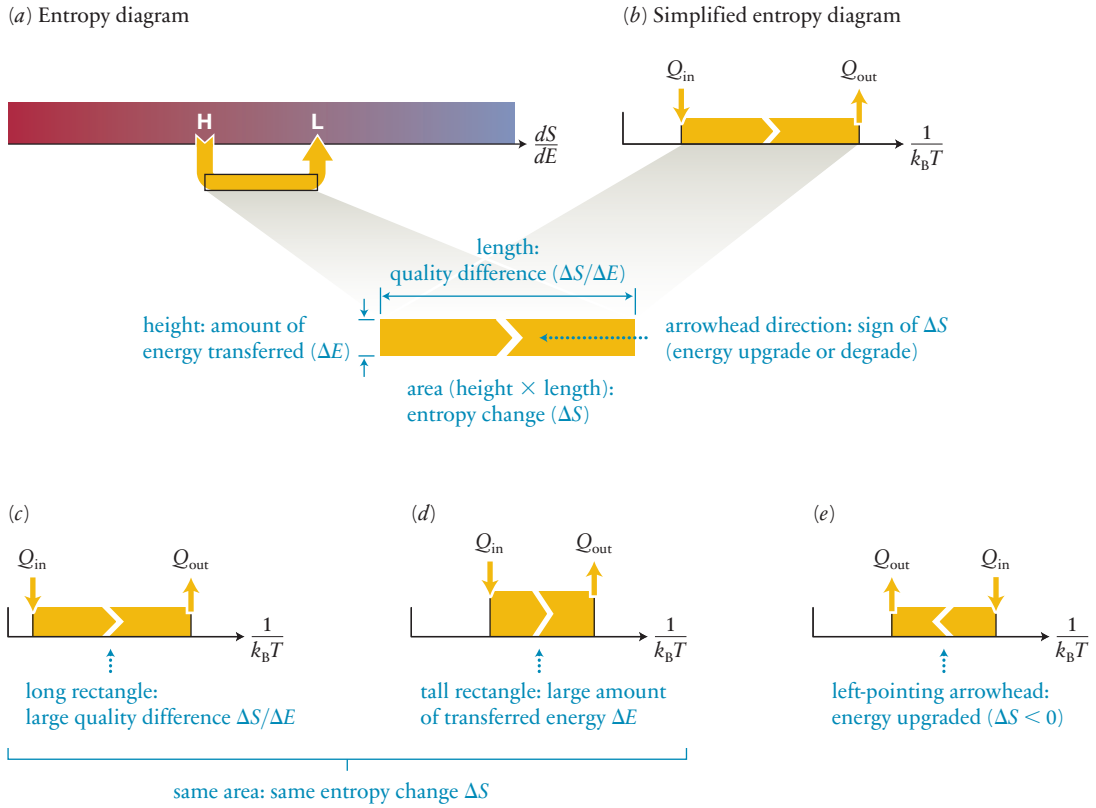


Figure 21.19 Energy input-output diagram for an automobile internal combustion engine, which is one type of heat engine.

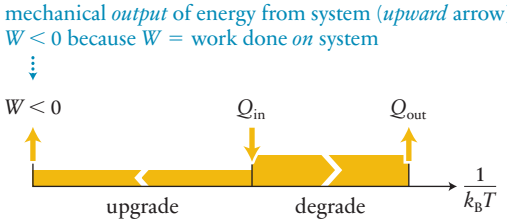
One familiar heat engine that carries out the process illustrated in Figure 21.18 is the internal combustion engine we discussed briefly in Section 21.1. As shown in **Figure 21.19**, the thermal input of energy is provided by the combustion of gasoline at high temperature (about 2700 K). Roughly two-thirds of this input energy is discarded to the environment by the car's exhaust and cooling system, both of which are roughly at 400 K. The remaining one-third of the input energy is turned into mechanical output of energy (part of which is lost due to friction in the moving parts of the car). As you can see by the relative sizes of the Q_{out} and W_{out} arrows in Figure 21.19, in a typical internal combustion engine more energy is degraded than upgraded in order to satisfy the entropy law and keep the engine's final state the same as its initial state.

Because we arrange energy inputs and outputs on the horizontal scale of an entropy diagram according to their entropy gradient, the length of an arrow in the diagram is a measure of the quality difference $\Delta S/\Delta E$ between the input and output. If we take the width of each arrow to represent the amount of energy ΔE transferred, then the area of the horizontal part of the arrow (the product of the arrow's width and length) represents the magnitude of the change in entropy (**Figure 21.20*a***).

Figure 21.20 Obtaining entropy changes from entropy diagrams.



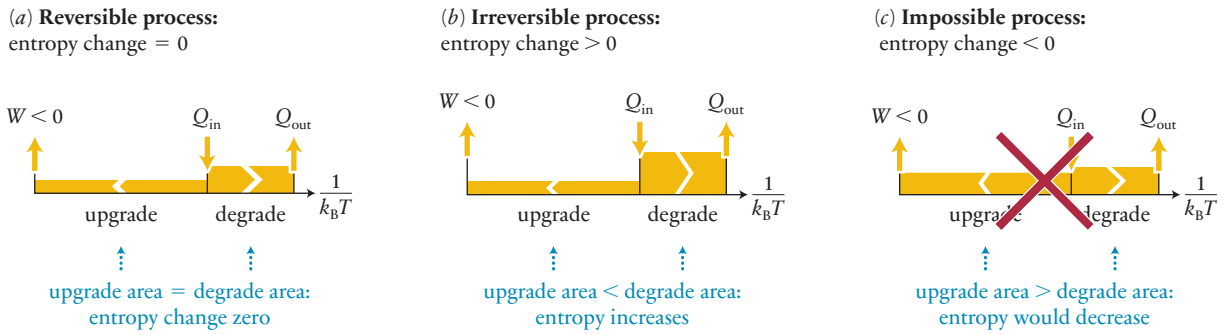
CONCEPTS

Because it is difficult to draw curved arrows and determine their area, we simplify our procedure for drawing entropy diagrams, replacing the arrows with rectangles (Figure 21.20*b*). The length of the rectangle corresponds to the quality difference between the energy output and input, and the height of the rectangle corresponds to the amount of energy transferred. The area of the rectangle thus represents the entropy change in the environment caused by the energy conversion or transfer. The direction of the energy transfer is indicated by an arrow inside the rectangle. In addition we mark the energy inputs and outputs by vertical arrows: down for input and up for output. Finally, because the entropy gradient dS/dE is equal to $1/k_BT$ (Eq. 19.38), we label the axis with $1/k_BT$.

There are two ways to increase the magnitude of the entropy change. The greater the quality difference between the input and output, the greater the entropy change. For example, in Figure 21.20*c* the energy input is of higher quality than in Figure 21.20*b*. Consequently, the entropy change produced by the conversion of this higher-quality energy is greater. Shifting the input of the arrow to the left (higher quality) increases its length and therefore its area (which represents the entropy change). As you can see from Eq. 20.54, $\Delta S = Q/k_BT$, the entropy change is also proportional to the quantity of energy Q being transferred. So, a second way to induce a greater entropy change between two fixed-temperature reservoirs is to increase the amount of energy being transferred (represented by the greater height of the rectangle in Figure 21.20*d*). Finally, if the direction of an energy transfer is reversed, the sign of the entropy change is reversed but its magnitude remains the same (compare Figure 21.20*e* with 21.20*b*). **Figure 21.21** shows the entropy diagram for a process that both upgrades and degrades energy, with rectangles used to represent the transfers.

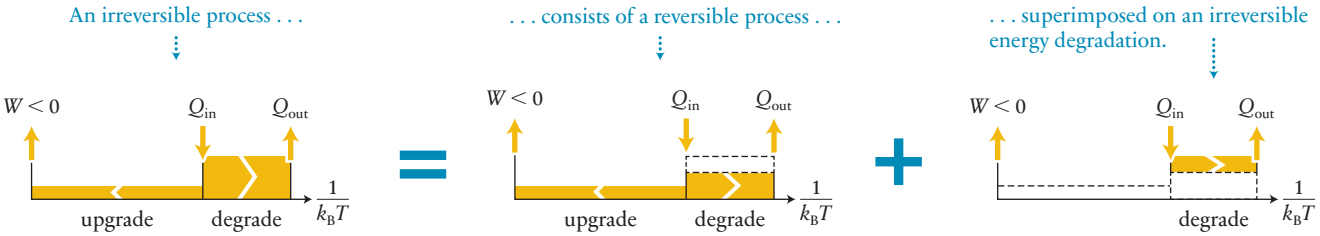
Because thermal inputs and outputs of energy occur at different temperatures, they are separated on the dS/dE scale. Mechanical inputs and outputs of energy, however, are always located at $dS/dE = 0$, and so they overlap in an entropy diagram. The end of an arrow (or rectangle) at $dS/dE = 0$ therefore does not represent

Figure 21.21 Entropy diagram for a process that upgrades and degrades energy (compare with Figure 21.18).



W_{in} or W_{out} but rather the difference between these two, $W = W_{in} - W_{out}$, which is the work done on the system. When the arrow points up, energy is transferred mechanically from the system to the environment and hence $W < 0$ (Figure 21.21). When the arrow points down, work is done on the system, indicating a mechanical transfer of energy into the system, $W > 0$.

For a steady device, the entropy law requires the entropy change in the environment to be greater than or equal to zero, and so the area of the degrade rectangle must be larger than or equal to the area of the upgrade rectangle. **Figure 21.22*a*** shows a process for which the energy upgrade and energy degradation cause equal-magnitude changes in entropy. For such a process, the entropy change is zero, so the process is reversible and allowed. Figure 21.22*b* shows a process for which the magnitude of the entropy change caused by the energy upgrade is smaller than the magnitude of the entropy change caused by the energy degradation. For such a process, the entropy change is positive, so the process is irreversible and allowed. Figure 21.22*c* shows a process for which the magnitude of the entropy change caused by the energy upgrade is greater than the magnitude of the entropy change caused by the energy degradation. For such a process, the entropy change is negative, so the process is forbidden by the entropy law. The procedure for drawing entropy diagrams is shown in the Procedure box on page 754.



21.7 Draw an entropy diagram for the refrigerator in Figure 21.2*b*.

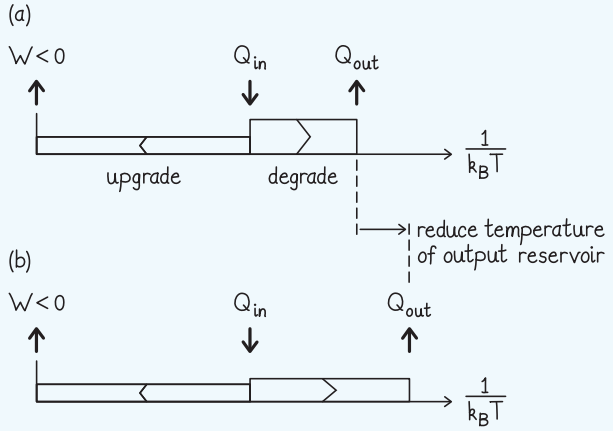
Figure 21.22 For a steady device, the entropy change in the environment must be greater than or equal to zero.

CONCEPTS

Figure 21.23 Entropy diagram for an irreversible process.

The entropy diagram for an irreversible process such as the one in Figure 21.22*b* can be treated as the entropy diagram for an irreversible degradation of energy (that is, hot to cold) superimposed on the entropy diagram for a reversible process (**Figure 21.23**). The upgrade rectangles in Figure 21.23*a* and *b* are the same, but in Figure 21.23*b* the height of the degrade rectangle has been adjusted so that the areas of the upgrade and degrade rectangles are the same. The entropy change in Figure 21.23*b* is therefore zero, and the process represented by this entropy diagram is reversible. Figure 21.23*c* shows the remainder of the energy transferred to the low-temperature reservoir. This process increases the entropy of the environment and is irreversible. The mechanical energy generated in Figure 21.23*b* is retrievable. Because the process is reversible, the mechanical energy can be converted back to thermal energy. The energy in Figure 21.23*c*, on the other hand, has been degraded and is irretrievable. It cannot be transferred back to the high-temperature reservoir without some other associated energy degradation. For now, the only processes we consider are reversible ones for which the entropy change is zero.

21.8 Why must the degrade rectangle in Figure 21.22*a* have a greater height than the upgrade rectangle?



EXAMPLE 21.3 Hot or cold?

A reversible heat engine converts energy taken from a thermal reservoir at temperature T_{in} by doing work on the environment and thermally transferring energy to a thermal reservoir at temperature $T_{out} < T_{in}$. How do the thermal input and output of energy change if the temperature of the output reservoir is lowered without changing the amount of work done by the engine on the environment?

1 GETTING STARTED I begin by drawing an entropy diagram for the heat engine (**Figure 21.24*a***). Because the engine is reversible, the area of the upgrade rectangle must equal the area of the degrade rectangle. The height of the upgrade rectangle is equal to the magnitude of W and is fixed. The height of the degrade rectangle is equal to Q_{out}.

2 DEVISE PLAN To determine how the thermal input and output of energy change as the temperature of the output reservoir is lowered, I need to draw another entropy diagram (Figure 21.24*b*), keeping the upgrade rectangle the same as in Figure 21.24*a* and shifting the right side of the degrade rectangle to the right to represent the lower temperature of the output reservoir. When I make this change, I must remember that the upgrade and degrade rectangles must still have the same area, and so now my degrade rectangle is not as tall as in Figure 21.24*a*. Also, I know that the sum of the outputs must equal the sum of the inputs, and so $W_{out} + Q_{out} = Q_{in}$.

Figure 21.24 Example 21.3.

3 EXECUTE PLAN In any entropy diagram, the height of the degrade rectangle represents Q_{out}. Because the height of the degrade rectangle is less in Figure 21.24*b* than in Figure 21.24*a*, I conclude that Q_{out} decreases when the temperature of the output reservoir is lowered. Because $W_{out} + Q_{out} = Q_{in}$ and W_{out} is not changed, Q_{in} must also decrease. ✔

4 EVALUATE RESULT My result means that if the temperature difference between the reservoirs increases, I need less energy Q_{in} to do the same amount of work on the environment. The reason is that I can compensate for the energy upgrade from thermal to mechanical with less energy: At low temperature a given amount of energy causes a greater entropy change and so my answer makes sense.

21.9 Suppose you keep W and T_{out} in the reversible process of Figure 21.24*a* fixed but increase T_{in}. Do the magnitudes of these quantities increase, decrease, or stay the same: (*a*) ΔS associated with the upgrade, (*b*) ΔS associated with the degradation, (*c*) Q_{in}?

CONCEPTS

PROCEDURE: Drawing entropy diagrams for a steady device

1. Draw an entropy gradient axis pointing right. Add a short vertical axis to indicate the origin of the axis. Label the axis $1/k_BT$ to remind yourself of the relationship between entropy gradient and temperature.
2. Mark the positions along the axis of the thermal inputs and outputs of energy of the device. Transfers at higher temperature are on the left; transfers at lower temperature are on the right. Use downward-pointing arrows for inputs, use upward-pointing arrows for outputs, and label these Q_{in} and Q_{out}.
3. Mechanical transfers of energy are placed at the origin of the axis. Use a downward-pointing arrow when the work done on the system is positive and an upward-pointing arrow when the work done on the system is negative. Label this arrow by W and indicate whether $W > 0$ or $W < 0$.
4. Draw rectangles to represent each energy transfer. Make the height of each rectangle proportional to the amount of energy transferred (but see point 5 below). Use an arrowhead to indicate the direction of each transfer.
5. For the operation of the device to be permitted by the entropy law, the combined area of the rectangles in which the arrows point right must be at least as large as the combined area of the rectangles in which the arrows point left.

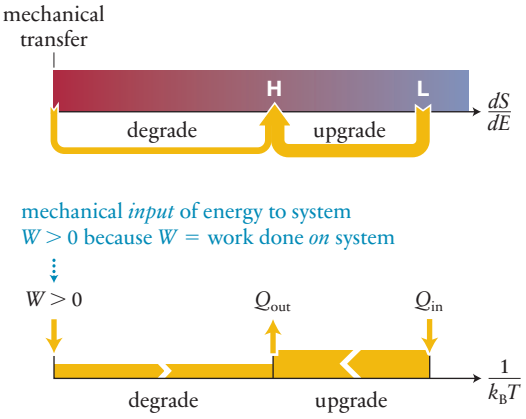
Example 21.3 and Checkpoint 21.9 show that it is beneficial to take energy in at the highest possible temperature and discard energy at the lowest possible temperature. Doing so minimizes the thermal input of energy for a fixed amount of work done on the environment.

We can define the **efficiency** of a heat engine as follows:

> **The efficiency of a heat engine is the ratio of the work done by the engine on the environment to the thermal input of energy into the engine. For a heat engine operating between two fixed-temperature reservoirs, the efficiency is greatest when the thermal input of energy takes place at the highest possible temperature and the thermal output of energy takes place at the lowest possible temperature.**

We see now that no heat engine—even a reversible one—can have an efficiency of 1.00 because some fraction of the thermal input of energy has to be degraded to make up for the entropy decrease that occurs in the process of upgrading the energy. The imperfect efficiency of heat engines has nothing to do with friction in the moving parts or other irreversible phenomena; rather, it is a direct consequence of the entropy law.

CONCEPTS



21.10 When the temperature of the output reservoir in Example 21.3 is lowered, does the efficiency increase, remain the same, or decrease?

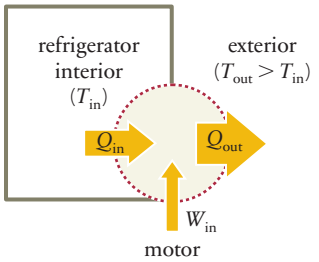
As you saw in Checkpoint 21.7, there are more ways to cause a degradation of energy that compensates for an upgrade than the one shown in Figure 21.21. For example, you can swap the roles of the upgrade and degradation shown in Figure 21.21. The resulting entropy diagram, shown in **Figure 21.25a**, represents the operation of a **heat pump.** In a heat pump, mechanical energy is degraded in order to thermally transfer energy from a lower-temperature region of the environment to a higher-temperature region of the environment—a direction opposite the natural direction in which energy is transferred thermally. Note that work is done on the device, so $W > 0$.

The refrigerator is one familiar example of a heat pump (Figure 21.25*b*). The interior of the refrigerator constitutes the reservoir at T_{in}; the air surrounding the

Figure 21.25 Energy conversions in a heat pump.

(*a*) Entropy diagrams for energy conversions in heat pump

(*b*) Energy input-output diagram for refrigerator (a type of heat pump)



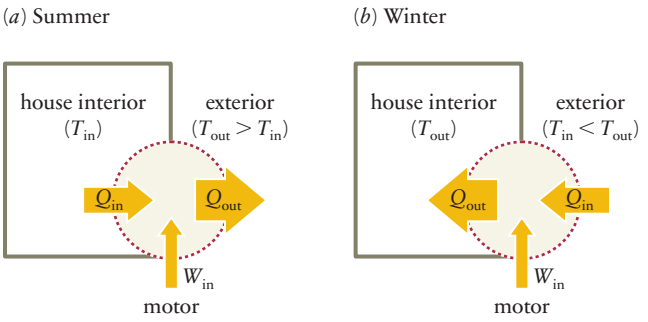


Figure 21.26 A heat pump can serve as an air-conditioner in summer by removing energy from inside the house and as a heater in winter by transferring energy thermally from outside to inside the house.

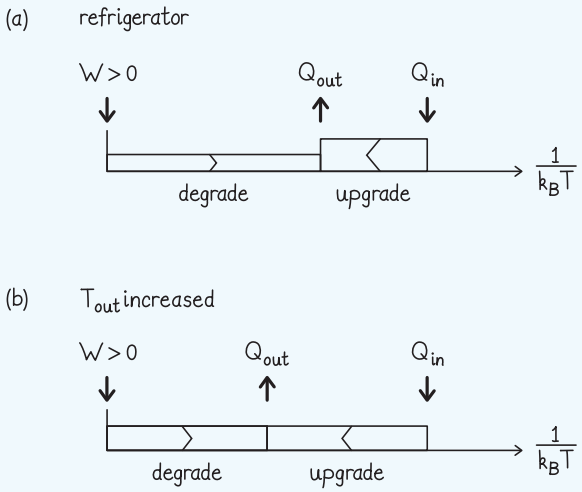
refrigerator is the reservoir at T_{out} (coils at the back or bottom of the refrigerator transfer the energy Q_{out} to the air).

Heat pumps are also used to heat and cool houses. In the summer, a heat pump operates as an air-conditioner and cools a house by moving energy from inside the house to outside (from cold to hot; **Figure 21.26*a***). In the winter, the same heat pump heats by moving energy from outside the house to inside (again from cold to hot, Figure 21.26*b*).

In designing a heat pump for cooling, we want to maximize the amount of energy transferred thermally from the low-temperature reservoir for a given amount of work done on the heat pump. The **coefficient of performance of cooling** of a heat pump is defined as the ratio of the thermal input of energy (the energy transferred thermally from the space that must be cooled) to the work done on the heat pump.



EXAMPLE 21.4 Cooling performance

For a set temperature T_{in} of a refrigerator interior, does the coefficient of performance of cooling increase, decrease, or stay the same as the temperature T_{out} of the room that contains the refrigerator increases? Assume the refrigerator is a reversible heat pump.

❶ **GETTING STARTED** I begin by drawing an entropy diagram for the refrigerator (**Figure 21.27*a***). Because the refrigerator is reversible, the areas of the upgrade and degrade rectangles are equal. The coefficient of performance of cooling is the ratio of the thermal input of energy Q_{in} (the height of the upgrade rectangle) to the work W done on the refrigerator (the height of the degrade rectangle).

❷ **DEVISE PLAN** To determine how the coefficient of performance of cooling changes as T_{out} increases, I must draw another entropy diagram, shifting the thermal output (the point where the two rectangles meet) to the left (Figure 21.27*b*). I must still have the area of the upgrade rectangle equal the area of the degrade rectangle, so in this diagram, I increase the height of the degrade rectangle and decrease that of the upgrade rectangle.

Figure 21.27

❸ **EXECUTE PLAN** The height of the upgrade rectangle corresponds to Q_{in}, and the height of the degrade rectangle corresponds to W. Shifting Q_{out} leftward to represent the increased T_{out} made the height of the upgrade rectangle (Q_{in}) smaller and the height of the degrade rectangle (W) greater. The ratio Q_{in}/W therefore decreases, which means that the coefficient of performance of cooling decreases. ✔

❹ **EVALUATE RESULT** The fact that the coefficient of performance of cooling decreases means that more energy is required to cool the refrigerator interior when the air outside the refrigerator is at a higher temperature, which makes sense intuitively. The reason is that when the refrigerator discards energy to the environment at a higher temperature, a given amount of energy causes a smaller entropy increase than when the energy is discarded at a lower temperature. This degradation of energy therefore compensates a smaller upgrade, reducing the coefficient of performance of cooling.

In designing a heat pump for heating, we want to maximize the thermal output of energy to the high-temperature reservoir for a given amount of work done on the heat pump. The **coefficient of performance of heating** of a heat pump is defined as the ratio of the thermal output of energy (the energy delivered thermally to the space that must be heated) to the work done on the heat pump.

Ordinary heating transfers energy from a high-temperature reservoir (say, burning fuel) to a low-temperature reservoir (a room to be heated, say), and the thermal input of energy Q_{in} is equal to the thermal output of energy Q_{out} (Figure 21.11). Equivalently, in Figure 21.14, $W = W_{in} > 0$ is converted to an identical amount of energy Q_{out}. In a heat pump, however, $Q_{out} > Q_{in}$, as Figure 21.26 indicates, because $Q_{out} = Q_{in} + W$. Note that while heat engines have an efficiency less than 1, the coefficient of performance of heating always exceeds 1. A typical heat pump has a coefficient of performance of heating of 3 to 4.

CONCEPTS

21.11 Estimate these quantities for the heat pump in Figure 21.26: (*a*) coefficient of performance of cooling and (*b*) coefficient of performance of heating.

21.4 Thermodynamic cycles

Heat engines and heat pumps are made up of three important components: a collection of moving parts, thermal reservoirs, and a *working substance* that undergoes a series of thermodynamic processes. For example, in the (heat) engine of an automobile, a mixture of air and gasoline is the working substance that produces the motion of the pistons that propels the automobile. Thermal energy generated in the combustion is transferred thermally to the environment through the engine's exhaust, and so the environment serves as a thermal reservoir. In a power plant, the working substance is water, which drives the blades of steam turbines. The steam boiler and the outside air serve as thermal reservoirs that transfer energy thermally to and from the water.

In this section we look at the thermodynamic processes that the working substance undergoes during the operation of a heat engine or heat pump. As we have seen, the engine or pump is a steady device: It must periodically return to a certain initial state. The working substance must therefore undergo a *cyclic process*—a sequence of steps in which the working substance begins and ends in the same thermal equilibrium state. Under those circumstances, the energy and the entropy of the working substance return to their initial values in one cycle.

Figure 21.28*a* illustrates a cyclic process that involves an expansion from state 1 to state 2 and then a compression back to state 1 via another path. We saw in Chapter 20 that during an expansion the work done on the system is negative and during a compression the work done on the system is positive. If the expansion takes place at a lower pressure than the compression (as it does in Figure 21.28*a*), the work done on the system during the expansion is smaller in magnitude than the work done during the compression. Therefore the work done on the system during a complete cycle from 1 to 2 and back to 1 is positive.

As we saw in Chapter 20, the magnitude of the negative work done on the system during the expansion $1 \rightarrow 2$ is equal to the hatched area in Figure 21.28*b*. The magnitude of the positive work done on the system during the compression $2 \rightarrow 1$ is equal to the shaded area in Figure 21.28*c*. Adding these two areas and taking their signs into account, we see that the work done on the system during a complete cycle is equal to the shaded area enclosed by the path that represents the cycle, as illustrated in 21.28*d*.

21.12 If you begin at state 1 again but this time go through the cycle in Figure 21.28 clockwise rather than counterclockwise, what are the magnitude and sign of (*a*) the work done on the system and (*b*) the work done on the environment?

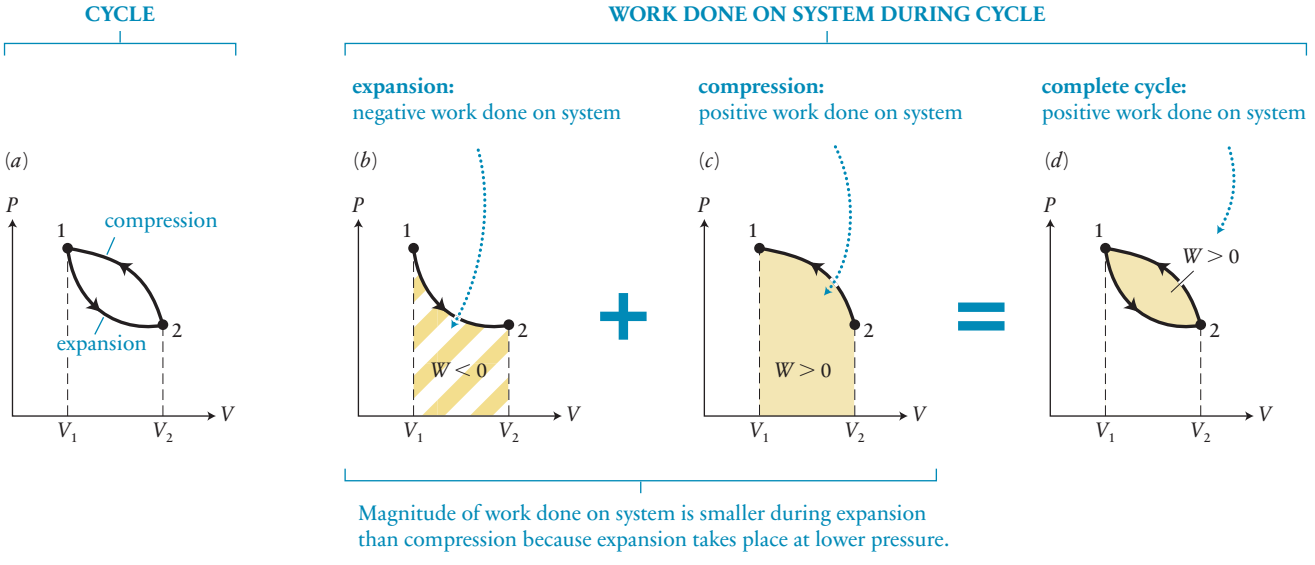
Figure 21.28 and Checkpoint 21.12 demonstrate an important point:

The magnitude of the work done on a system during a cycle is equal to the area enclosed by the path that represents the cycle in a *PV* diagram. The work done on the system is negative for a clockwise cycle and positive for a counterclockwise cycle.

Because heat engines do positive work on the environment, their cycles are clockwise. Conversely, the environment

CONCEPTS

Figure 21.28 The work done on a system during a thermodynamic cyclic process is equal in magnitude to the area enclosed by the pathways making up the cycle.



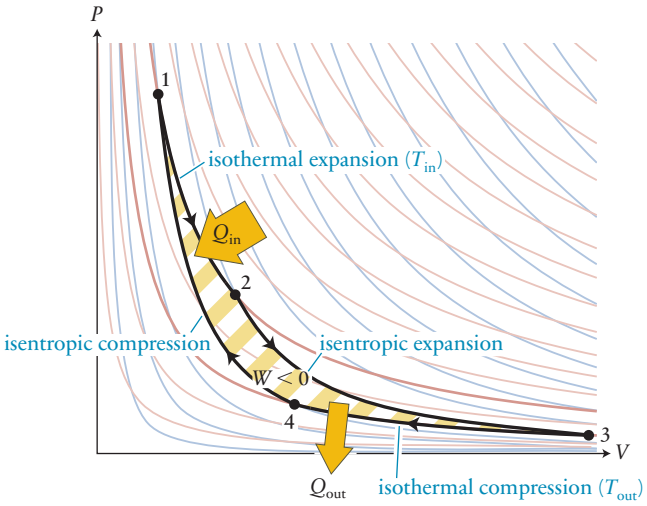


Figure 21.29 *PV* diagram for the thermodynamic process known as the Carnot cycle.

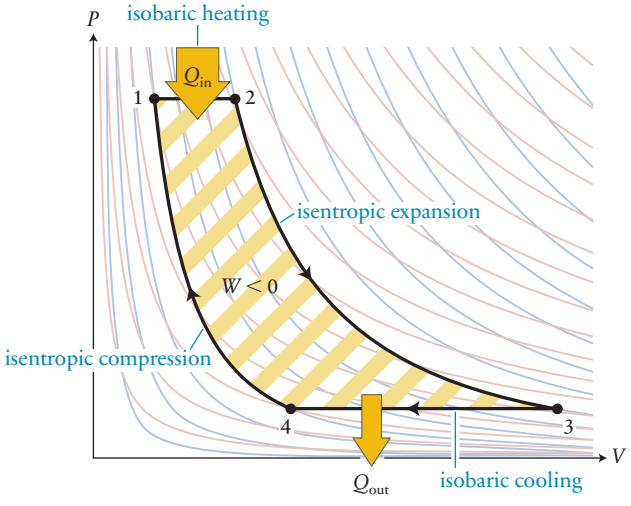
does positive work on heat pumps, and so their cycles are counterclockwise.

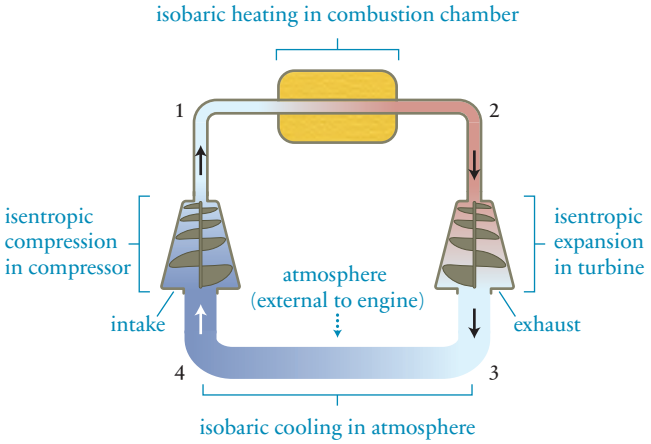
What thermodynamic processes occur in a heat engine? To answer this question, let us consider first the thermal input of energy from the high-temperature reservoir. This process takes place at a constant temperature T_{in} and so is isothermal. The thermal output of energy at temperature $T_{out} < T_{in}$ is also isothermal. It is not possible to construct a cycle from two isotherms, so we need other processes to connect the two isotherms. Because no other thermal exchange of energy takes place, these other processes we are looking for must be isentropic. **Figure 21.29** shows a thermodynamic cycle that consists of two isothermal processes ($1 \rightarrow 2$ and $3 \rightarrow 4$) and two isentropic processes ($2 \rightarrow 3$ and $4 \rightarrow 1$). Because of its importance in thermodynamics, this cycle is called the **Carnot cycle** after the French physicist Sadi Carnot (1796–1832), who produced the first successful description of the operation of heat engines.

Beginning in state 1 in Figure 21.29, the working substance expands isothermally at a temperature T_{in} until it reaches some state 2 (at which point its volume has increased). The working substance then undergoes an isentropic expansion during which its temperature drops from T_{in} to T_{out}. From this state 3, the working substance is compressed isothermally to state 4, from where it undergoes an isentropic compression back to state 1, completing the cycle.



Energy is transferred thermally into and out of the system only during the two isothermal processes, but all four processes involve work. The work done on the system during the cycle is equal to the area enclosed by the cycle and has been shaded in Figure 21.29. Because W is negative, the shading is hatched. (Remember that is what we want: The heat engine must do positive work *on its environment*, and so the work done *on the system* is negative.)

The Carnot cycle has a number of deficiencies that makes it impractical for a heat engine. First of all, as you can see from the small hatched area in Figure 21.29, the amount of work done on the environment in each cycle is small. More important, the presence of the isotherms means that the cycle cannot be repeated quickly. As we saw in Section 20.7, isothermal processes are very slow, and so an engine that operates on the Carnot cycle would put out mechanical energy at a very low rate; that is, its power would be very small.



To alleviate these problems, we want to avoid isotherms and "open up" the cycle so that more work is done on the environment. If we replace the two isotherms in Figure 21.29 by isobars, we obtain the cycle shown in **Figure 21.30*a***. This cycle, called the **Brayton cycle**, does substantially more work on the environment than the Carnot cycle and can be carried

Figure 21.30 The thermodynamic process known as the Brayton cycle.

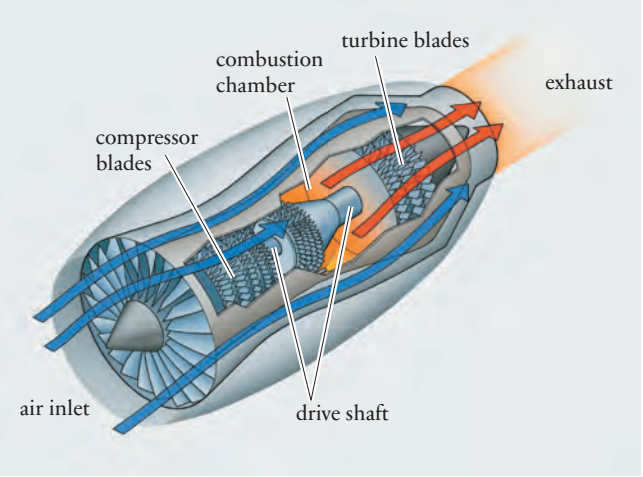
(*a*) *PV* diagram for Brayton cycle

(*b*) Flow chart for gas turbine operating on Brayton cycle

CONCEPTS

out fairly quickly. Gas turbines and jet engines operate on a cycle that is closely approximated by the Brayton cycle.

In the Brayton cycle, the working substance undergoes two isobaric processes ($1 \rightarrow 2$ and $3 \rightarrow 4$) and two isentropic processes ($2 \rightarrow 3$ and $4 \rightarrow 1$). Energy thermally enters and leaves the system during the isobaric processes. If we begin and end the isentropic compression in Figures 21.29 and 21.30 from the same states 4 and 1, the hatched area enclosed by the Brayton cycle is much larger than the area enclosed by the Carnot cycle. The larger hatched area means that a steady device that operates on the Brayton cycle has a much greater mechanical output of energy than a steady device that operates on the Carnot cycle. Also, the isobaric and isentropic processes can be carried out rapidly, which means the power output in a Brayton cycle can be high.



A gas turbine engine that operates on the Brayton cycle has three main components: a gas compressor, a combustion chamber, and an expansion turbine. In practice, such an engine is an open system: Fresh air flows in at one end, and hot gases are expelled at the other end. For the purpose of thermodynamic analysis, however, we can pretend that the exhaust gases are reused in the intake.

Figure 21.30*b* shows a flow chart for a gas turbine engine. Gas—typically ambient air—is drawn into the compressor, which isentropically compresses the air to high pressure $4 \rightarrow 1$. The compressed air then flows into the combustion chamber, where it is heated to temperatures as high as 2000 K at constant pressure ($1 \rightarrow 2$). The heated, pressurized air then expands isentropically ($2 \rightarrow 3$), and the hot gases are expelled at high speed from the rear of the engine, driving the engine forward. The exhaust gases then cool back down to the intake temperature—another constant-pressure process ($3 \rightarrow 4$)—and the cycle is complete.

To power the compressor, a turbine is placed in the expansion chamber. The expanding gases drive this turbine, which in turn feeds some energy from the expanding gases to the compressor. In a jet engine, for example, the turbine and the compressor are placed on a single drive shaft, so the turbine directly feeds the compressor (**Figure 21.31**).

Although the Brayton cycle delivers more energy and power than the Carnot cycle, it is not as efficient, which means that the work done on the environment divided by the thermal input of energy is smaller. The reason for this diminished efficiency is illustrated in **Figure 21.32*a***. In the Brayton cycle, the thermal input and output of energy do not take place at fixed temperatures as in the Carnot cycle. The Brayton thermal input of energy starts at the temperature T_1 reached during compression and then moves up to a higher

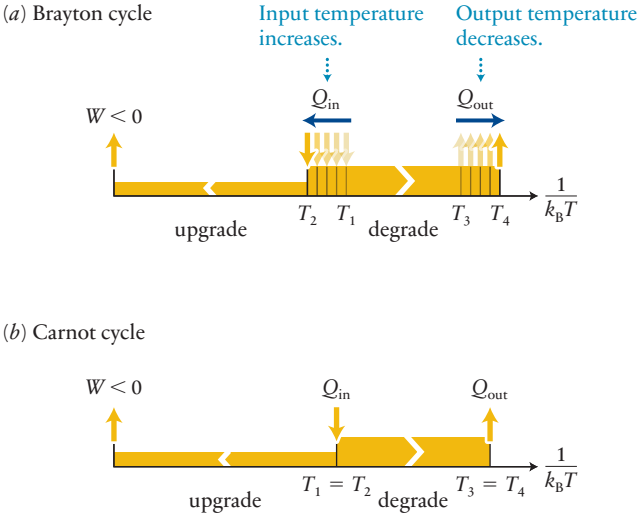


Figure 21.31 Jet engine.

temperature T_2 during combustion. The thermal output of energy starts at temperature T_3 (the temperature at the end of the isentropic expansion) and then slides down to the lower temperature T_4 (the temperature at the beginning of the isentropic compression).

As we saw in Section 21.3, the efficiency of a heat engine is highest when the thermal input of energy takes place at the highest possible temperature and the output at the lowest possible temperature. So the part of the cycle where thermal input of energy occurs at T_2 and thermal output of energy occurs at T_4 has the greatest efficiency. All other parts of the cycle have lower efficiency, which contributes to an overall efficiency that is lower than the efficiency we would see if *all* energy exchange had taken place at only the highest and lowest temperatures, T_2 and T_4, respectively. By contrast, thermal input of energy at one

CONCEPTS

Figure 21.33 A Brayton cycle run in reverse is the cycle for a heat pump.

(*a*) *PV* diagram for Brayton cycle run in reverse

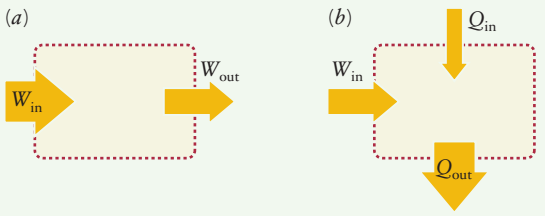
(*b*) Flow chart for refrigerator operating on reverse Brayton cycle

fixed high temperature and output at one fixed low temperature is exactly what happens in a Carnot cycle (Figure 21.32*b*).

By running the Brayton cycle in reverse (**Figure 21.33*a***), we obtain a heat pump. The cycle used in refrigerators, air-conditioners, and home heat pumps is a bit more complex because the working substance in these devices changes from liquid to vapor and back. However, if we assume the working substance is a gas, the basic thermodynamic processes are the isentropic ($3 \rightarrow 2$ and $1 \rightarrow 4$) and isobaric ($2 \rightarrow 1$ and $4 \rightarrow 3$) ones illustrated in Figure 21.33*a*.

Figure 21.33*b* shows a flow chart of the reverse Brayton cycle that takes place in a refrigerator. The working substance is first isentropically compressed by a motor-driven piston ($3 \rightarrow 2$). The compression raises both the temperature and the pressure in the working substance, which is then cooled down at constant pressure in a long coiled tube called the *condenser* ($2 \rightarrow 1$). This tube is exposed to the ambient temperature. After passing through the condenser, the high-pressure and now somewhat cooler working substance passes through an expansion valve ($1 \rightarrow 4$) and expands isentropically. In the process of expanding, the working substance cools significantly. It then passes through a second set of coils called the *evaporator* ($4 \rightarrow 3$). Because the temperature of the space around the evaporator is higher than the temperature of the working substance in the evaporator, energy is thermally transferred from the surrounding space to the evaporator. As Figure 21.33*b* shows, this space surrounding the evaporator is the interior of the refrigerator, where food is stored and thus kept cold. After passing through the evaporator, the working substance is returned to the compressor, where the cycle repeats.

Note that a heat pump transfers energy from the interior of the refrigerator at low temperature to the room at a higher temperature. To accomplish this, it needs mechanical energy to first raise the temperature of the working substance above that of the room so that energy can be transferred thermally out of the hot working substance into the room. Then the temperature of the working substance is lowered to below that of the interior of the refrigerator so that energy can be transferred thermally from the interior of the refrigerator into the working substance.



21.13 Why doesn't the transfer of energy from the interior of the refrigerator to the room violate the entropy law?

Answers

1. (*a*) More work is done on the system than the system does on the environment, so the energy of the system increases. (*b*) More energy is transferred thermally out of the system than into it, and work is done on the system. Depending on how the work done on the system compares to the difference between the thermal transfers of energy, the energy of the system can increase, decrease, or stay the same.
2. In both cases mechanical energy is degraded into thermal energy of a high-temperature reservoir while thermal energy of a low-temperature reservoir is upgraded to thermal energy of a high-temperature reservoir. (*a*) Because the area of the degrade rectangle is larger than the area of the upgrade rectangle, entropy is increasing, so this process is possible. (*b*) Because the area of the upgrade rectangle is larger than the area of the degrade rectangle, entropy is decreasing, so this process is not possible.
3. Efficiency $= -W/Q_{in}$, the coefficient of performance of cooling $= Q_{in}/W$, and the coefficient of performance of heating $= Q_{out}/W$. The quantities in the numerator are the desired results: work done by the engine on the environment, energy transferred thermally out of the contents of the refrigerator, and energy transferred thermally into the room to be heated. The quantities in the denominator are the energies required to obtain the desired result: the thermal transfer of energy required to run the engine and the work required to run the refrigerator or heat pump.
4. ΔE: $1 \rightarrow 2 = 0$ (isotherm); $2 \rightarrow 3 = -$ (temperature decreases); $3 \rightarrow 4 = 0$ (isotherm); $4 \rightarrow 1 = +$ (temperature increases). W: $1 \rightarrow 2 = -$ (expansion); $2 \rightarrow 3 = 0$ (isochoric process); $3 \rightarrow 4 = +$ (compression); $4 \rightarrow 1 = 0$ (isochoric process). Q (sign follows from signs of ΔE and W): $1 \rightarrow 2 = +$; $2 \rightarrow 3 = -$; $3 \rightarrow 4 = -$; $4 \rightarrow 1 = +$.

21.5 Entropy constraints on energy transfers

In the first part of this chapter, we used entropy diagrams to describe the energy conversions that occur in heat engines and pumps. We stated, without proof, that the area of the rectangle for any energy conversion or transfer represented in such a diagram is a measure of the corresponding entropy change. In this section we develop the quantitative framework for computing entropy changes from entropy diagrams.

Steady devices return to the same state after one cycle, so that

$$\Delta E = 0 \quad \text{(steady device, complete cycle)}. \tag{21.1}$$

The energy law (Eq. 20.1) then tells us that for a steady device $Q + W = 0$. Because $Q = Q_{\text{in}} - Q_{\text{out}}$, we see that over one cycle the work done on a steady device must be equal to the difference in the thermal output and input of energy:

$$W = Q_{\text{out}} - Q_{\text{in}} \quad \text{(steady device, complete cycle)}. \tag{21.2}$$

Because the initial and final states are the same, the entropy of a steady device doesn't change either:

$$\Delta S_{\text{dev}} = 0 \quad \text{(steady device, complete cycle)}. \tag{21.3}$$

From Chapter 19 we know that only processes in which the entropy either increases or remains unchanged can occur:

$$\Delta S_{\text{dev}} + \Delta S_{\text{env}} \geq 0. \tag{21.4}$$

Equation 21.3 thus means that we must have

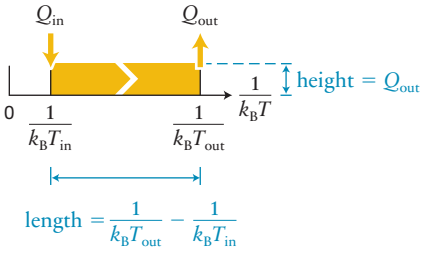
$$\Delta S_{\text{env}} \geq 0 \quad \text{(steady device, complete cycle)}. \tag{21.5}$$

As we saw in the first part of this chapter, the entropy constraint in Equation 21.5 limits the type of energy transfers that can occur in a steady device.

21.14 What is the change in the energy of the environment in a device for which Eqs. 21.1–21.5 hold?

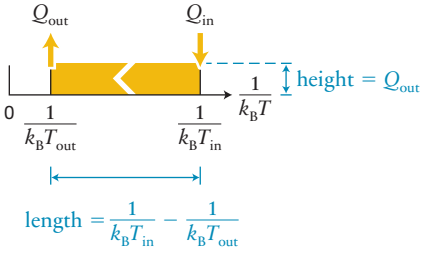
We begin by considering a steady device that transfers energy thermally from a reservoir at temperature T_{in} to a reservoir at a lower temperature $T_{\text{out}} < T_{\text{in}}$ (**Figure 21.37*a***).

In Chapter 20 we saw that the entropy change associated with energy transferred thermally at a fixed temperature is given by (Eq. 20.54)



$$\Delta S = \frac{Q}{k_{\text{B}}T} \quad \text{(isothermal process)}. \tag{21.6}$$

The entropy diagram in Figure 21.37*a* shows two thermal transfers of energy—a transfer out of the environment at the high-temperature reservoir and a transfer into the environment at the low-temperature reservoir. Let us first apply Eq. 21.6 to the high-temperature reservoir. Because energy is transferred thermally out of that reservoir, $Q_{\text{H}} = -Q_{\text{in}} < 0$. Equation 21.6 thus yields a negative entropy change of the high-temperature reservoir, which is at temperature T_{in}:



$$\Delta S_{\text{H}} = -\frac{Q_{\text{in}}}{k_{\text{B}}T_{\text{in}}}. \tag{21.7}$$

Figure 21.37 Entropy diagram for thermal transfer of energy (*a*) from a high-temperature reservoir to a low-temperature reservoir and (*b*) from a low-temperature reservoir to a high-temperature reservoir.

(*a*) Transfer to lower-temperature reservoir

(*b*) Transfer to higher-temperature reservoir

QUANTITATIVE TOOLS

Likewise, for the low-temperature reservoir, which is at temperature T_{out}, $Q_L = Q_{out} > 0$, so the entropy change is positive:

$$\Delta S_L = \frac{Q_{out}}{k_B T_{out}}. \tag{21.8}$$

Adding the entropy changes in the environment, we get for the environment entropy change during the complete cycle represented in the entropy diagram

$$\Delta S_{env} = \Delta S_H + \Delta S_L = -\frac{Q_{in}}{k_B T_{in}} + \frac{Q_{out}}{k_B T_{out}} \quad \text{(steady state)}. \tag{21.9}$$

Because $\Delta E = 0$ (Eq. 21.1) and because no work is involved, the energy law tells us that $\Delta E = Q_{in} - Q_{out} = 0$, so $Q_{in} = Q_{out}$. Substituting this result in Eq. 21.9, we obtain for the entropy change in the environment

$$\Delta S_{env} = -\frac{Q_{out}}{k_B T_{in}} + \frac{Q_{out}}{k_B T_{out}} = Q_{out}\left(\frac{1}{k_B T_{out}} - \frac{1}{k_B T_{in}}\right) \quad \text{(steady state)}. \tag{21.10}$$

The right side of this equation gives exactly what we have been calling the area of the rectangle representing the energy transfer in the entropy diagram. As Figure 21.37*a* shows, the height of this rectangle is Q_{out} (a positive quantity):

$$\text{height of rectangle} = Q_{out}. \tag{21.11}$$

If we use the quantity $1/k_B T$ to quantify the horizontal scale in the diagram, we see that the left edge of the rectangle is at $1/k_B T_{in}$ and the right edge is at $1/k_B T_{out}$. The length of the rectangle is thus

$$\text{length of rectangle} = \frac{1}{k_B T_{out}} - \frac{1}{k_B T_{in}}. \tag{21.12}$$

Because $T_{out} < T_{in}$, this quantity is positive. Note that the length is exactly equal to the term in parentheses in Eq. 21.10, so the product of the height and the length—the area—of the rectangle indeed represents the entropy change of the environment ΔS_{env} due to the transfer of energy from the high-temperature reservoir to the low-temperature reservoir.

Let us next consider the reverse process: a thermal transfer of energy from a low-temperature reservoir to a high-temperature reservoir. As we saw in Section 21.2, such an upgrade of energy is not possible. The entropy diagram for this impossible process is shown in Figure 21.37*b*. Note that the rectangle has the same length and height as the one in Figure 21.37*a*. It points to the left (from low temperature to high temperature), indicating that the entropy change is negative. Therefore we take the negative of the area of the rectangle to compute the entropy change in the environment:

$$\Delta S_{env} = -Q_{out}\left(\frac{1}{k_B T_{in}} - \frac{1}{k_B T_{out}}\right) \quad \text{(steady state)}. \tag{21.13}$$

Because the entropy change in the environment must be positive (Eq. 21.5), we see that this type of transfer cannot occur by itself.

The procedure for computing the entropy change from an entropy diagram is presented in the Procedure box "Computing entropy changes from entropy diagrams."

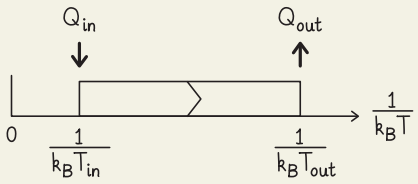
QUANTITATIVE TOOLS

PROCEDURE: Computing entropy changes from entropy diagrams

To determine the entropy change in the environment from an entropy diagram, compute the area of the rectangles that represent the energy transfers as follows:

1. Determine the length of the horizontal part of each rectangle by subtracting the position of the left end of the rectangle on the $1/k_BT$ scale from the position of the right end on the scale. The position of mechanical energy is always at the zero point on this scale. Verify that the result is a positive quantity. (If it isn't, you made a mistake somewhere.)
2. Express the height of each rectangle in terms of Q_{in}, Q_{out}, and W. Remember that the height must be a positive quantity; Q_{in} and Q_{out} are always positive, but W can be positive or negative. Avoid using the input or output where two rectangles meet; if necessary, you can use Eq. 21.2, $W = Q_{out} - Q_{in}$, to express the height in terms of the quantities that are given in the problem.
3. Determine the sign of the entropy change. If the rectangle points left (energy upgrade), the entropy change is negative. If the rectangle points right (energy degradation), the entropy change is positive.
4. The entropy change for each rectangle is given by the area of the rectangle (the length multiplied by the height computed in steps 1 and 2) preceded by the algebraic sign determined in step 3:

$$\Delta S = (\text{sign}) \times (\text{length}) \times (\text{width}).$$



5. The entropy change for the process is the sum of the individual entropy changes you have calculated.

EXAMPLE 21.5 Thermal transfer of energy

A steel bar transfers energy from a thermal reservoir at 750 K to one at 520 K. If the bar transfers 1.5×10^6 J of energy during a certain time interval over which the temperature distribution of the bar does not change, what is the entropy change of the environment?

❶ **GETTING STARTED** Because the temperature distribution does not change, the state of the bar remains constant and I can consider the bar to be a steady device. I begin by drawing an entropy diagram (**Figure 21.38**), showing a right-pointing arrow in the rectangle because the direction of the energy transfer is from the higher-temperature reservoir to the lower-temperature one. I am given $T_{in} = 750$ K, $T_{out} = 520$ K, and the amount of energy transferred $Q_{in} = Q_{out} = 1.5 \times 10^6$ J.

Figure 21.38

❷ **DEVISE PLAN** To determine the entropy change of the environment, I follow the procedure shown above that tells me how to compute the entropy change from my entropy diagram.

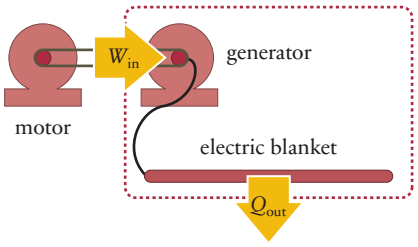
❸ **EXECUTE PLAN** Because the rectangle arrow points to the right, I know that the entropy of the environment increases and thus the entropy change is positive. The height of the rectangle is Q_{in}. The length is $[1/k_BT_{out} - 1/k_BT_{in}]$. The entropy change is thus

$$\Delta S_{env} = +Q_{in}\left[\frac{1}{k_BT_{out}} - \frac{1}{k_BT_{in}}\right] = \frac{+Q_{in}}{k_B}\left[\frac{1}{T_{out}} - \frac{1}{T_{in}}\right].$$

Substituting the values given, I obtain

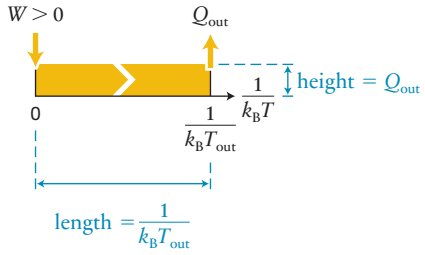
$$\Delta S_{env} = \frac{1.5 \times 10^6 \text{ J}}{1.38 \times 10^{-23} \text{ J/K}}\left[\frac{1}{520 \text{ K}} - \frac{1}{750 \text{ K}}\right]$$

$$= 6.4 \times 10^{25}. \checkmark$$



❹ **EVALUATE RESULT** Energy is degraded (hot to cold), so I expect a positive entropy change. The number I obtained for the magnitude of the entropy change is very large, but I know from Chapter 19 that entropy values are very large, and so my answer is not unreasonable.

21.15 Suppose the bar in Example 21.5 is disconnected from the high-temperature reservoir and allowed to thermally equilibrate with the low-temperature reservoir. (*a*) Are the changes in the energy and entropy of the bar during this process positive, negative, or zero? (*b*) Is there any change in the entropy of the environment? (*c*) Does the sum $S_{bar} + S_{env}$ change?



Next we consider a device that converts mechanical energy (work) to thermal energy. In Section 21.1 we discussed a paddle wheel immersed in water. Now we consider a somewhat different situation: a motor doing work on an electric generator that delivers electrical energy to an electric blanket,

Figure 21.39 A setup that converts mechanical energy (from the motor) to thermal energy.

(*a*)

(*b*)

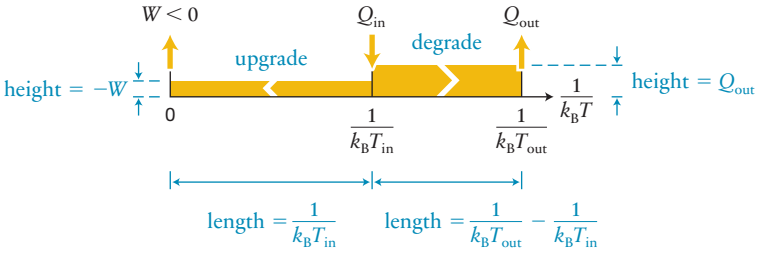
which converts the electrical energy to thermal energy (**Figure 21.39*a***). We define the generator, blanket, and wires that connect the two as our system. The motor (which is part of the environment) does work on the system, and energy is transferred thermally by the blanket (part of the system) to the environment. We assume that the temperatures of the blanket and the environment remain constant. This assumption ensures that the initial and final states of the system are the same.

Figure 21.39*b* shows the entropy diagram for this process. Because the transfer is to the right, the entropy change is positive. The height of the rectangle is Q_{out}. (Because $W = Q_{out}$ we could also write the height of the rectangle as W.) The rectangle stretches from the origin (0 on the $1/k_B T$ scale) to $1/k_B T_{out}$, so its length is $1/k_B T_{out}$. The entropy change is thus

$$\Delta S_{env} = +Q_{out}\frac{1}{k_B T_{out}} = \frac{Q_{out}}{k_B T_{out}} \quad \text{(steady state)}. \qquad (21.14)$$

This is indeed the result we would expect: No entropy change is associated with the work done on the system, and the entropy change caused by the thermal transfer of energy to the environment is $Q_{out}/k_B T_{out}$, which is exactly the result we obtain in Eq. 21.14.

21.16 (*a*) Draw an entropy diagram for a steady device that converts thermal energy from a thermal reservoir to mechanical energy. (*b*) From the diagram, compute the entropy change that occurs during the process and show that such a device is impossible.



21.6 Heat engine performance

Consider a heat engine that takes in energy thermally from a high-temperature reservoir, converts part of this energy to mechanical energy by doing work on the environment ($W < 0$), and discards the remainder to a low-temperature reservoir. As we saw in Section 21.3, the entropy diagram has two rectangles: one for the energy upgrade and the other for the degradation (**Figure 21.40**). To determine the entropy change in the environment over one complete cycle, we add the entropy changes of the two rectangles:

$$\Delta S_{env} = \Delta S_{upgrade} + \Delta S_{degrade} \quad \text{(complete cycle)}. \qquad (21.15)$$

The entropy change for the degradation is given by Eq. 21.10, so we need only calculate the change for the upgrade. The height of the upgrade rectangle is $-W$. Because $W = Q_{out} - Q_{in}$ (Eq. 21.2), the height of the rectangle can also be written as $Q_{in} - Q_{out}$. The rectangle stretches from the origin (0 on the $1/k_B T$ scale) to $1/k_B T_{in}$, so its length is $1/k_B T_{in}$. Because

Figure 21.40 Entropy diagram for a heat engine that upgrades a portion of the thermal energy to mechanical energy and degrades the rest.

QUANTITATIVE TOOLS

the transfer is to the left, the entropy change is negative. The entropy change associated with the upgrade is thus

$$\Delta S_{\text{upgrade}} = -(Q_{\text{in}} - Q_{\text{out}})\left[\frac{1}{k_B T_{\text{in}}}\right]. \tag{21.16}$$

Substituting Eqs. 21.16 and 21.10 into Eq. 21.15 gives

$$\Delta S_{\text{env}} = -(Q_{\text{in}} - Q_{\text{out}})\left[\frac{1}{k_B T_{\text{in}}}\right] + Q_{\text{out}}\left[\frac{1}{k_B T_{\text{out}}} - \frac{1}{k_B T_{\text{in}}}\right], \tag{21.17}$$

or

$$\Delta S_{\text{env}} = -\frac{Q_{\text{in}}}{k_B T_{\text{in}}} + \frac{Q_{\text{out}}}{k_B T_{\text{out}}} \quad \text{(complete cycle)}, \tag{21.18}$$

which is exactly Eq. 21.9, the expression we derived for the entropy change for a simple device that thermally transfers energy from a high-temperature reservoir to a low-temperature reservoir. The reason we obtain the same expression for the more complicated case of a heat engine is that no entropy change is associated with mechanical transfers of energy. Only the thermal transfers of energy to and from the thermal reservoirs contribute to the entropy change.

For a reversible heat engine, the entropy change in the environment must be equal to zero over one cycle (everything is back to what it was before), $\Delta S_{\text{env}} = 0$, so

$$-\frac{Q_{\text{in}}}{k_B T_{\text{in}}} + \frac{Q_{\text{out}}}{k_B T_{\text{out}}} = 0 \quad \text{(reversible heat engine)}. \tag{21.19}$$

Rearranging this equation, we get

$$\frac{Q_{\text{out}}}{Q_{\text{in}}} = \frac{T_{\text{out}}}{T_{\text{in}}} \quad \text{(reversible heat engine)}. \tag{21.20}$$

For a reversible heat engine that transfers energy from a thermal reservoir at T_{in}, the amount of energy discarded is proportional to T_{out}. The amount of energy discarded is independent of the type of working substance used and depends on only the temperatures of the two reservoirs. If we lower T_{out}, we decrease the amount of discarded energy, which means a greater portion of the input energy can be converted to mechanical energy. So we can maximize the work done on the environment by minimizing the temperature of the low-temperature reservoir.

21.17 Is it possible to reduce the amount of thermally discarded energy to zero by bringing T_{out} down to absolute zero?

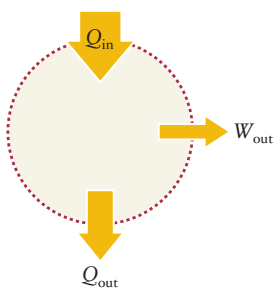


Figure 21.41 shows the energy input-output diagram for a heat engine. In Section 21.3 we defined the efficiency of such an engine as the ratio of the work done on the environment ($-W$) to the thermal input of energy (Q_{in}). Using the symbol η (lowercase Greek eta) for efficiency, we can write

$$\eta \equiv \frac{-W}{Q_{\text{in}}}. \tag{21.21}$$

Substituting W from Eq. 21.2 yields

$$\eta = \frac{Q_{\text{in}} - Q_{\text{out}}}{Q_{\text{in}}} = 1 - \frac{Q_{\text{out}}}{Q_{\text{in}}}. \tag{21.22}$$

Figure 21.41 Energy input-output diagram for a heat engine.

Equation 21.22 is a consequence of the energy law and holds for both reversible and irreversible heat engines that involve transfers of energy to and from two thermal reservoirs.

Figure 21.23 shows that for a given amount of work $-W$ done by a heat engine, Q_{in} is smallest when the engine is reversible. Therefore the efficiency of a heat engine is maximum when it is reversible. For a reversible heat engine, we can substitute Eq. 21.20 into Eq. 21.22 to obtain an expression for the maximum efficiency:

$$\eta_{max} = 1 - \frac{T_{out}}{T_{in}} = \frac{T_{in} - T_{out}}{T_{in}} \quad \text{(reversible heat engine)}. \quad (21.23)$$

In practice, the efficiency of a heat engine is always smaller than this maximum efficiency because it is impossible to completely eliminate irreversible processes. The important point to remember, however, is that even for a reversible heat engine, the efficiency is less than 1. The maximum efficiency is obtained with a minimum transfer of thermal energy to the low-temperature reservoir and has *nothing* to do with the details of the workings of the heat engine. *Only* the temperatures of the two reservoirs have any effect on the maximum efficiency: It is greatest when the ratio T_{out}/T_{in} is smallest.

EXAMPLE 21.6 Environmental impact of power plant

A power plant burns fossil fuel to produce steam at 650 K. The pressurized steam drives a steam turbine, where the steam condenses to water and is discarded at 310 K. What is the minimum quantity of energy discarded thermally by a 1.0-GW power plant to the environment during one day?

❶ **GETTING STARTED** Because I am interested in the minimum quantity of thermal energy discarded, I can treat the turbine as a reversible heat engine. Energy is thermally transferred to the turbine from the steam, which serves as the high-temperature reservoir at $T_{in} = 650$ K. Energy is thermally discarded along with the condensed steam at $T_{out} = 310$ K.

❷ **DEVISE PLAN** To calculate the minimum quantity of energy discarded to the environment, $Q_{out,min}$, I can use Eq. 21.2, which tells me that for a given value of W, Q_{out} is minimum when Q_{in} is minimum. No value is given for Q_{in}, but Eq. 21.21 tells me that Q_{in} is minimum when η has its maximum value, which I can calculate using Eq. 21.23. In one day, a 1.0-GW power plant delivers an amount of energy equal to $(24\text{ h})(3600\text{ s}/1\text{ h})\,(1.0 \times 10^9\text{ J/s}) = 8.6 \times 10^{13}$ J, and so $W = -8.6 \times 10^{13}$ J.

❸ **EXECUTE PLAN** The maximum efficiency is (Eq. 21.23)

$$\eta_{max} = \frac{650\text{ K} - 310\text{ K}}{650\text{ K}} = 0.523,$$

and so the minimum quantity of energy transferred thermally to the turbine is

$$Q_{in,min} = \frac{-W}{\eta_{max}} = \frac{8.6 \times 10^{13}\text{ J}}{0.523} = 1.6 \times 10^{14}\text{ J}.$$

From Eq. 21.2 I thus calculate the minimum quantity of energy discarded thermally:

$$Q_{out,min} = Q_{in,min} + W = (1.6 \times 10^{14}\text{ J}) - (8.6 \times 10^{13}\text{ J})$$
$$= 7.8 \times 10^{13}\text{ J}. \checkmark$$

❹ **EVALUATE RESULT** The quantity of thermal energy leaving the turbine is smaller than the quantity of thermal energy entering it (as it should be) and approximately equal to the quantity of energy delivered by the plant. This makes sense because the maximum efficiency is close to $\frac{1}{2}$. I assumed the turbine to be reversible, which is unlikely. However, if the turbine is not reversible, more energy is dissipated, and so my result for the minimum amount of energy discarded still holds.

QUANTITATIVE TOOLS

21.18 A hurricane thermally takes in energy from ocean water at 26 °C, discards some of it to the upper atmosphere at −52 °C, and converts the remainder to mechanical energy in the form of wind. (*a*) What is the maximum possible efficiency for the thermal-to-mechanical conversion? (*b*) If the temperature of the water increases by 1 °C, by what amount does the maximum efficiency increase?

If we run a heat engine in reverse, we obtain a heat pump (Figure 21.42). When the heat pump is used as a heater, we define the **coefficient of performance of heating** as

$$\text{COP}_{\text{heating}} \equiv \frac{Q_{\text{out}}}{W}. \tag{21.24}$$

Because $W = W_{\text{in}} > 0$ and $W = Q_{\text{out}} - Q_{\text{in}}$, Q_{out} is always greater than or equal to W, and so $\text{COP}_{\text{heating}}$ for a heat pump is always greater than or equal to 1.

Substituting Eq. 21.2 into Eq. 21.24 gives

$$\text{COP}_{\text{heating}} = \frac{Q_{\text{out}}}{Q_{\text{out}} - Q_{\text{in}}} = \frac{1}{1 - Q_{\text{in}}/Q_{\text{out}}}. \tag{21.25}$$

For a reversible heat pump that transfers energy from a lower-temperature thermal reservoir at T_{in} to a higher-temperature reservoir at T_{out}, we can substitute Eq. 21.20 into Eq. 21.25 to obtain the maximum coefficient of performance of heating:

$$\text{COP}_{\text{heating,max}} = \frac{1}{1 - T_{\text{in}}/T_{\text{out}}} = \frac{T_{\text{out}}}{T_{\text{out}} - T_{\text{in}}} \quad \text{(reversible heat pump)}. \tag{21.26}$$

This expression tells us that the maximum coefficient of performance of heating is greatest when the ratio $T_{\text{in}}/T_{\text{out}}$ is close to 1.

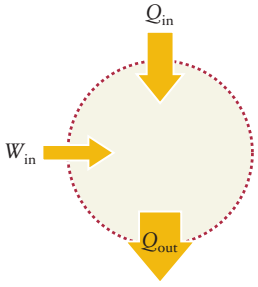
21.19 What is the coefficient of performance of heating for the electric blanket in Figure 21.39?

When a heat pump is used to cool (as a refrigerator or air conditioner), we define the **coefficient of performance of cooling** as

$$\text{COP}_{\text{cooling}} \equiv \frac{Q_{\text{in}}}{W}. \tag{21.27}$$

Substituting Q_{in} from Eq. 21.2 gives

$$\text{COP}_{\text{cooling}} = \frac{Q_{\text{out}} - W}{W} = \frac{Q_{\text{out}}}{W} - 1 = \text{COP}_{\text{heating}} - 1. \tag{21.28}$$



For a reversible heat pump, we can substitute Eq. 21.26 into Eq. 21.28 to obtain an expression for the maximum coefficient of performance of cooling:

$$\text{COP}_{\text{cooling,max}} = \frac{T_{\text{out}}}{T_{\text{out}} - T_{\text{in}}} - 1$$

$$= \frac{T_{\text{in}}}{T_{\text{out}} - T_{\text{in}}} \quad \text{(reversible heat pump)}. \tag{21.29}$$

For a refrigerator, the coefficient of performance of cooling is usually greater than 1 because the temperature of the interior T_{in} is around 255 K, and the temperature difference $T_{\text{out}} - T_{\text{in}}$ between the outside air and the interior is around 40 K.

Figure 21.42 Energy input-output diagram for a heat pump.

EXAMPLE 21.7 Cost of cooling off

The thermal insulation in a refrigerator is never perfect. Typically energy is transferred thermally from the room to the refrigerator interior at a rate of 60 W with the refrigerator door closed. Suppose the interior needs to be held at 4.0 °C and the temperature of the room is 20 °C. At what minimum rate must mechanical energy be delivered to the refrigerator to maintain the interior at 4.0 °C?

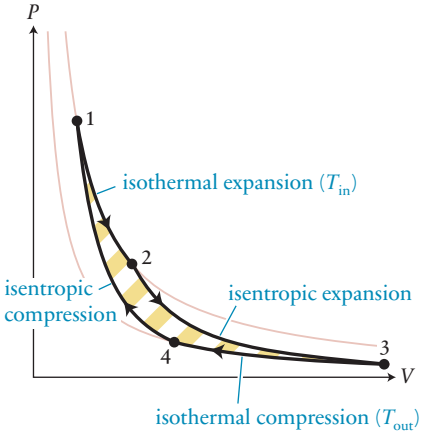
❶ **GETTING STARTED** Because I am interested in the minimum rate at which mechanical energy must be delivered, I can treat the refrigerator as a reversible heat pump. The room is the high-temperature reservoir, so $T_{out} = 20\ °C = 293\ K$. The refrigerator interior is the low-temperature reservoir, so $T_{in} = 4.0\ °C = 277\ K$. To maintain the temperature of the interior, the energy Q_{in} that leaks through the thermal insulation and moves from the room into the refrigerator must be transferred out. I am given that the rate at which this energy is transferred thermally into the refrigerator is $dQ_{in}/dt = 60\ W$.

❷ **DEVISE PLAN** To calculate the rate at which mechanical energy must be delivered to balance a given quantity Q_{in} moving from the room to the refrigerator interior, I should first calculate how much work needs to be done to transfer that quantity of energy out of the refrigerator. To calculate the work required to transfer this quantity of energy Q_{in} I can use Eq. 21.27: $W = Q_{in}/COP_{cooling}$. This expression tells me that the amount of work needed is minimum when $COP_{cooling}$ has its maximum value, which I can determine from Eq. 21.29. To obtain the rate at which mechanical energy must be delivered, I take the time derivative of W.

❸ **EXECUTE PLAN** The maximum coefficient of performance of cooling is (Eq. 21.29)

$$COP_{cooling,max} = \frac{277\ K}{293\ K - 277\ K} = 17,$$

so the minimum work required is $W_{min} = Q_{in}/COP_{cooling,max}$. Taking the derivative of this expression, I obtain



$$\left(\frac{dW}{dt}\right)_{min} = \frac{dQ_{in}/dt}{COP_{cooling,max}} = \frac{60\ W}{17} = 3.5\ W. \checkmark$$

❹ **EVALUATE RESULT** My calculated value for the rate at which mechanical energy must be delivered to cancel the thermal energy that leaks from the room to the refrigerator interior is 1/17 the rate at which that leaking occurs. This makes sense because the coefficient of performance of cooling is 17. This rate is small for what I expect for typical electrical appliances (several hundred watts), but I assumed the refrigerator was reversible. In reality, it is not reversible, and additional energy is dissipated, which means my calculated value is too low. Also, refrigerator doors are opened many times a day, thus increasing the rate of energy transferred thermally to the interior.

21.20 (*a*) If the heat pump from the refrigerator in Example 21.7 is used during the winter to heat a room to 20 °C when it's 4 °C outside, what is $COP_{heating}$? (*b*) At what rate must work be done on the heat pump if you want to heat the room at a rate of 500 W?

21.7 Carnot cycle

Figure 21.43 *PV* diagram for a Carnot cycle.

In Section 21.4, we identified the four processes that make up the Carnot cycle: two isothermal processes and two isentropic processes (**Figure 21.43**). Part of the energy taken in from a high-temperature reservoir is upgraded to mechanical energy, while the rest is degraded and discarded into a low-temperature reservoir (Figure 21.32*b*). The thermal transfer of energy occurs only during the isothermal processes at the two temperatures T_{in} and T_{out}.

As we study the Carnot cycle further, let us use an ideal gas as the working substance so that we can use our results for the entropy and thermal transfer of energy for each process from Tables 20.6 and 20.7, which are gathered together in **Table 21.1**.

To calculate the efficiency of a heat engine operating on this cycle from Eq. 21.21, we need to determine W and Q_{in}. We can obtain the work done on the working substance (our system) during the cycle from Table 21.1:

$$W = -Nk_B T_{in} \ln\left(\frac{V_2}{V_1}\right) - Nk_B T_{out} \ln\left(\frac{V_4}{V_3}\right) \quad \text{(Carnot cycle)}. \qquad (21.30)$$

We do not need to write the two isentropic work terms because they cancel out.

QUANTITATIVE TOOLS

Table 21.1 Entropy and energy changes for the working substance in a Carnot cycle (see Tables 20.6 and 20.7)

Process	Definition	ΔS_{dev}	ΔE_{th}	W	Q
$1 \rightarrow 2$ (*isothermal*)	$\Delta T = 0$	$N \ln\left(\frac{V_2}{V_1}\right)$	0	$-Nk_{\text{B}}T_{\text{in}} \ln\left(\frac{V_2}{V_1}\right)$	$Nk_{\text{B}}T_{\text{in}} \ln\left(\frac{V_2}{V_1}\right)$
$2 \rightarrow 3$ (*isentropic*)	$Q = 0$	0	$NC_V(T_{\text{out}} - T_{\text{in}})$	$NC_V(T_{\text{out}} - T_{\text{in}})$	0
$3 \rightarrow 4$ (*isothermal*)	$\Delta T = 0$	$N \ln\left(\frac{V_4}{V_3}\right)$	0	$-Nk_{\text{B}}T_{\text{out}} \ln\left(\frac{V_4}{V_3}\right)$	$Nk_{\text{B}}T_{\text{out}} \ln\left(\frac{V_4}{V_3}\right)$
$4 \rightarrow 1$ (*isentropic*)	$Q = 0$	0	$NC_V(T_{\text{in}} - T_{\text{out}})$	$NC_V(T_{\text{in}} - T_{\text{out}})$	0
cycle	reversible	0	0	$-Nk_{\text{B}}(T_{\text{in}} - T_{\text{out}}) \ln\left(\frac{V_2}{V_1}\right)$	$-W$

For a complete cycle the entropy change must be zero, and so summing the entropy changes in Table 21.1, we get

$$N \ln\left(\frac{V_2}{V_1}\right) + N \ln\left(\frac{V_4}{V_3}\right) = 0 \tag{21.31}$$

or

$$\ln\left(\frac{V_2}{V_1}\right) = -\ln\left(\frac{V_4}{V_3}\right), \tag{21.32}$$

which means that

$$\frac{V_2}{V_1} = \frac{V_3}{V_4} \quad \text{(Carnot cycle)}. \tag{21.33}$$

Substituting Eq. 21.32 into Eq. 21.30, we obtain

$$W = -Nk_{\text{B}}(T_{\text{in}} - T_{\text{out}}) \ln\left(\frac{V_2}{V_1}\right) \quad \text{(Carnot cycle)}. \tag{21.34}$$

Because the volume ratio V_2/V_1 is greater than 1, $\ln(V_2/V_1)$ is positive. Because $T_{\text{in}} - T_{\text{out}}$ is also positive, the work done on the system is negative, which is consistent with our observation in Section 21.4: The work done on the system for a clockwise cycle is negative. Hence for a clockwise Carnot cycle, the work done on the environment is positive.

The high-temperature reservoir transfers energy thermally to the working substance during the first isothermal process (the one at T_{in}). The quantity Q_{in} is thus equal to the energy transferred thermally during the first isothermal process (see Table 21.1):

$$Q_{\text{in}} = Q_{1\rightarrow 2} = Nk_{\text{B}}T_{\text{in}} \ln\left(\frac{V_2}{V_1}\right). \tag{21.35}$$

Remember that not all of this energy can be converted to mechanical energy because some of it must be transferred to the low-temperature reservoir during the second isothermal process to satisfy the entropy law (Figure 21.32*b*).

Substituting Eqs. 21.34 and 21.35 into Eq. 21.21 thus yields

$$\eta = \frac{-W}{Q_{\text{in}}} = \frac{Nk_{\text{B}}(T_{\text{in}} - T_{\text{out}}) \ln\left(\frac{V_2}{V_1}\right)}{Nk_{\text{B}}T_{\text{in}} \ln\left(\frac{V_2}{V_1}\right)} = \frac{T_{\text{in}} - T_{\text{out}}}{T_{\text{in}}} \quad \text{(Carnot cycle)}, \tag{21.36}$$

which is exactly the maximum efficiency we obtained in Eq. 21.23 for any heat engine, regardless of the working substance.

EXAMPLE 21.8 Carnot engine

In a reversible heat engine, 6.02×10^{23} molecules of nitrogen gas are used as the working substance. The gas undergoes a Carnot cycle as illustrated in Figure 21.43. The volume of the gas is 6.00×10^{-3} m^3 in state 1 and 14.0×10^{-3} m^3 in state 2. The low-temperature reservoir is at 320 K. How much energy is transferred thermally to the low-temperature reservoir during one cycle?

❶ **GETTING STARTED** The temperature of the low-temperature reservoir is $T_{out} = 320$ K. I am also given that $V_1 = 6.00 \times 10^{-3}$ m^3 and $V_2 = 14.0 \times 10^{-3}$ m^3. I need to determine Q_{out}, the amount of energy transferred thermally to the low-temperature reservoir in each cycle.

❷ **DEVISE PLAN** From Eq. 21.2 I know that $Q_{out} = W + Q_{in}$. Therefore this problem boils down to determining W and Q_{in}, which are given by Eqs. 21.34 and 21.35, respectively. These equations both contain T_{in}, which is not given, but the terms containing T_{in} cancel and so T_{in} drops out.

❸ **EXECUTE PLAN** Substituting Eqs. 21.34 and 21.35 into Eq. 21.2 after solving the latter for Q_{out}, I get

$$Q_{out} = W + Q_{in} = -Nk_B(T_{in} - T_{out}) \ln\left(\frac{V_2}{V_1}\right) + Nk_B T_{in} \ln\left(\frac{V_2}{V_1}\right) = Nk_B T_{out} \ln\left(\frac{V_2}{V_1}\right). \quad (1)$$

Substituting the values given yields

$$Q_{out} = (6.02 \times 10^{23})(1.38 \times 10^{-23}\ \text{J/K})(320\ \text{K}) \times \ln\left(\frac{14.0 \times 10^{-3}\ \text{m}^3}{6.00 \times 10^{-3}\ \text{m}^3}\right) = 2.25 \times 10^3\ \text{J}. \checkmark$$

❹ **EVALUATE RESULT** The quantity I obtain for Q_{out} is positive, as it should be. I also note that the expression I obtain for Q_{out} in Eq. 1 can be written as $-Nk_B T_{out} \ln(V_4/V_3)$ because $\ln(V_2/V_1) = -\ln(V_4/V_3)$ (Eq. 21.32). Therefore $Q_{out} = -Q_{3\to4}$ (Table 21.1). This makes sense because energy is transferred thermally to the low-temperature reservoir only during the second isothermal process ($3 \to 4$). The minus sign in $-Q_{3\to4}$ accounts for the fact that $Q < 0$ (energy transferred out of the system) and, by definition, Q_{out} is always positive.

21.21 What is the change in entropy during each of the four legs of the cycle in Example 21.8?

21.8 Brayton cycle

As we saw in Section 21.4, the Brayton cycle (**Figure 21.44**) produces more mechanical energy than the Carnot cycle. More importantly, because the Brayton cycle does not involve any isothermal processes, the rate at which work can be done is greater (yielding more power).

Figure 21.44 *PV* diagram for a Brayton cycle.

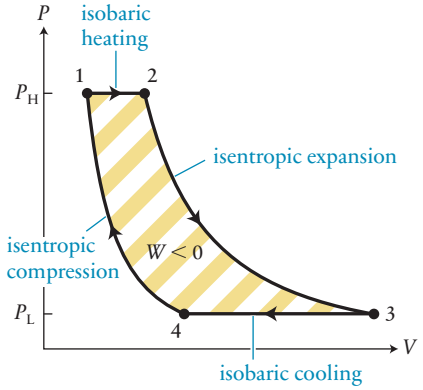


Table 21.2 Entropy and energy for the working substance in a Brayton cycle

Process	Definition	ΔS_{dev}	ΔE_{th}	W	Q
$1 \to 2$ (*isobaric*)	$\Delta P = 0$	$\frac{NC_P}{k_B}\ln\left(\frac{T_2}{T_1}\right)$	$NC_V(T_2 - T_1)$	$-Nk_B(T_2 - T_1)$	$NC_P(T_2 - T_1)$
$2 \to 3$ (*isentropic*)	$Q = 0$	0	$NC_V(T_3 - T_2)$	$NC_V(T_3 - T_2)$	0
$3 \to 4$ (*isobaric*)	$\Delta P = 0$	$\frac{NC_P}{k_B}\ln\left(\frac{T_4}{T_3}\right)$	$NC_V(T_4 - T_3)$	$-Nk_B(T_4 - T_3)$	$NC_P(T_4 - T_3)$
$4 \to 1$ (*isentropic*)	$Q = 0$	0	$NC_V(T_1 - T_4)$	$NC_V(T_1 - T_4)$	0
cycle	reversible	0	0	$-Q$	$NC_P(T_2 - T_1 + T_4 - T_3)$

To determine the efficiency of the Brayton cycle, we begin by collecting the appropriate values for the entropy and energy changes from Tables 20.6 and 20.7. The result is shown in **Table 21.2**.

Because the energy change over a cycle is zero, we have $W = -Q$. To obtain the work done during a cycle, therefore, we can sum the two terms in the rightmost column of Table 21.2 (which is simpler than taking the sum of the four W terms):

$$W = -Q = -NC_P(T_2 - T_1 + T_4 - T_3) \quad \text{(Brayton cycle)}. \quad (21.37)$$

To calculate the efficiency (Eq. 21.21; $\eta = -W/Q_{\text{in}}$), we must obtain expressions for $-W$ and Q_{in}, both of which must be positive. Because $T_2 > T_1$, Q is positive during the first isobaric process ($1 \to 2$) at the high pressure P_H. Likewise, because $T_4 < T_3$, Q is negative during the second isobaric process ($3 \to 4$) at the low pressure P_L. The energy transferred thermally from the environment to the working substance is thus equal to the energy transferred thermally during the isobaric process $1 \to 2$:

$$Q_{\text{in}} = NC_P(T_2 - T_1). \quad (21.38)$$

Substituting Eqs. 21.37 and 21.38 into Eq. 21.21 and dividing out the factor NC_P, we obtain

$$\eta \equiv \frac{-W}{Q_{\text{in}}} = \frac{T_2 - T_1 + T_4 - T_3}{T_2 - T_1} = 1 - \frac{T_3 - T_4}{T_2 - T_1}. \quad (21.39)$$

We can simplify this expression for the efficiency of the Brayton cycle by using our knowledge about entropy. The entropy change for the cycle is zero (Table 21.2). This ΔS_{dev} for the cycle is the sum of the two nonzero ΔS_{dev} terms in Table 21.2, so setting the sum of these two terms equal to zero gives

$$\frac{NC_P}{k_B}\ln\left(\frac{T_2}{T_1}\right) + \frac{NC_P}{k_B}\ln\left(\frac{T_4}{T_3}\right) = 0 \quad (21.40)$$

$$\ln\left(\frac{T_2}{T_1}\right) = -\ln\left(\frac{T_4}{T_3}\right) = \ln\left(\frac{T_3}{T_4}\right), \quad (21.41)$$

which means that

$$\frac{T_2}{T_1} = \frac{T_3}{T_4} \quad \text{(Brayton cycle)}. \quad (21.42)$$

We now rewrite Eq. 21.39 as

$$\eta = 1 - \frac{T_4}{T_1}\left[\frac{(T_3/T_4) - 1}{(T_2/T_1) - 1}\right]. \tag{21.43}$$

By Eq. 21.42, the term inside the square brackets is equal to 1, so the efficiency is

$$\eta = 1 - \frac{T_4}{T_1} \quad \text{(Brayton cycle)}. \tag{21.44}$$

The temperature T_4 is the lowest temperature in the cycle. The temperature T_1 is the temperature of the working substance at the completion of the isentropic compression, when the working substance exits the compressor (shown in Figure 21.30*b*).

During the isentropic compression, we have, from Eq. 20.47,

$$(P_H)^{(1/\gamma)-1}T_1 = (P_L)^{(1/\gamma)-1}T_4, \tag{21.45}$$

where γ is the heat capacity ratio C_P/C_V given by Eq. 20.26. The temperature ratio in Eq. 21.44 then becomes

$$\frac{T_4}{T_1} = \left(\frac{P_H}{P_L}\right)^{(1/\gamma)-1}. \tag{21.46}$$

The efficiency in Eq. 21.44 can thus be expressed in terms of the pressure increase accomplished by the compressor in the process $4 \rightarrow 1$:

$$\eta = 1 - \left(\frac{P_H}{P_L}\right)^{(1/\gamma)-1} \quad \text{(Brayton cycle)}. \tag{21.47}$$

The ratio P_H/P_L is called the *pressure ratio*. For aircraft engines, this ratio typically is between 4 and 30. The higher the pressure ratio of an engine running on the Brayton cycle, the more efficient the engine.

EXAMPLE 21.9 Performance and pressure ratio

Consider a jet engine operating on the Brayton cycle. The working substance is air, which consists primarily of diatomic molecules. The air is drawn in at atmospheric pressure, 1.01×10^5 Pa, at 288 K. In the combustion chamber, the temperature of the air is raised to 1520 K, and the engine has a pressure ratio of 30. What are the temperatures at the end of the two isentropic processes?

❶ **GETTING STARTED** Air enters the engine at point 4 in the cycle in Figure 21.44. Therefore I know that $T_4 = 288$ K. The air is compressed between state 4 and state 1 and the combustion takes place between state 1 and state 2, so I also know that $T_2 = 1520$ K. The isentropic processes end at states 1 and 3, so I need to determine T_1 and T_3.

❷ **DEVISE PLAN** To determine T_1 I can use Eq. 21.46, which relates T_1 to T_4 and the pressure ratio, both of which are given. This equation also contains the heat capacity ratio γ, which I can determine from Eq. 20.26, $\gamma = C_P/C_V = 1 + 2/d$, because I know that $d = 5$ for diatomic molecules. Once I have T_1, I can use Eq. 21.42 to determine T_3.

❸ **EXECUTE PLAN** From Eq. 20.26, I get

$$\gamma = 1 + \frac{2}{5} = \frac{7}{5},$$

so the exponent in Eq. 21.46 is $\frac{1}{\gamma} - 1 = \frac{5}{7} - 1 = -\frac{2}{7}$. I can then solve Eq. 21.46 for T_1:

$$T_1 = \frac{T_4}{(P_H/P_L)^{(1/\gamma)-1}} = \frac{288\text{ K}}{30^{-2/7}} = 760\text{ K}. \checkmark \tag{1}$$

Now that I have T_1 and T_2, I can get T_3 from Eq. 21.42:

$$T_3 = \frac{T_2 T_4}{T_1} = \frac{(1520\text{ K})(288\text{ K})}{760\text{ K}} = 575\text{ K}. \checkmark$$

❹ **EVALUATE RESULT** I know from Section 20.4 that on a given PV diagram, isentropes are steeper than isotherms, so Figure 21.44 tells me that T_1 and T_3 should lie between $T_4 = 288$ K and $T_2 = 1520$ K. The values I obtain indeed satisfy this condition.

21.22 (*a*) What is the efficiency of the jet engine in Example 21.9? (*b*) If the jet engine were to operate on a Carnot cycle between the same highest and lowest temperatures, what would its efficiency be?

QUANTITATIVE TOOLS

Chapter Summary

Converting energy (Sections 21.1, 21.5)

Concepts A system's **energy input** is the sum of the mechanical input of energy W_{in} and the thermal input of energy Q_{in}. The **energy output** is the sum of the mechanical output of energy W_{out} and the thermal output of energy Q_{out}.

The work done on a system is

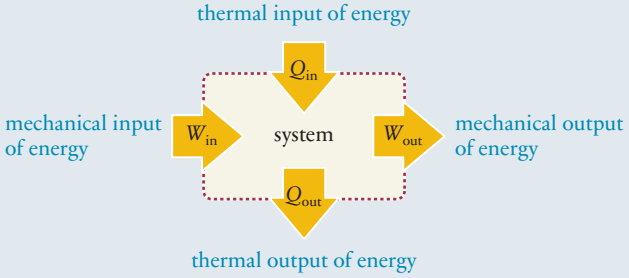
$$W = W_{in} - W_{out},$$

and the energy transferred thermally to the system is

$$Q = Q_{in} - Q_{out}.$$

A **steady device** converts energy in such a way that the energy changes and entropy changes of the device are zero either continuously or over some repeating time interval (a *cycle*).

Quantitative Tools For a steady device over one cycle:



$$\Delta E = 0 \tag{21.1}$$

$$W = Q_{out} - Q_{in} \tag{21.2}$$

$$\Delta S_{dev} = 0 \tag{21.3}$$

$$\Delta S_{env} \geq 0. \tag{21.5}$$

Figure SUM21.1

Entropy and energy quality (Sections 21.2, 21.5)

Concepts An **entropy diagram for a steady device** consists of an entropy gradient axis, one or more rectangles representing energy transfers from input to output, and downward- or upward-pointing arrows representing thermal or mechanical inputs or outputs of energy. Each rectangle has an arrowhead to indicate the direction of energy transfer. Thermal energy transferred into the device causes the entropy of the environment to decrease; thermal energy transferred out of the device causes the entropy of the environment to increase. (See the Procedure box "Drawing entropy diagrams for a steady device.")

A *degradation* in an environment's **energy quality** is associated with an increase in the environment's entropy; an *upgrading* in an environment's energy quality is associated with a decrease in the environment's entropy. The higher the quality of energy transferred, the smaller the associated entropy change. The amount of useful work obtainable from a quantity of energy decreases as the quality of the energy decreases.

Quantitative Tools The **entropy gradient** dS/dE of a system is the rate at which the entropy of the system changes with a change in thermal energy:

$$\frac{dS}{dE} \equiv \frac{1}{k_B T}.$$

See the Procedure box "Computing entropy changes from entropy diagrams" for how to use an entropy diagram to compute an entropy change.

Heat engines and heat pumps (Sections 21.3, 21.6)

Concepts A **heat engine** does work on its environment by thermally taking in energy Q_{in} at a high temperature and thermally expelling energy Q_{out} at a lower temperature.

A **heat pump** uses mechanical energy to take in energy thermally at a low temperature and transfer out energy thermally at a higher temperature.

Quantitative Tools For a reversible heat engine in which Q_{in} enters at temperature T_{in} and Q_{out} leaves at T_{out},

$$\frac{Q_{out}}{Q_{in}} = \frac{T_{out}}{T_{in}}. \tag{21.20}$$

The **efficiency** η of a heat engine is

$$\eta \equiv -\frac{W}{Q_{in}} = 1 - \frac{Q_{out}}{Q_{in}}, \tag{21.21, 21.22}$$

where W is the work done on the steady device during one cycle. The maximum efficiency is achieved by a reversible heat engine and is

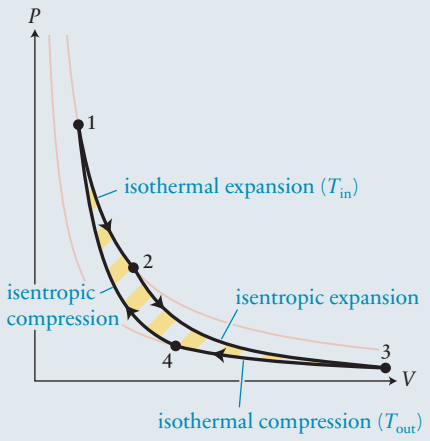
$$\eta_{max} = 1 - \frac{T_{out}}{T_{in}}. \tag{21.23}$$

The **coefficient of performance of heating** for a heat pump is

$$\text{COP}_{heating} \equiv \frac{Q_{out}}{W}. \tag{21.24}$$

The **coefficient of performance of cooling** for a heat pump is

$$\text{COP}_{cooling} \equiv \frac{Q_{in}}{W} = \text{COP}_{heating} - 1. \tag{21.27, 21.28}$$



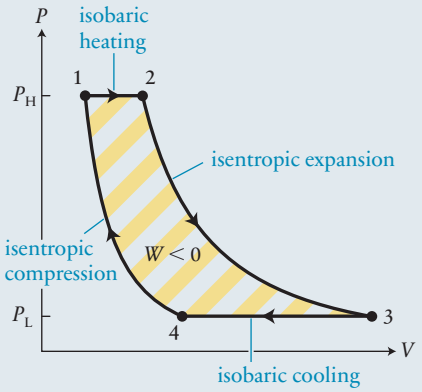
Thermodynamic cycles (Sections 21.4, 21.7, 21.8)

Concepts The magnitude of the work done on a system during one thermodynamic cycle is equal to the area enclosed by the path that represents the cycle in a PV diagram. The work done on the system is negative for a clockwise cycle and positive for a counterclockwise cycle.

The **Carnot cycle** consists of two isothermal processes and two isentropic processes. It operates at the maximum possible efficiency between two temperature reservoirs.

Quantitative Tools

Figure SUM21.2



The **Brayton cycle** consists of two isobaric processes and two isentropic processes.

The efficiency of a Carnot engine is

$$\eta = \frac{T_{in} - T_{out}}{T_{in}}. \tag{21.36}$$

Figure SUM21.3

The efficiency of a Brayton cycle that operates between pressures P_H and P_L is

$$\eta = 1 - \frac{T_4}{T_1} = 1 - \left(\frac{P_H}{P_L}\right)^{\frac{1}{\gamma}-1}, \tag{21.44, 21.47}$$

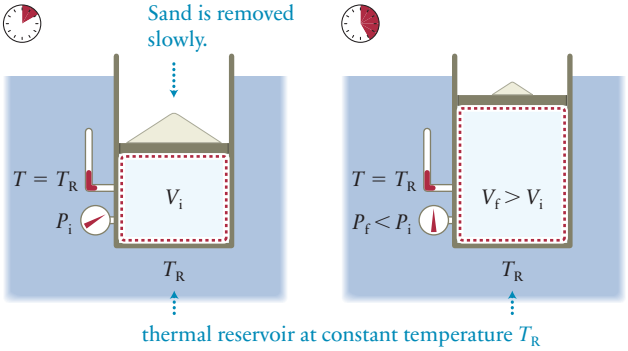
where T_1 is the temperature of the working substance when it exits the compressor, T_4 is the lowest temperature in the cycle, and γ is C_P/C_V. The quantity P_H/P_L is the *pressure ratio* of the cycle.

Summary of Tables 21.1 and 21.2 (from Tables 20.6 and 20.7)

Process	W	Q	ΔE_{th}	ΔS
isochoric	0	$NC_V\Delta T$	Q	$\frac{NC_V}{k_B}\ln\left(\frac{T_f}{T_i}\right)$
isothermal	$-Nk_BT\ln\left(\frac{V_f}{V_i}\right)$	$-W$	0	$N\ln\left(\frac{V_f}{V_i}\right) = \frac{Q}{k_BT}$
isobaric	$-Nk_B\Delta T$	$NC_P\Delta T$	$NC_V\Delta T$	$\frac{NC_P}{k_B}\ln\left(\frac{T_f}{T_i}\right)$
isentropic	ΔE_{th}	0	$NC_V\Delta T$	0

Questions and Problems

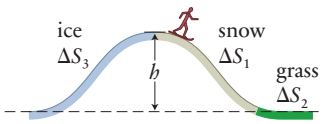
For instructor-assigned homework, go to Mastering Physics



Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

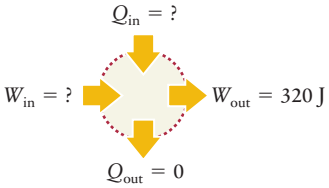
Unless stated otherwise, take the working substance in all heat engines, heat pumps, and thermodynamic cycles to be an ideal gas.

21.1 Converting energy



1. Figure P21.1 shows a gas confined to a cylinder fitted with a movable piston. The cylinder is immersed in a tank of water that acts as a thermal reservoir, so that the temperature of the gas never changes. (*a*) With the system defined as the gas, draw an energy input-output diagram for the system as sand grains are slowly removed from the top of the piston and the piston rises. (*b*) Does the system's energy change? Does its entropy change? (*c*) Is this a steady device? •

Figure P21.1



2. Draw an energy input-output diagram for a steady device that partially converts thermal energy to work, drawing your input and output arrows such that their relative sizes indicate the relative amounts of the quantities being represented. Label changes in the energy and entropy of the device. •
3. The snowboarder in Figure P21.3 starts at the top of a snow-covered hill and boards down the hill, which produces a change in entropy ΔS_1. At the bottom, she slides over a patch of grass, which quickly slows her down and produces a change in entropy ΔS_2. She then climbs back up and slides down the other side of the hill, which is covered in ice rather than snow, producing a change in entropy ΔS_3. Rank the entropy changes by magnitude, smallest first. •

Figure P21.3

4. For the steady device shown in Figure P21.4, determine the values of W_{in} and Q_{in}. ••

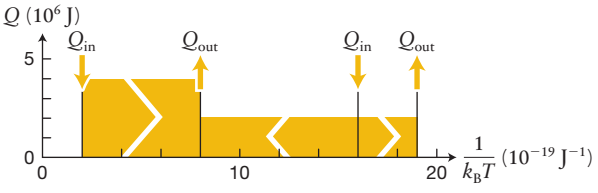
Figure P21.4

5. A steady heat engine, in contact with its environment, absorbs energy of magnitude Q_H as heat from a high-temperature reservoir, while 120 J of work is done on it. Without specifying anything about the way the entropy of the engine, source, or environment responds to change in energy, find the value of Q_H when the maximum amount of work the engine can do is arbitrarily close to 375 J. •
6. A 1500-kg car constantly moving at 90 kmph accidentally crashes into a concrete wall. The impact produces 750 J of sound energy. The car gains 3.8 kJ of thermal energy from the impact, and 15 kJ of thermal energy escapes after the impact. How much energy does the concrete wall absorb? ••
7. A steady device operates on the 600-W output of a motor. The device runs at 20 Hz and can convert 68% of its input to usable power to pump water. (*a*) How much thermal energy does the device output per cycle? (*b*) How much thermal energy does the device output in 8.0 h? (*c*) If 50% of the output thermal energy of part *b* were captured and recycled, how many kilograms of water could it raise from ground level to a height of 10 m? ••

21.2 Quality of energy

8. Three reservoirs of heated water are represented on the entropy diagram in Figure P21.8. All three reservoirs contain equal amounts of energy, so that $E_1 = E_2 = E_3$. (*a*) For which reservoir would you be least concerned about burning yourself if you dunked your hand into the water? (*b*) Which reservoir is most useful for converting thermal energy to mechanical energy? •

Figure P21.8



9. The entropy of material A varies as $S_1 = -4\gamma/E$, where γ is a constant, and the entropy of material B varies as $S_2 = \gamma E^2/4$. Which material is better suited to converting higher-quality thermal energy to useful, higher-quality mechanical energy when $E = 2$ units of energy? ••
10. A reversible steady device operates between two thermal reservoirs, one at 390 K and one at 250 K. If no work is done on the device, what is the maximum value for the percentage of thermal energy input Q_{in} converted to mechanical energy W_{out}? (Hint: Consider the entropy diagram of a reversible process and the change in entropy.) ••
11. Find the temperature in Kelvin and degree Celsius of a thermal reservoir with an entropy gradient value of $1.985 \times 10^{20}\ \text{J}^{-1}$. •
12. The entropy of a thermal reservoir of unknown temperature is defined by the function $S = aE^3/3b^2$. (*a*) Derive an expression for the entropy gradient dS/dE. (*b*) Calculate the entropy gradient of the reservoir if the ratio E/b is $3.00\ \text{J}^{-1}$ and $a = 1.00$ J. (*c*) Find the temperature of the reservoir. ••

21.3 Heat engines and heat pumps

13. Draw an entropy diagram for a reversible steady device that takes seawater at 29 °C and upgrades as much energy as possible to a reservoir filled with water at 100 °C and on the verge of boiling. The rest of the energy is deposited at 14 °C, the temperature of deeper seawater. •
14. A composite of several processes that take place in a steady device is represented by the entropy diagram in Figure P21.14. What is ΔS for the composite? •

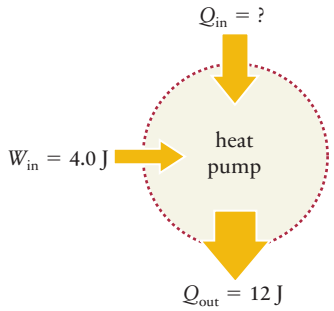


Figure P21.14

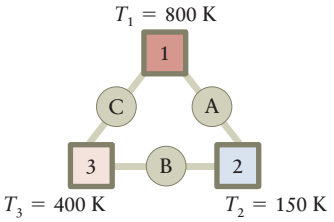
15. A reversible steady device puts out $W_{out} = 750$ J of mechanical energy. The only input energy is the quantity Q_{in} transferred thermally from a thermal reservoir at 355 K. If the temperature of the environment (which serves as a low-temperature reservoir) is 300 K, what quantity of energy Q_{out} is transferred thermally out of the device? ••



16. The energy input-output diagram for a heat pump is shown in Figure P21.16. What are (*a*) the value of Q_{in}, (*b*) the coefficient of performance of heating, and (*c*) the coefficient of performance of cooling? ••

Figure P21.16

17. Three identical steady devices, A, B, and C, operate between three thermal reservoirs, 1, 2, and 3, as shown in Figure P21.17. Each device takes thermal energy from the warmer of its two reservoirs, and each upgrades to mechanical energy as much of that thermal energy as possible without lowering the entropy of the three-device, three-reservoir system. (*a*) Which reservoir has the highest-quality energy? (*b*) Is enough information provided to determine which device can upgrade the highest percentage of its input thermal energy to mechanical energy? If so, which is the most efficient of the three devices? If not, what information is lacking? •••

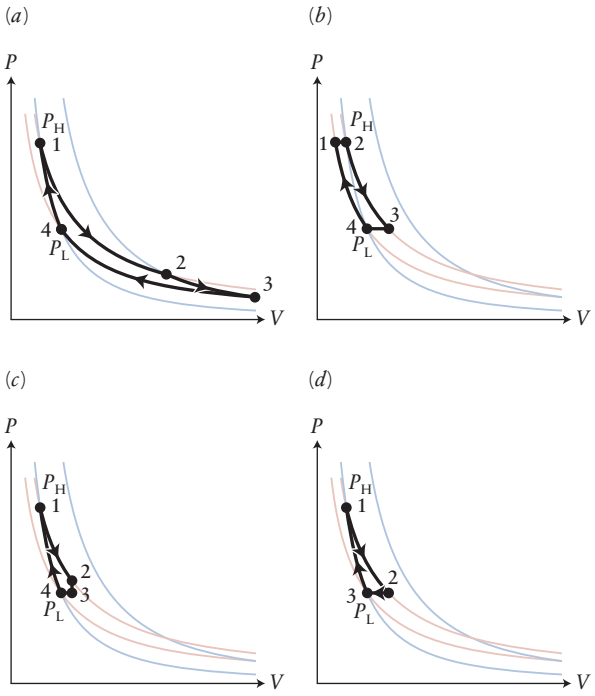


Figure P21.17

21.4 Thermodynamic cycles

18. Figure P21.18 shows *PV* diagrams for four thermodynamic cycles. In each case, the cycle consists of three or four processes carried out on identical working substances, and each process is isothermal, isobaric, isochoric, or isentropic. The pressures P_H and P_L have the same values in all four cycles. For which single cycle is the most work done on the gas? •

Figure P21.18

19. Which of the four thermodynamic cycles illustrated in Figure P21.18 has the greatest efficiency? ••

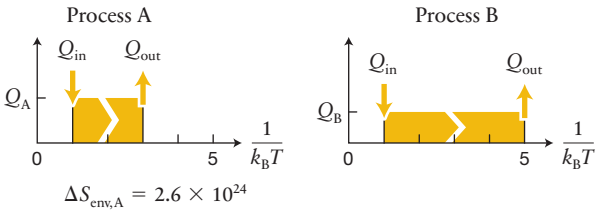
20. Two thermodynamic processes, each involving the same type and amount of monatomic gas as a working substance and each working as a heat engine, begin and end their cycles from a common state: $P_1 = 1.00 \times 10^5$ Pa, $V_1 = 2.50 \times 10^{-2}$ m^3, and $T_1 = 300$ K. The first is a Carnot cycle, the second is a Brayton cycle, and each does 200 J of work on the environment during each cycle. (*a*) Draw an entropy diagram for each process. (*b*) Which process causes the greater change in entropy of the environment? ••

21.5 Entropy constraints on energy transfers

21. The working substance in a steady device is a gas that undergoes expansion followed by compression. The work done by the gas during expansion is 6.4 J, and the work done on it during compression is 8.2 J. What is the work done on the gas during the cycle? •

22. What is the entropy change in the environment when 5.0 MJ of energy is transferred thermally from a reservoir at 1000 K to one at 500 K? •

23. In one cycle, a steady device transfers 1.55×10^6 J of thermal energy from a reservoir at 450 K to a reservoir at 300 K. Calculate the entropy change for the device and for the environment. •



24. Draw an entropy diagram for a steady device that in each cycle converts 135 J of work to thermal energy that is released into a reservoir at 340 K. Calculate numerical values for the length and height of the entropy bar and for the change in entropy that results from this transfer. ••

25. An ideal gas is held at 70 K in a cylinder fitted with a movable piston. When a 5.0-kg cube is placed on the piston, the piston slides down a distance of 200 mm. What

is the entropy change in the environment that results from the change in the gas volume? ••

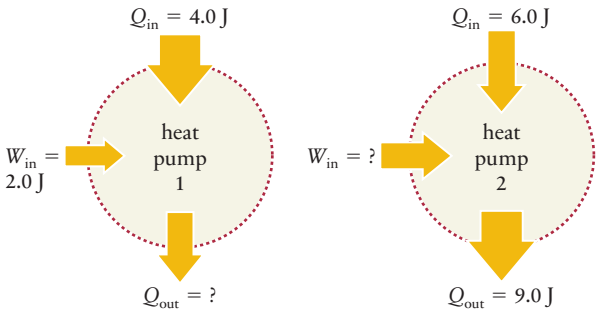
26. Processes A and B in Figure P21.26 each transfer energy thermally. If the energies transferred thermally by the two processes are related by $Q_A = \sqrt{2} \times Q_B$, and process A causes $\Delta S_{env} = 2.6 \times 10^{24}$, what is ΔS_{env} for process B? ••

Figure P21.26

21.6 Heat engine performance

27. A reversible heat engine transfers energy from a 426-K reservoir to second reservoir. What must be the temperature of the second reservoir if the engine has a maximum efficiency of 0.350? •

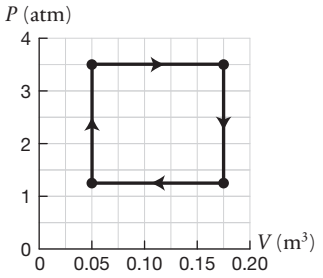
28. A heat engine takes in 6.45×10^3 J of thermal energy from a reservoir at 500 K and returns some of this energy to a reservoir at $T_L < 500$ K. If this engine operates at an efficiency of 0.450, what is the maximum value possible for T_L? •



29. What is the coefficient of performance of heating of a heat engine that takes in 6.45 kJ and expels 7.30 kJ of thermal energy? •

30. A heat pump with a coefficient of performance of heating of 14 supplies thermal energy to a house to maintain a comfortable temperature for the occupants. Calculate the daily thermal energy supplied to the house if 6.8 kW of power is needed to drive the heat pump. ••

31. A heat engine does 85 J of work per cycle while expelling 110 J of waste thermal energy. How much energy is transferred thermally to this engine each cycle, and what is the efficiency of the engine? ••



32. Energy input-output diagrams for two heat pumps are shown in Figure P21.32. What are (*a*) Q_{out} for pump 1 and (*b*) W_{in} for pump 2? ••

Figure P21.32

33. The heat engine represented by the *PV* diagram in Figure P21.33 exhausts 43.5 kJ of thermal energy per cycle. What is the engine's efficiency? ••

Figure P21.33

34. During each cycle, a heat engine ejects 75 J of thermal energy for every 115 J of input thermal energy. This engine is used to lift a 375-kg load a vertical distance of 27.0 m at a steady rate of 52.5 mm/s. How many cycles of the engine are needed to accomplish this task? ••

35. In winter, you like to keep your house interior at 21.0 °C. Your geothermal heating system, which was advertised as being reversible, draws thermal energy from an underground reservoir at 347 K. In a cold winter, with the average outdoor temperature being 0.0 °C, thermal energy escapes from the house at a rate of 1000 W ± 5%. Distributing the thermal energy supplied by the heating system throughout the house requires 180 W (provided by the heating system). Is your heating system reversible within your 5% margin of error, or was the advertisement false? Ignore any inefficiency in converting electrical energy to mechanical energy. ••

36. An engine has a rated maximum efficiency of 0.22 when burning a certain fuel, but the manufacturer claims that burning a new type of fuel will increase the maximum efficiency. In testing this claim, you determine that, with an identical energy input, the ratio of the work done on the environment using the new fuel to the work done on the environment using the old fuel is 1.14. What is the efficiency using the new fuel? ••

37. For a heat pump that operates on a Carnot cycle, calculate (*a*) the coefficient of performance of cooling when the pump is used to cool a house to 72 °F on a day when the outside air is at 105 °F and (*b*) the coefficient of performance of heating when the pump is used to heat a house to 72 °F on a day when the outside air is at −15 °F. ••

38. Reversible heat engines 1 and 2 are connected to each other in such a way that the output temperature of engine 1 is the input temperature of engine 2, $T_{1out} = T_{2in}$, and the quantity of energy transferred thermally out of engine 1 is the quantity transferred into engine 2, $Q_{1out} = Q_{2in}$. Calculate Q_{2out} if $T_{1in} = 270$ K, $T_{2out} = 422$ K, and $Q_{1in} = 3.70 \times 10^{11}$ J. ••

39. On a day when the outdoor temperature is 35 °C, a walk-in freezer in a butcher shop where there is no air-conditioning must remove 3000 J of thermal energy from its interior each second to maintain an interior temperature of −4 °C. (*a*) What is the maximum coefficient of performance of cooling of the heat pump in the freezer? (*b*) What would this maximum coefficient be if the freezer were installed in the shop's basement, where the air temperature is 19 °C? (*c*) How much energy could the owner save in a day by installing the freezer in the basement? •••

40. The internal temperature of a freezer is 269 K, and the temperature of the cooling coils on the back of the freezer is 325 K. (*a*) What is the maximum coefficient of performance of cooling of the freezer? (*b*) You measure the time interval it takes to freeze a sample of water and estimate that, during each cycle, the freezer absorbs 118 J from its interior. How much thermal energy does the freezer transfer to the environment during each cycle? (*c*) How much work is done on the freezer each cycle? (*d*) You notice that the room in which the freezer is located is warmer than nearby rooms, and you wonder how efficient the freezer is at warming the room compared with the efficiency of a small electric space heater. Estimate the relative heating efficiencies of these two devices. ●●●

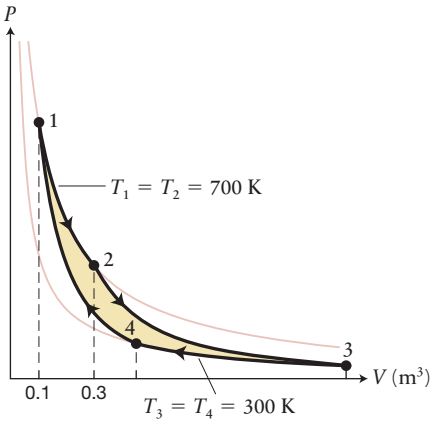
21.7 Carnot cycle

41. How much work is done by a Carnot cycle that doubles the volume of 1.00 mol of a monatomic ideal gas during isothermal expansion and triples the initial temperature of 0.0 °C during isentropic compression? ●

42. What is the maximum efficiency of a Carnot heat engine that operates between 485 K and 625 K? ●

43. Two Carnot heat engines have the following values for the temperatures T_{in} and T_{out} of the reservoirs:

Engine 1: $T_{in} = 450$ K and $T_{out} = 350$ K



Engine 2: $T_{in} = 550$ K and $T_{out} = 450$ K

Determine which of the two engines is more efficient. ●●

44. A heat engine operates on a Carnot cycle that runs clockwise between a reservoir at 340 K and a reservoir at 280 K. One cycle moves enough energy from the high-temperature reservoir to raise the temperature of 1.0 kg of water by 1.0 K. How much work is done by the engine in one cycle? ●●

45. The Carnot cycle shown in Figure P21.45 uses 1.00 mol of a monatomic ideal gas as its working substance. From the information given in the graph, determine the values of P_1, P_2, P_3, P_4, V_3, and V_4. ●●

Figure P21.45

46. Carnot cycles A and B run on the same amount of the same working substance and draw their thermal energy from the same high-temperature reservoir. The two cycles start with their working substances occupying different volumes. During the isothermal expansion, cycle A doubles its volume and cycle B triples its volume. If cycle A does twice as much work as cycle B, which cycle is more efficient and by how much? ●●

47. Heat engines 1 and 2 operate on Carnot cycles, and the two have the same efficiency. Engine 1 takes in boiling water at 373 K and outputs water that is twice as hot as the output water from engine 2. What is the temperature of the input water for engine 2? ●●

48. A heat pump that operates on a Carnot cycle cools a house in a very hot climate. During the hottest part of the day, the outside temperature is 45 °C, and you want to keep the inside temperature at 20 °C. The heat pump operates on electricity. (*a*) What is the coefficient of performance of cooling during the hottest part of the day? (*b*) At what maximum rate does the pump use electrical energy if it removes thermal energy from the house at a rate of 1.50 kW? ●●

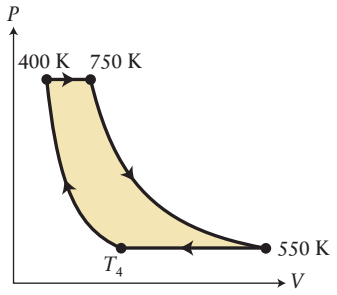
49. A heat pump that operates on a Carnot cycle uses N_2 gas and operates on electricity. (*a*) At what rate is it using electrical energy when it adds thermal energy at a rate of 1.35 kW to a room that is at 22 °C when the outside temperature is −25 °C? (*b*) What is the pump's coefficient of performance of heating? ●●

50. To meet energy regulations, the coefficient of performance of cooling of a refrigerator that operates on a Carnot cycle must be 4.00. At what rate is this refrigerator expelling thermal energy into the kitchen if it consumes electrical energy at a rate of 225 W? ●●

51. A heat engine that operates on a Carnot cycle uses a low-temperature reservoir at 25 °C and runs at an efficiency of 0.350. The working substance is nitrogen gas, and the gas chamber contains 7.50×10^{23} N_2 molecules. What is the change in the thermal energy of the N_2 gas between its lowest and highest temperatures? ●●

52. An electric heat pump used as a heater operates on a Carnot cycle. The low-temperature reservoir consists of a pipe driven 10 m into the ground to a region where the temperature is always 10 °C. The high-temperature reservoir is the interior of a house, kept at 20 °C. (*a*) For every 1.0 J of electrical energy used to run the heat pump, what quantity of thermal energy is delivered to the house? (*b*) If the low-temperature reservoir were the air outside the house at −23 °C rather than underground, what quantity of thermal energy would 1.0 J of electrical energy deliver to the house? Does it seem to be worth the added expense of drilling to tap the underground reservoir? (*c*) What is the coefficient of performance of heating of the heat pump in part *a* and in part *b*? ●●

53. The temperature of Earth's oceans at a depth of 2500 m is about 4 °C. Suppose you want to use this water as the low-temperature thermal reservoir for an electric heat pump to heat the cabin of a boat to 20 °C. If the pump operates on a Carnot cycle and uses electrical energy at a rate of 75 W, at what rate are you changing the entropy of the deep ocean and the entropy of the air in the cabin? ●●



54. An experimental six-cylinder engine that operates on a Carnot cycle has been proposed for a car. Each cylinder is fitted with a movable piston that allows the cylinder to fill with 1.00 mol of a monatomic ideal gas. During isothermal expansion at 700 K, the length of each cylinder increases from 100 mm to 200 mm as the piston moves. The isothermal compression occurs at 400 K. Each isothermal process takes 9.00 s, and each isentropic process takes 2.00 s. If the mass of the car is 750 kg, how long a time interval is required for this car and its 70.0-kg driver to accelerate from rest to 50.0 km/h? Ignore drag and friction. •••

55. A freezer that operates on a Carnot cycle maintains an interior temperature of –18 °C and exhausts thermal energy into a kitchen at 22 °C. You place a tray containing 0.500 kg of water at 0 °C in the freezer and observe that the freezer draws electrical energy at a rate of 115 W. (*a*) How long does it take to transform all the water to ice? (*b*) What is the freezer's coefficient of performance of cooling? (*c*) How much thermal energy is exhausted into the kitchen during the time interval it takes to freeze the water? (*d*) What is the change in entropy of the water as it freezes? (*e*) What is the change in entropy of the system that consists of the water plus the kitchen? For water, the specific transformation energy for melting is $L_{\text{melting}} = 334$ kJ/kg. •••

21.8 Brayton cycle

56. Determine T_4 for the Brayton cycle represented in Figure P21.56. •

Figure P21.56

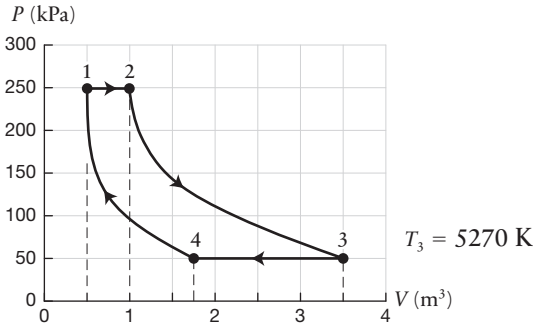
57. An engine that operates on a Brayton cycle uses oxygen gas (diatomic molecules, O_2) as the working substance. During the isobaric cooling, the temperature decreases by 85 °C. During the isobaric heating, the temperature increases by 100 °C. What is the maximum efficiency of this cycle? •

58. A gas engine that operates on a Brayton cycle has an efficiency of 0.22. On a cold day, the temperature of the air drawn into the engine is 267 K. What is the temperature of the air exhausted from the engine? •

59. An experimental car engine operates on a Brayton cycle and uses a monatomic ideal gas as the working substance. If the pressure in front of the moving car is 103,500 Pa and the pressure behind the moving car is 99,700 Pa, what is the maximum efficiency possible for the engine? ••

60. An engine that operates on a Brayton cycle uses air as its working substance, compressing ambient air initially at a pressure of 1.0 atm to 6.0 atm. (*a*) What is the engine's pressure ratio? (*b*) If the heat capacity ratio $\gamma = C_P/C_V$ is 1.40 for air, what is the engine's efficiency? (*c*) At high altitudes, $\gamma = 1.44$ and the ambient air pressure is 0.40 atm. If the engine compresses this air to 4.8 atm, what is its efficiency now? ••

61. A heat engine that operates on a Brayton cycle has a pressure ratio of 5 and uses as its working substance a gas for which the heat capacity ratio C_P/C_V is 1.333. You wish to replace this engine with one that operates on a Carnot cycle and has the same efficiency as the Brayton engine. If the low-temperature reservoir for the Carnot engine is to be 15 °C, what must the temperature of the high-temperature reservoir be? ••



62. You need to replace a heat engine that operates on a Carnot cycle with one that has the same efficiency but operates on a Brayton cycle. The Carnot engine low and high temperatures are −10 °C and 225 °C. If the working substance in your replacement engine has a C_P/C_V ratio of 1.667, what must the engine's pressure ratio be? ••

63. A heat engine that operates on a Brayton cycle uses N_2 gas and has a pressure ratio of 10. It is being used to lift a 535-kg pallet of bricks vertically at a steady rate of 100 mm/s. At what rate must thermal energy be supplied to this engine to accomplish this task? ••

64. You need to design a heat engine that operates on a Brayton cycle and, during each cycle, does 175 J of work while exhausting 65 J of energy. (*a*) If the working substance is helium gas, what should the pressure ratio be? (*b*) If the working substance is carbon dioxide gas, CO_2, is the pressure ratio the same as with helium gas? If so, prove it; if not, determine the new pressure ratio. ••

65. If the Brayton cycle represented in Figure P21.65 operates on 4.0 mol of an ideal gas, how many degrees of freedom do the particles of the gas have? •••

Figure P21.65

66. You are designing a gas engine that operates on a Brayton cycle and uses air ($\gamma = 1.4$) as its working substance. By making the engine larger and larger, you can have the pressure ratio be 16, 17, 18, 19, or 20. At the higher pressure ratios, however, the efficiency is a smaller fraction of the ideal Brayton cycle efficiency. You determine that, over this range of ratios, the factor relating the efficiency of the real engine to that of the ideal cycle, $\eta_{\text{real}} = f\eta_{\text{ideal}}$, can be described by the formula $f = (1.45)(1 - \eta_{\text{ideal}})^{0.8}$. (*a*) Which pressure ratio do

you choose to maximize efficiency? (*b*) This is a simplified problem. Other than increasing mass, what other reasons can you think of for why engine designers don't have the pressure ratio as great as possible? •••

Additional Problems

67. A thermal reservoir is held at 265 K. If 4180 J of energy is transferred thermally to it, what is the change in entropy of the reservoir? •

68. The entropy of a system is increased by 3.8×10^{21} for every 10 J of energy added to it. What is the temperature of this system? •

69. In the past 40 years, the average power a refrigerator requires to provide a given amount of cooling has dropped from 160 W to 40 W. By what factor has the COP of cooling for refrigerators changed during this time interval? •

70. A 1000-kg iceberg at 0 °C falls into the ocean at a location where the water temperature is 2 °C, and all the ice melts by absorbing thermal energy from the water. What is the entropy change for the system comprising the water and the iceberg? For ice, the specific transformation energy for melting is 334 kJ/kg. ••

71. The low-temperature reservoir for a heat engine that operates on a Carnot cycle is at –5 °C. Using only 1.00 MJ of thermal energy, this engine needs to pull a 1200-kg boulder at a steady rate 65.0 m up a ramp inclined at 35.0° above the horizontal. (*a*) What must the temperature of the high-temperature reservoir be? (*b*) How much of the 1.00 MJ of input energy is wasted as the boulder travels this distance? Ignore any friction between the boulder and the ramp surface. ••

72. An electric heat pump that operates on a Carnot cycle is used to cool a house interior to 20 °C on a day when the outside temperature is 38 °C. (*a*) For every 1.0 J of electrical energy used, what quantity of thermal energy is removed from the house? (*b*) What is the pump's coefficient of performance of cooling? ••

73. A Carnot heat engine in a factory operates at an efficiency of 0.33 when it takes in thermal energy from a reservoir of heated water and releases thermal energy into the 28 °C surface water of an outdoor pool. By how much could the efficiency be improved if the thermal energy were released into the pool at a depth where the water temperature is 18 °C? ••

74. A heat engine that operates on a Carnot cycle is used to pump water out of a well that is 45.0 m deep. The high-temperature reservoir for the heat engine is at 215 °C, and the low-temperature reservoir is at −10 °C. The engine must move water from the bottom of the well to the surface at a rate of 6600 L/min, and the speed of the water when it reaches the surface is negligible. At what rate must thermal energy be supplied to the engine? ••

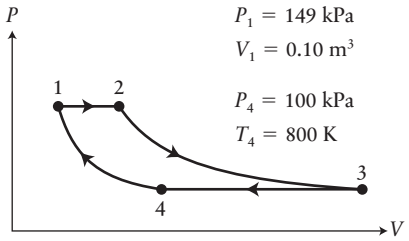
75. An electric heat pump that operates on a Carnot cycle is used to keep the air in a laboratory chamber at a constant 35 °C by extracting energy from outside air that is at 5 °C. Due to conduction and small leaks, the chamber loses thermal energy at a rate of 12.0 W. (*a*) At what rate must the pump extract energy from the outside air? (*b*) At what rate is the pump using electrical energy? ••

76. A heat pump that operates on a Carnot cycle must deliver thermal energy to your house at a rate of 12.5 kW to keep the rooms at 22 °C. The pump uses outside air at −10 °C as its low-temperature reservoir and runs on electricity that costs 2.69¢/MJ. How much does it cost to keep your house at 22 °C from 8 a.m. to 10 p.m.? ••

77. The thermal gradient of Earth's crust is approximately 25 K/km at locations away from tectonic plate boundaries. Suppose you want to use this thermal gradient to run a heat engine that operates on a Carnot cycle at a location where the base of the crust is 30 km below Earth's surface and the surface temperature is 28 °C. (*a*) What is the maximum efficiency the engine can achieve at this location? (*b*) Because drilling 30 km into the crust presents great technological problems, you will settle for an efficiency of 0.50. How deep into the crust must your high-temperature reservoir be in order for the engine to have an efficiency of 0.50? ••

78. The average daytime temperature at the surface of the Moon is 380 K, and the temperature of the lunar core is estimated at 1000 K. Suppose you want to run a heat engine that operates on a Carnot cycle to use this temperature difference to run a 2.50-MW power station at some future lunar colony. (*a*) At what rate does this engine extract thermal energy from the lunar core? (*b*) At what rate does the process change the entropy of the core system? (*c*) What is the thermal efficiency of this engine? ••

79. A heat engine that operates on a Carnot cycle has efficiency η. When the engine is run in reverse as a heat pump, what are, in terms of η, (*a*) the coefficient of performance of cooling when the pump is used for cooling and (*b*) the coefficient of performance of heating when the pump is used for heating? (*c*) For each case, check your answer to see whether the range of the coefficients of performance is physically reasonable. ••



80. A heat engine that operates on a Carnot cycle is used to pump crude oil at a rate of 25,000 barrels/day from a well that is 1.70 km deep. The mass density of the oil is 850 kg/m^3, the oil is under minimal pressure and so has no initial speed, and it has negligible speed as it reaches the surface. The engine operates between 50 °F and 250 °F, and each barrel has a volume of 0.159 m^3. At what rate must thermal energy be supplied to this heat engine? ••

81. A heat engine that operates on a Carnot cycle between 150 °C and 10 °C is used to accelerate a flywheel from rest to a rotational speed of 8.50 s^{-1}. The 1500-kg flywheel is a solid uniform cylinder that rotates about its long central axis without appreciable friction. Its diameter is 1.00 m, and it is 750 mm long. How much thermal energy must be transferred into this engine to accelerate the flywheel to the desired rotational speed, and how much of this thermal energy is wasted in the process? ••

82. A 950-kg car uses an engine that operates on a Brayton cycle for which the pressure ratio is 8 and the working substance is helium (He) gas. During each cycle, 25% of the work done by the engine is used to overcome friction. If the engine must accelerate the car from rest to 30 m/s, how much energy must be transferred thermally to the engine? ••

83. The Brayton cycle represented in Figure P21.83 operates with 2.00 mol of working substance. How many degrees of freedom does each particle of the working substance have? ●●●

Figure P21.83

84. You have taken a job as a patent examiner, and your first assignment is to evaluate a "zero-point energy perpetual motion machine." You are skeptical, but after the applicant gives it an initial energy of 1000 J, the machine starts operating and does not immediately run down. Hours later, tired of waiting for the machine to stop, you use an infrared sensor and determine that the machine is losing thermal energy at an average rate of 200 μJ/s. You would like to examine other devices while waiting for the machine to stop, but you do not want to miss its final few minutes of operation, and you are also concerned about its effect on the entropy of the environment. ●●● CR

85. Working for an automotive journal, you are reviewing two proposed new models that have identical frame shapes and identical masses. Car 1 runs on a Brayton cycle that does enough work to accelerate the car from 0 to 100 km/h in 11.5 s when internal friction, air resistance, and other retarding factors are left out of the equations. When air resistance is taken into account, the car's top speed is 105 km/h. In the cycle, the isobaric cooling is accomplished by exposing the working substance to normal atmospheric pressure and 350 K, the temperature under the car's hood. When the working substance is compressed, the pressure increases by a factor of 5.00, and the temperature of the working substance after the isobaric combustion is 700 K. At the compressor, the engine takes in 1.00 mol of the working substance (which the designer has modeled as having four degrees of freedom) and the operating speed is 8.00 cycles/s. Car 2 runs on a Carnot cycle that has the same minimum and maximum temperatures of 350 K and 700 K, the same fuel intake, and the same piston volume. The frame shapes and masses of the cars are nearly identical. The only difference (other than the cycle itself) is that car 2 runs at only 1.00 cycle per second. ●●● CR

86. You work for a toy company that wants to produce a bathtub toy boat that operates on a Carnot cycle and slowly putts around the bathtub. It is assumed that the temperature of the bathwater will be about 100 °F and the air temperature will be about 70 °F. After some experimenting, you determine that your prototype model operates at about 40% of the efficiency of an ideal Carnot cycle between these two temperatures. Your engineer tells you that the boat needs to have an efficiency of 0.045 in order to move around well in the tub. You begin to consider simple design modifications in an attempt to reach this goal. ●●● CR

22.6 Forces exerted by distributions of charge carriers

CONCEPTS

QUANTITATIVE TOOLS

Electricity is a familiar term—outlets, batteries, light bulbs, computers all involve electricity. It is no understatement to say that modern life depends on electricity, but what exactly *is* electricity? We all know what electricity does, but it's not that easy to explain what electricity *is*.

Electricity manifests itself in many ways: from the sparks that fly when you scuff your feet across a carpet on a dry winter day to the electricity we use in our homes to the transmission of radio and television programs. Even the attraction between magnets has to do with electricity. In this chapter, we begin our treatment of electricity with a discussion of static electricity.

22.1 Static electricity

When you tear off some plastic wrap from its roll, the wrap is attracted to anything that gets close: your hand, the countertop, a dish. This interaction between the plastic wrap and other objects doesn't have to involve any physical contact. For example, you can feel the presence of a piece of freshly torn-off plastic wrap with your cheek or the back of your hand even when your face or hand is held some distance away from the piece. You may have experienced many similar interactions: Styrofoam peanuts are attracted to your arms when you unpack a box full of them (**Figure 22.1**). Running a comb through your hair on a dry day causes the comb to attract your hair. After rubbing a balloon against a woolen sweater, you can hold the balloon close to a wall and *see* the attraction as the balloon moves toward the wall. In all these instances, the mass of the objects is too small for the interactions to be gravitational. What, then, is this interaction?

You may never have thought of these interactions as being particularly strong, but consider this: If you rub a comb through your hair and then pass the comb over some small bits of paper, the bits of paper jump up to your comb and stick to it. In other words, the bits of paper accelerate upward, which means the force exerted by your comb on them must be *greater* than the gravitational force exerted on them by Earth!

Figure 22.1 Styrofoam peanuts cling to a person's arms because of static electricity.

Now try this: Quickly pull a 20-cm strip of transparent tape* out of a dispenser and suspend it from the edge of a table (just be sure the table is not metal). Notice how the tape is attracted to anything brought nearby. It might even take some practice to prevent the tape from curling up and sticking to the underside of the table or to your hand. Bring a few objects near the suspended tape and notice the attractive interaction between them.† Go ahead—experiment!

22.1 Suspend a freshly pulled piece of transparent tape from the edge of your desk. (*a*) What happens when you hold a battery near the tape? Does it matter whether you point the + side or the − side of the battery toward the tape? Does a spent battery yield a different result? Does a wooden object yield a different result? (*b*) What happens when you hold a strip of freshly pulled tape near the power cord of a lamp? Does it make any difference if the lamp is on or off?

All these interactions involving static electricity are examples of **electric interactions.** The experiment you just did tells you there is no obvious connection between electric interactions and the electricity we think of as "flowing" in electric circuits and batteries. In Chapter 31 we shall see, however, that the two are connected.

Objects that participate in electric interactions exert an **electric force** on each other. The electric force is a field force (see Section 8.3): Objects exerting electric forces on each other need not be physically touching. As you may have noticed from the interaction between the strips of tape and various nearby objects, the magnitude of the electric force depends on distance: It decreases as you increase the separation.

22.2 Suspend a freshly pulled strip of transparent tape from the edge of your desk. (*a*) Pull a second strip of tape out of the dispenser and hold it near the first strip. What do you notice? (*b*) Does it matter which sides of the strips you orient toward each other?

As Checkpoint 22.2 makes clear, not all electric interactions are attractive. Even if you increase the mass of the strips by suspending paper clips from them, the repulsion between the strips is great enough to keep the paper clips apart (**Figure 22.2**). Now place your hand between two repelling strips and notice how both strips fly toward your hand! Then run each strip of tape several times between your fingers and notice how the electric interaction diminishes or even disappears.

*For best results, use the type called "magic" tape.

†If you find something that *repels* the tape, wipe the entire surface of the object with your hand and see if it still repels—it shouldn't. Mystified? Hang on! We'll soon be able to resolve your questions.

CONCEPTS

Figure 22.2 Strips of tape just pulled out of a dispenser repel each other. The repulsive force is great enough to keep the strips apart even when they are weighted down by paper clips.

22.3 Suspend two freshly pulled 20-cm strips of transparent tape from the edge of your desk. Cut two 20-cm strips of paper, making each strip the same width as the tape, and investigate the interactions between the paper strips and the tape by bringing them near each other. Which of the following combinations display an electric interaction: paper-paper, tape-paper, tape-tape?

22.2 Electrical charge

As we saw in the preceding section, electric interactions are sometimes attractive and sometimes repulsive. In addition, the experiment you performed in Checkpoint 22.3 demonstrates that paper strips, which do not interact electrically with each other, do interact electrically with transparent tape. What causes these interactions? To answer this question, we need to carry out a systematic sequence of experiments.

Figure 22.4

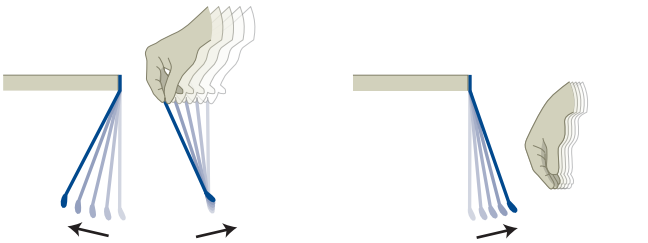

Figure 22.3 illustrates a simple procedure for reproducibly creating strips of tape that interact electrically. A suspended strip created according to this procedure interacts in the following ways: It repels another strip created in the same manner, and it attracts any other object that does not itself interact electrically with other objects (**Figure 22.4**).

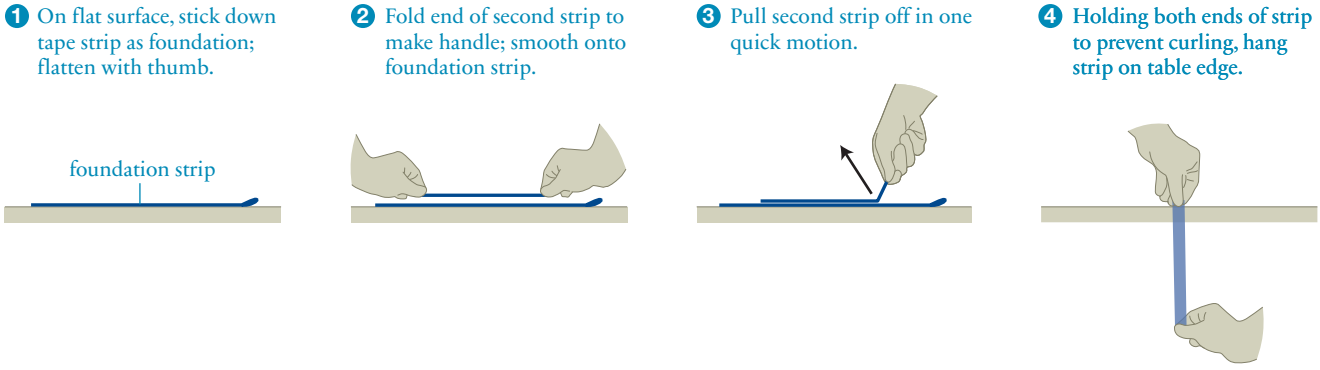
Let us call the attribute responsible for the electric interaction **electrical charge,** or simply **charge.** Saying that something carries an electrical charge is just another way of saying that that object interacts electrically with other objects that carry electrical charge. Freshly pulled strips of tape carry electrical charge, and two such strips interact because each possesses an electrical charge, just as your body and Earth interact because each possesses mass. The general term for any microscopic object that carries an electrical charge, such as an electron or a proton, is **charge carrier.**

It is not immediately clear what attributes to assign to objects that do not interact electrically with each other but do interact with a charged tape strip—a strip of paper, your hand, an eraser, you name it. All we know for now is that the interaction between these objects and a charged tape is attractive rather than repulsive.

The electric charge on an object is not a permanent property; if you let a charged strip of tape hang for a while, it loses its ability to interact electrically. In other

CONCEPTS

Figure 22.3 Procedure for making strips of transparent tape that interact electrically. The purpose of the foundation strip is simply to provide a standard surface.



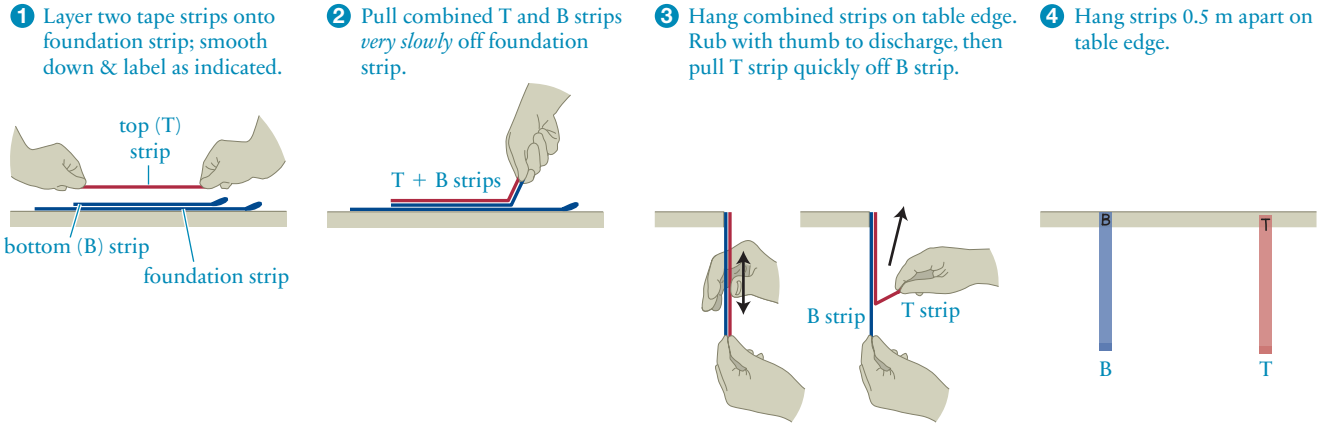


Figure 22.5 Procedure for making strips of transparent tape that carry opposite charges.

words, the strip is no longer charged—it is *discharged*. Depending on the humidity of the air, the discharging can take minutes or hours, but you can speed up the discharging by rubbing your fingers a few times over the entire length of a suspended charged strip of tape.* (The rubbing allows the charge to "leak away" from the tape by distributing itself over your body.)

22.4 (*a*) Prepare a charged strip of transparent tape as described in Figure 22.3 and then suspend the strip from the edge of your desk. Verify that the tape interacts as you would expect with your hand, with a strip of paper, and with another charged strip of tape. (*b*) Rub your fingers along the hanging strip to remove all the charge from it, and then verify that it no longer interacts with your hand. If it does interact, rub again until it no longer interacts. (*c*) Predict and then verify experimentally how the uncharged suspended strip interacts with a strip of paper and with a charged strip of tape.

CONCEPTS

To restore the charge on a discharged strip, stick the strip on top of the foundation strip from which you pulled it off (step 1 in Figure 22.3), smooth it out, and then quickly pull it off again. You can recharge a strip quite a few times before it loses its adhesive properties. Once the tape does lose its adhesiveness, however, recharging it becomes impossible. It is generally a good idea to rub your finger over the foundation strip before you reuse it to make sure that it, too, is uncharged.

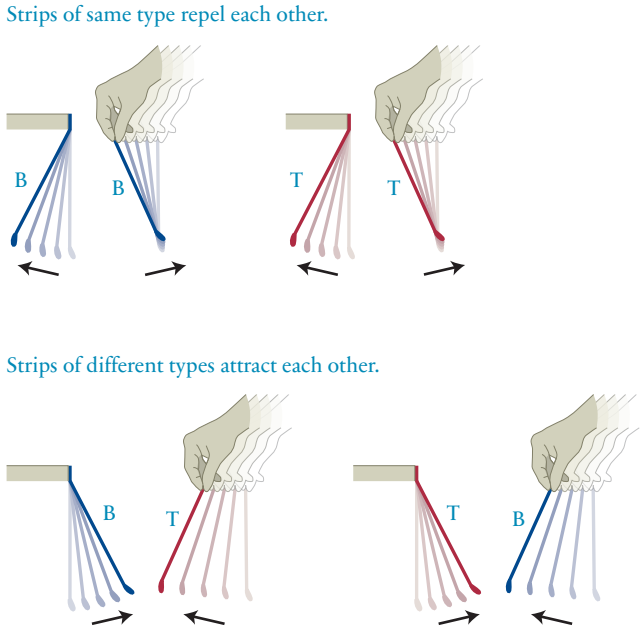
22.5 Recharge the discharged strip from Checkpoint 22.4 and verify that it interacts as before with your hand, with a strip of paper, and with another charged strip of tape.

A discharged tape strip interacts in the same way as objects that carry no charge. Such objects are said to be electrically **neutral.** They do not interact electrically with other neutral objects, but they do interact electrically with charged objects. We shall examine this surprising fact in more detail in Section 22.4.

Where does the electrical charge on a charged tape strip come from? Is charge *created* when two strips are pulled apart as in Figure 22.3? This is something we can check by sticking two strips of tape together, rubbing with our fingers to remove all charge from the combination, and then quickly separating the two strips (**Figure 22.5**).

22.6 Follow the procedure illustrated in Figure 22.5 to separate a pair of charged strips. (*a*) How does strip B interact with a neutral object? How does strip T interact with a neutral object? (*b*) Create a third charged strip and see how it interacts with strip B and with strip T. (*c*) Is strip T charged? (*d*) Is strip B charged? (*e*) Check what happens to the interactions with B and T strips when you discharge a B or a T strip by rubbing your fingers along its length.

As Checkpoint 22.6 shows, separating an uncharged pair of strips produces two charged ones, but the behavior of strip B is different from that of the other strips we have encountered so far!



22.7 Make two charged pairs of strips (B and T) following the procedure illustrated in Figure 22.5. Investigate the interaction of B with T, T with T, and B with B.

The interactions between the B and T strips are illustrated in **Figure 22.6**: Strips of the same type repel each other, while strips of different types attract each other. This series of experiments leads us to conclude that there are two types of charge on the tapes, one type on B strips and another type on T strips. Strips that carry the same type of charge, called *like charges*, exert repulsive forces on each other; strips that carry different types of charge, called *opposite charges*, exert attractive forces on each other.

Having determined that two types of electrical charge exist, a logical next question is: Are there even more types?

*If rubbing your fingers along the tape doesn't do the job, try wetting them before rubbing them over the tape.

Figure 22.6 Interactions of B and T charged strips.

22.8 (*a*) Prepare one charged strip of tape according to Figure 22.3 and hang it from the edge of your desk. Hang a narrow strip of paper from the desk edge also, about 0.5 m away from the tape strip. Pass a *plastic* comb six times quickly through your hair and then show that the comb is charged. Be sure to use a plastic comb; combs made from other materials do not acquire a charge when passed through hair. The cheapest type of comb usually works best. (*b*) Make a pair of oppositely charged B and T strips (Figure 22.5) and investigate how they interact with a charged comb. (*c*) Does your comb behave like a B strip, a T strip, or neither?

Experiments show that *any* charged object—obtained by rubbing objects together or otherwise—always attracts either a B strip or a T strip and repels the other. No one has ever found a charged object that repels or attracts *both* types of strips. In other words:

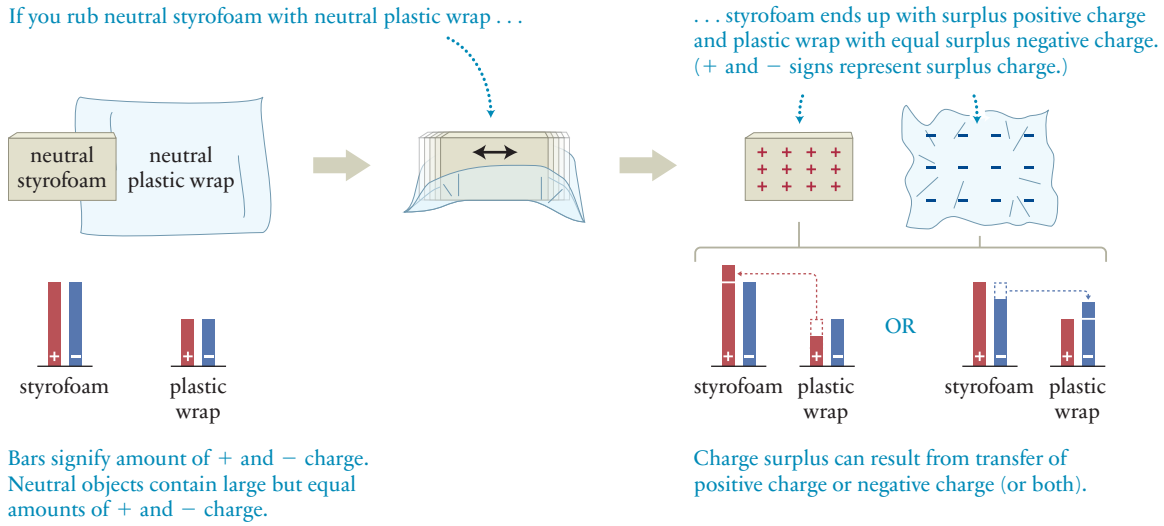
There are two and only two types of charge. Objects that carry like charges repel each other; objects that carry opposite charges attract each other.

The two types of charge never appear independently of each other: Whenever two neutral objects are either rubbed together and then separated or, if an adhesive surface is involved, stuck together and then separated and one of them acquires a charge of one type, the other object always acquires a charge of the other type. The generation of opposite charges is obvious when you separate a neutral pair of tape strips. When you pass a comb through your hair, the comb acquires a charge of one type and your hair acquires a charge of the other type. On a dry day, you may have noticed that some hair strands stand up away from your head. Each charged strand is being repelled by the other charged strands, and so they are all getting as far away from one another as possible.

It can be shown that when two tape strips are separated, the forces exerted by the B strip and the T strip on a third charged strip are equal in magnitude, although one is attractive and the other repulsive. Furthermore, when the B and T strips are recombined, the combination is neutral again. These observations suggest that after you rub and then separate a pair of objects, the objects carry equal amounts of opposite charge. Combining these equal amounts of opposite charge produces zero charge. These observations indicate that all neutral matter contains equal amounts of positive and negative charge. The two types of charge are called **positive** and **negative charges.** The definition of negative charge is as follows:*

Negative charge is the type of charge acquired by a plastic comb that has been passed through hair a few times.

22.9 Does the B strip you created in Checkpoint 22.8 carry a positive charge or a negative charge?



When two neutral objects touch, some charge can be transferred from one object to the other, with the result that one object ends up with a surplus of one type of charge and the other object ends up with an equal surplus of the other type of charge. For example, when a neutral piece of styrofoam is rubbed with a neutral piece of plastic wrap, the styrofoam acquires a positive charge (meaning it contains more positive than negative charge) and the plastic wrap acquires a negative charge (it has a surplus of negative charge). Without further information, however, we cannot tell whether positive charge has been transferred from the wrap to the styrofoam, or negative charge has been transferred from the styrofoam to the plastic wrap, or a combination of these two. (See **Figure 22.7** on the next page.) Summarizing:

All neutral matter contains equal amounts of positive and negative charge; charged objects contain unequal amounts of positive and negative charge.

In illustrations, surplus charge is represented by plus or minus signs. Keep in mind, however, that these signs never represent the only type of charge in an object. The plus signs on the positively charged styrofoam in Figure 22.7, for example, mean only that the styrofoam

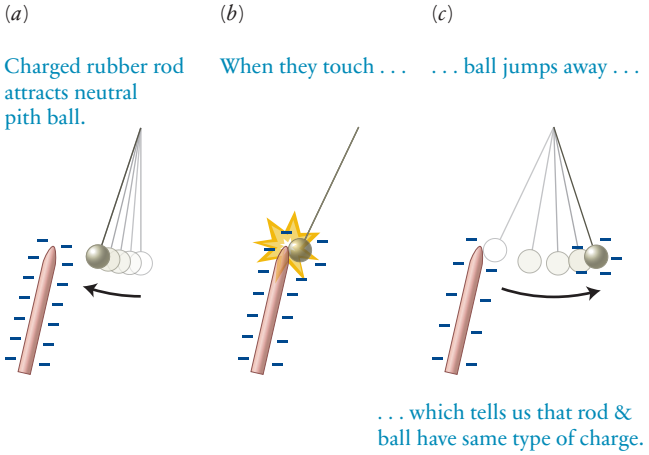
*Historically, negative charge was (arbitrarily) defined by Benjamin Franklin (1706–1790) as the charge acquired by a rubber rod rubbed with cat fur. Because plastic combs and hair are more easily accessible than rubber rods and cat fur, the definition of negative charge given here is more convenient.

Figure 22.7 Rubbing neutral styrofoam with neutral plastic wrap leaves the two objects with equal charges of opposite types.

contains more positive than negative charge, either because some of its negative charge has been removed or because some positive charge has been added. In addition to the 12 positive charge carriers shown in Figure 22.7, the styrofoam contains millions and millions of positive charge carriers paired with millions and millions of negative charge carriers. A drawing such as Figure 22.7 shows only *unpaired* charge carriers (usually referred to as *surplus charge*).

As our observations in Figure 22.6 show, oppositely charged B and T strips attract each other. The interaction between positive and negative charge tends to bring positive and negative charge carriers as close together as possible. Because combining equal amounts of positive and negative charge results in zero charge, we can say that charge carriers always tend to arrange themselves in such a way as to produce uncharged objects—indeed, all matter around us tends to be neutral.

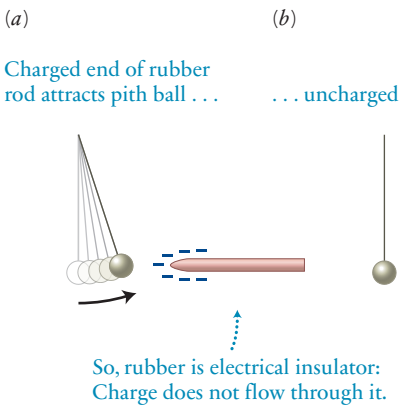
CONCEPTS



22.10 Imagine having a collection of charged marbles that retain their charge even when they touch other objects. Red marbles are positively charged, and blue marbles are negatively charged. (*a*) What happens if you place a bunch of red marbles close together on a flat horizontal surface? (*b*) What happens if you do the same with a bunch of blue marbles? (*c*) What happens if you do the same with an equal mixture of red and blue marbles? (*d*) What happens in part *c* if you have a few more red marbles than blue ones? (*e*) As a whole, is the collection of marbles in part *d* positively charged, negatively charged, or neither?

22.3 Mobility of charge carriers

To gain a better understanding of electrical charge, many additional experiments are required, most of which require items not easily found at home. A rubber rod rubbed with a piece of cat fur acquires—by Benjamin Franklin's original definition—a negative charge (and the fur acquires a positive charge). A glass rod rubbed with silk acquires a positive charge (and the silk a negative charge). Other materials also acquire a charge upon contact or rubbing, but these two combinations of rubber/fur and glass/silk provide the most convenient means of generating relatively large amounts of charge.



Interesting things happen when a charged rubber rod is brought into contact with an uncharged pith ball.* As the rod is brought near the ball, the ball moves toward the rod because of the attraction between the charged rod and the neutral ball (**Figure 22.8*a***). As the ball touches the rod, however (Figure 22.8*b*), the crackling sounds of tiny sparks may be heard. The ball suddenly jumps away from the rod (Figure 22.8*c*), indicating that the interaction between rod and ball has become repulsive. This repulsive interaction indicates that the ball has acquired the same type of charge as the rod (negative).

Figure 22.8 A charged rubber rod can transfer charge to a neutral pith ball.

Pith is the soft, lightweight, spongelike material that makes up the interior of the stems of flowering plants.

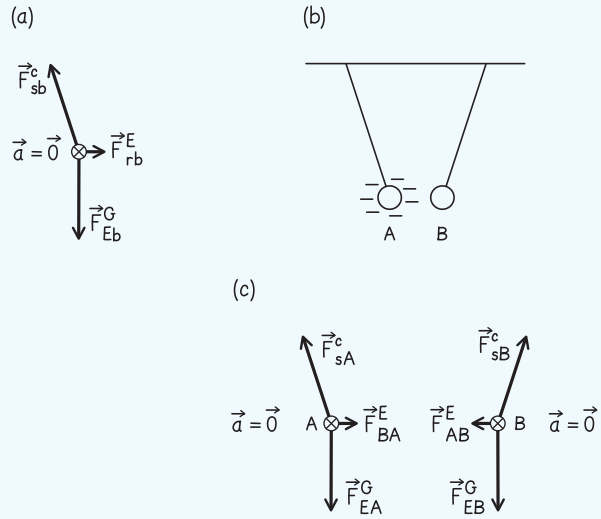
Figure 22.9 A rubber rod is an example of an electrical insulator.

In other words, some of the surplus negative charge on the rod has been transferred to the ball.

Charge can be transferred from one object to another by bringing the two into contact.

We can use this phenomenon to investigate the electrical behavior of different kinds of materials. For example, if we transfer some charge to one end of an uncharged rubber rod and then extend the charged end toward an uncharged pith ball, the two interact electrically, as shown in **Figure 22.9*a***. If we hold the *uncharged* end near the pith ball, as in Figure 22.9*b*, however, no interaction occurs. This tells us that the charge does not flow from one end of the rubber rod to the other; instead, it remains near the spot where it has been deposited. Any material in which charge doesn't flow (or moves only with great difficulty) is called an **electrical insulator.**

Electrical insulators are materials through which charge carriers cannot flow easily. Any charge transferred to an insulator remains near the spot at which it was deposited.



Glass, rubber, wood, and plastic are examples of electrical insulators. Air, particularly dry air, is also an insulator, although the presence of large amounts of charge can cause charge carriers to "jump" from one object to another, causing sparks.

EXERCISE 22.1 Electric forces

(*a*) Draw a free-body diagram for the pith ball in Figure 22.9*a*. (*b*) Two identical neutral pith balls A and B are suspended side by side from two vertical strings. After some charge is transferred from a charged rubber rod to A, A and B interact. (B remains neutral because the two balls never come into contact with each other.) Sketch the orientation of A and B after the charge has been transferred to A. (*c*) Draw a free-body diagram for each ball.

SOLUTION (*a*) The ball is subject to three forces: a gravitational force, a contact force exerted by the string, and an attractive electric force exerted by the charged particles in the rod. This last force is directed horizontally toward the rod. Because the ball is at rest, I know that the vector sum of these three forces is zero. So the horizontal component of the force exerted by the string on the ball must be equal in magnitude to the electric force exerted by the rod on the ball, and the vertical component of the force exerted by the string on the ball must be equal in magnitude to the gravitational force exerted by Earth on the ball (**Figure 22.10*a***).

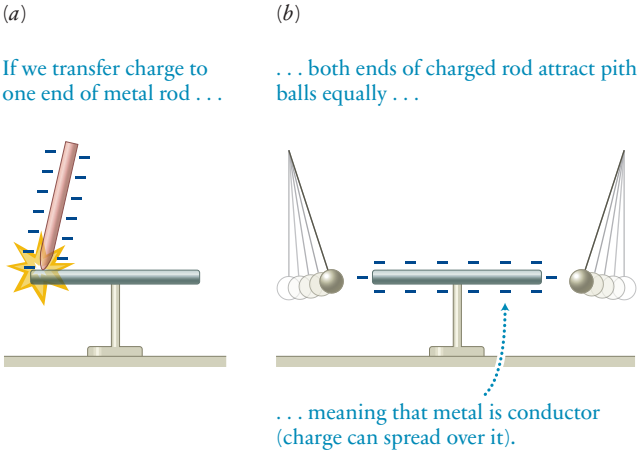


Figure 22.10

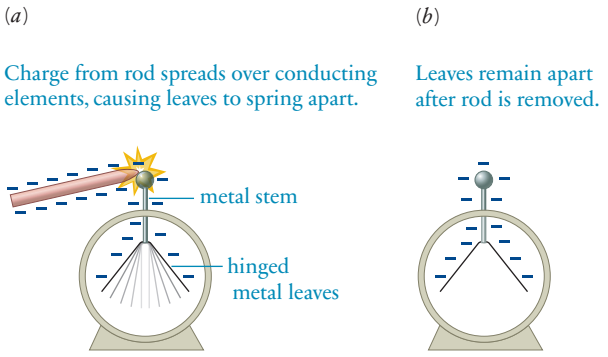
(*b*) As we saw in Section 22.2, a neutral object interacts electrically with a charged object. The electric force exerted by A on B and that exerted by B on A form an interaction pair and so their magnitudes are equal. Because the masses of the pith balls are the same, each is pulled in by the same distance. Thus my sketch is as shown in Figure 22.10*b*. (*c*) See Figure 22.10*c*.

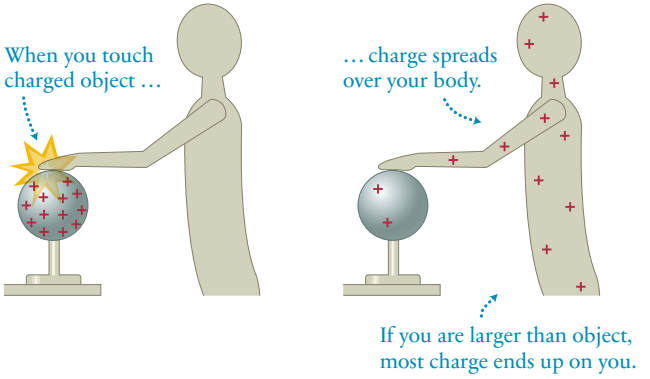


In **Figure 22.11**, a charged rubber rod is brought into contact with an uncharged metal rod supported on an electrically insulating stand. Once the charged rod has touched the metal rod, *all* points on the surface of the

Figure 22.11 A metal rod is an electrical conductor.

CONCEPTS

Figure 22.12 An electroscope depends on electrical conduction.



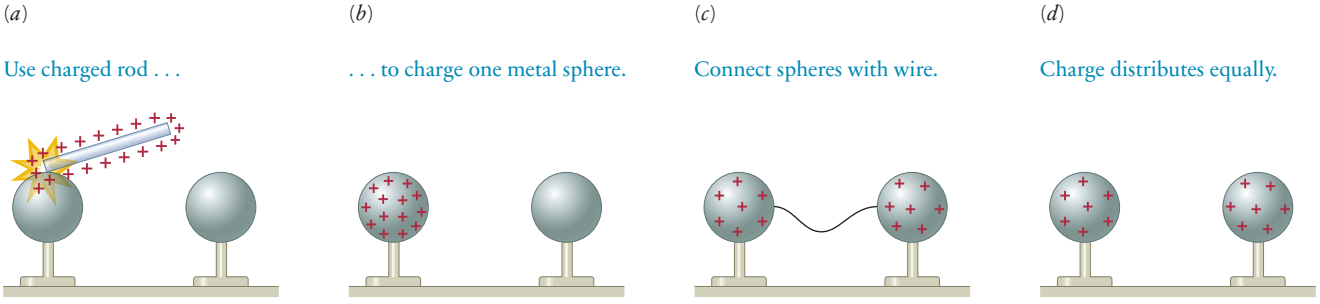
metal rod interact electrically with other objects, indicating that the charge spreads out over the metal rod. The tendency of charge to spread out over metal objects can be demonstrated with an *electroscope* (**Figure 22.12*a***). Two strips made of metal foil are suspended from a small metal rod in an electrically insulating enclosure; the rod is connected to a metal ball on top of the enclosure. When the metal ball is charged by an exterior source, the strips move away from each other. The explanation for this movement is that the added charge quickly moves from the metal ball through the metal rod and onto the two metal strips. Once the strips carry the same type of charge, they repel each other (Figure 22.12*b*).

Another demonstration of the free motion of charges through metals is shown in **Figure 22.13**: When a long wire is used to connect a charged metal sphere to an uncharged metal sphere, charged particles flow from the charged sphere to the uncharged one. Because wires are made of metal, this experiment shows that, in contrast to what happens with electrical insulators, charge moves easily through a metal and across a metal-to-metal contact. Materials through which charge carriers can flow easily are called electrical **conductors,** and the flow of charge carriers through conductors is called **conduction.**

Electrical conductors are materials through which charge carriers can flow easily. Any charge transferred to a conductor spreads out over the conductor and over any other conductors in contact with it.

Metals are the only solid materials that are conductors at room temperature. (As noted earlier, glass, plastic, and most other solids are electrical insulators.) Although charge does not flow easily through pure water, minute amounts of impurities turn water into a good conductor. Because most water contains some impurities, water is therefore usually considered a conductor.

Figure 22.14 Because of its water content, the human body is a conductor.



Except for the outer layer of soil, Earth is also a good conductor. Consequently, when a charged, conducting object is connected to Earth by a wire, a process called **grounding,** charge carriers can flow between Earth ("ground") and the object. Because Earth is so large, it can supply or absorb a nearly unlimited number of charge carriers. In the absence of other nearby electrical influences, the grounded object is left with no surplus of either type of charge.

Because of its high water content, the interior of the human body is a conductor. Consequently, any time you touch a charged object, as in **Figure 22.14**, some of the charge moves into you—you act like a grounding agent just the way Earth does. As long as you keep touching the object, charge flows into your body, reducing the charge on the object (Figure 22.14). If the charge on the object is large, the charge that accumulates on your hair makes your hair stand up and separate as far as possible, like the leaves of an electroscope (**Figure 22.15**).

22.11 (*a*) Why is it impossible to charge a metal rod held in your hand by rubbing the rod with other materials? (*b*) Why can you charge a rubber rod even when you hold it in your hand?

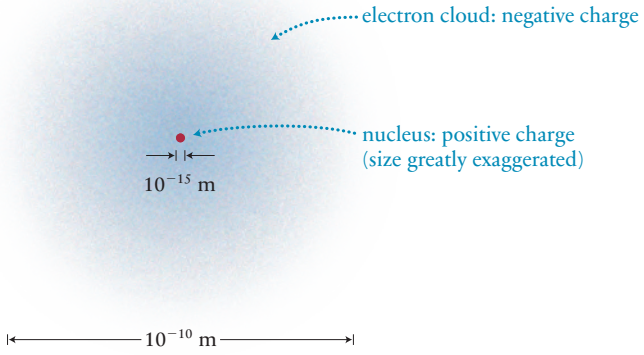
Figure 22.13 A conducting wire distributes charge between two conducting spheres.

CONCEPTS

Figure 22.15 Charge spreads over the human body, so a large charge will cause your hairs to repel one another and stand on end.

Is charge some sort of fluid that flows from one object to another, or is it composed of small particles that can be peeled off or stuck onto objects? To answer this question, we must look at the atomic structure of matter. All matter on Earth consists of atoms (see Section 1.3), the structure of which is schematically illustrated in **Figure 22.16**. Nearly all the atom's mass is concentrated in the extremely small nucleus at the center. The nucleus is composed of protons and neutrons. The region surrounding the nucleus, representing most of the atom's volume, is a cloud of electrons.

Experiments show that electrons have a negative electrical charge—they are repelled by a charged comb* and by other electrons. Protons carry a positive charge, and neutrons carry no charge. The protons and neutrons in the nucleus are held together tightly by the strong interaction (see Chapter 7), which is great enough to overcome the electrical repulsion between the positively charged protons. The electrical attraction between the positively charged nucleus and the negatively charged electrons is responsible for keeping the electrons bound to the nucleus. The electron cloud does not collapse on the nucleus because of additional constraints imposed on the electrons by the laws of quantum mechanics.



Charge is an inherent property of the electron, which means it is impossible to remove the charge from an electron—there is no such thing as a discharged electron. Experiments show that, excluding quarks (Section 7.6),

All electrical charge comes in whole-number multiples of the electrical charge on the electron.

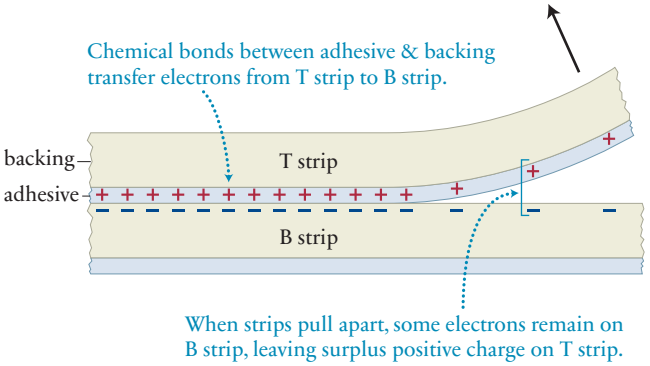
For this reason, the magnitude of the charge on the electron, designated by the letter e, is called the **elementary charge.**

*Recall from our discussion of positive and negative charge carriers in Section 22.2 that a plastic comb carries a negative charge.

Figure 22.16 Structure of the atom (not to scale).

Every atom contains equal numbers of electrons and protons. Because atoms are neutral, the fact that they contain equal numbers of electrons and protons tells us that the magnitude of the positive charge on the proton is also e. The charge on an electron is $-e$, and that on a proton $+e$. As with electrons, the charge cannot be removed from a proton.

Given that macroscopic objects contain an immense number of atoms and that each atom can contain dozens of electrons and protons, we see that ordinary objects contain an immense number of positively charged protons, exactly balanced by an equal number of negatively charged electrons. A surplus of just a minute fraction of these numbers is sufficient to give rise to a noticeable macroscopic charge. For example, when you pull apart two strips of transparent tape, the separation causes a surplus of less than one in a trillion (10^{12}) electrons. (Because there are about 10^{22} electrons in the strip, that fraction represents some 10^{10}, or ten billion electrons.)



When two atoms are brought close together, they may form a chemical bond by transferring or sharing one or more electrons from one atom to the other. When an electron transfer takes place, both atoms contain unequal numbers of electrons and protons and are now called **ions** instead of atoms. One of the two ions has gained one or more electrons, meaning it contains more electrons than protons and therefore carries a negative charge. The other ion, the one that lost electrons, contains more protons than electrons and so carries a positive charge.

Ions in solids move very little, but ions in liquids can move freely. For instance, in table salt, a compound made of pairs of sodium (Na^+) and chloride (Cl^-) ions, the charged ions hardly move at all, meaning that solid table salt is an electrical insulator. Dissolve table salt in water, however, and the solution contains large quantities of positively charged sodium ions and negatively charged chloride ions. Because these ions can move freely, the solution is an electrical conductor.

Some solids are made not of paired ions the way sodium chloride is but rather of individual atoms. In atomic solids that are electrical insulators, the electrons

CONCEPTS

Figure 22.17 How strips of tape can acquire opposite charges when pulled apart.

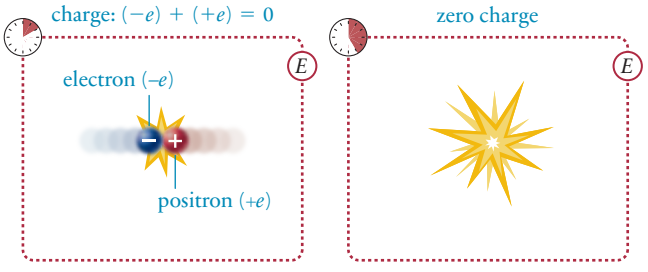
in the atoms are unable to move because each electron is bound to a specific atom. Diamond (made of the element carbon) and glass are two familiar examples. Metals are also atomic solids rather than ionic solids, but in metals, each atom gives up one or more electrons to a shared "gas" of electrons that spreads throughout the volume of the metal. The metal as a whole is still neutral: The negative charge of the electron gas is exactly balanced by the positive charge of the ions. The electrons in the gas are called *free electrons* because they can move freely inside the metal; these electrons are responsible for the easy flow of charge through a metal.

Nearly all electrical phenomena are due to the transfer of electrons—and therefore charge—from one atom to another. For example, when the sticky side of one strip of transparent tape is applied on top of the nonsticky side of a second strip, atoms in the adhesive from the top strip form chemical bonds with atoms in the nonsticky surface of the bottom strip by transferring electrons, as shown in **Figure 22.17**. These bonds are responsible for the adhesion of one strip to the other. When the strips are pulled apart quickly, the bonds are broken, but not all electrons manage to get back to the top strip. The bottom strip thus ends up with a surplus of electrons, making it negatively charged, and the top one with a deficit of electrons, making it positively charged.*

As we saw in Section 10.4, friction between two surfaces also involves the breaking of chemical bonds. As with the separation of the tape strips, this bond breaking sometimes leaves surplus charge on the surfaces. When you touch a piece of plastic food wrap to a piece of styrofoam, for instance, chemical bonds form between atoms on the two surfaces. In these bonds, electrons from the styrofoam move to the wrap. If you then rub the surfaces against each other, these bonds are broken, and some of the electrons originally on the styrofoam stay on the wrap. If the breaking of the chemical bonds occurs slowly, the electrons migrate back and no surplus charge builds up. For that reason it is necessary to rub vigorously or to separate strips of tape quickly. The key point is:

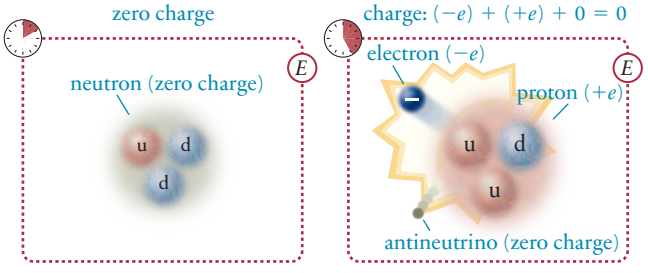
*Depending on the type of adhesive and the material of the backing, the transfer of electrons can also be in the other direction.

Any two dissimilar materials become charged when brought into contact with each other. When they are separated rapidly, small amounts of opposite charge may be left behind on each material.



Because charging by breaking of chemical bonds is due to a transfer of charge, we now see that for every surplus of negative charge that appears in one place, an equal surplus of positive charge appears somewhere else. After the two strips in Figure 22.17 are separated, the sum of the positive charge on the T strip and the negative charge on the B strip is still zero. No creation or destruction of charge is involved, suggesting that electrical charge—like momentum, energy, and angular momentum—is a conserved quantity. The principle of **conservation of charge** states:

Electrical charge can be created or destroyed only in identical positive-negative pairs such that the charge of a closed system always remains constant.



No process has ever been found to violate this principle. Even when charged subatomic particles, such as electrons and protons, are created or destroyed—a process that can be observed in high-energy particle accelerators—charge is conserved. For example, when an electron (charge $-e$) collides with a subatomic particle called the *positron* (charge $+e$), both particles are destroyed, leaving nothing but a flash of highly energetic radiation (**Figure 22.18***a*). The charge of the electron-positron system before the collision is $(-e) + (+e) = 0$, and it is still zero after the collision. Likewise, in a process called beta decay, when a free neutron (carrying

Figure 22.18 Because charge is conserved, the charge of a closed system does not change even when particles are created or destroyed.

(*a*) Electron-positron annihilation

(*b*) Decay of a free neutron

CONCEPTS

zero charge and made up of two down quarks and one up quark) decays into a proton (charge $+e$, one down and two up quarks), an electron (charge $-e$), and a neutral subatomic particle called the antineutrino (zero charge), the charge of the system comprising the neutron and the particles into which it decays remains zero (Figure 22.18*b* and Section 7.6).

22.12 When two objects made of the same material are rubbed together, friction occurs but neither material acquires surplus charge. Why?

22.4 Charge polarization

Let us now reexamine the interaction between a charged object and a neutral one. **Figure 22.19** shows the interaction between a charged rubber rod and an uncharged electroscope. With the rod far away (Figure 22.19*a*), the leaves of the electroscope hang straight down. When the rod is brought near the ball of the electroscope (Figure 22.19*b*), the leaves separate even without any contact between the rod and the electroscope. As the distance between the rod and the electroscope is increased again, the leaves drop down, showing that no charge has been transferred from the rod to the electroscope.

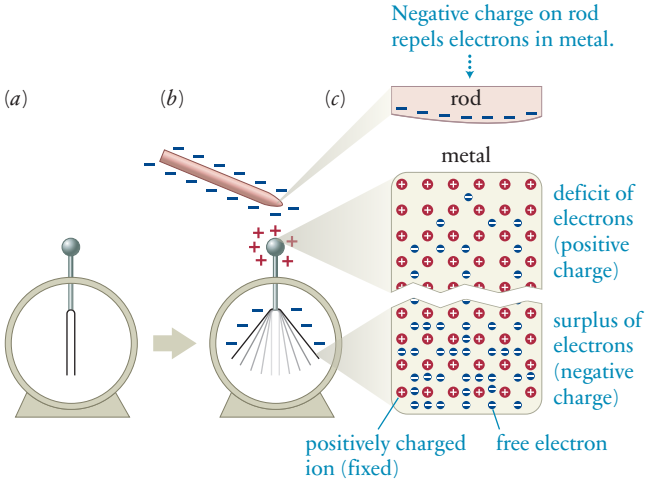
Why do the leaves separate even though the electroscope remains neutral? They separate because the negative charge on the rod repels the free electrons in the metallic parts of the electroscope: The free electrons are pushed as far away as possible from the rod (Figure 22.19*c*) and pile up in the leaves. This redistribution of charge is nearly instantaneous. The top of the electroscope thus ends up with a deficit of electrons—a positive charge—and the leaves end up with a surplus of electrons—a negative charge. The negative charge on the leaves is responsible for the repulsion between them. When the rod is removed, the electrons, being repelled by one another and attracted to the positive charge on the electroscope ball, immediately flow back to their normal positions, evening out the distribution of positive and negative charge.

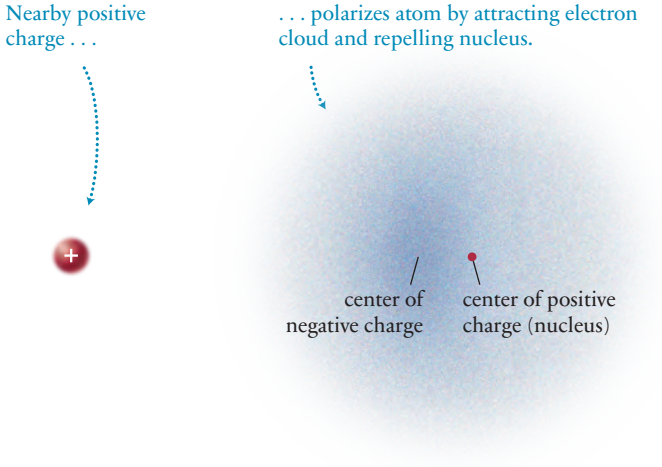
22.13 (*a*) In Figure 22.19*b*, is the electroscope as a whole positively charged, negatively charged, or neutral? (*b*) How does the magnitude of the positive charge on the electroscope ball compare with the magnitude of the negative charge on the leaves? (*c*) Is the force exerted by the rod on the electroscope ball attractive or repulsive? Is the force exerted by the rod on the leaves attractive or repulsive? (*d*) How do you expect the magnitude of the force the rod exerts on the ball to compare with the magnitude of the force the rod exerts on the leaves?

Any separation of charge carriers in an object is called **charge polarization,** or simply **polarization,** and an object in which charge polarization occurs is said to be *polarized*. The electroscope of Figure 22.19*b*, for instance, is polarized by the nearby charged rod. In any object in which charge is polarized, there are two charged *poles*, one positive and the other negative. In the electroscope of Figure 22.19*b*, the positive pole is at the ball and the negative pole is in the foil strips.

In metals, the polarization induced by the presence of a nearby charged object is very great because the free electrons in the metal move easily in response to the presence of the charged object. Even in electrical insulators, however, where there are no free electrons moving about, a nearby charged object induces some polarization. The basic reason for the polarization of insulators is illustrated in **Figure 22.20**: In the presence of an external charge, the center of the electron cloud and the nucleus of an atom shift away from each other, causing the atom to become polarized. So, when a negatively charged comb is brought near a small piece of paper, each atom in the paper becomes polarized—the electron clouds are pushed away from the comb, and the nuclei are pulled toward the comb. If we consider the paper as consisting

Figure 22.19 In (*a*) and (*b*), a charged rod induces polarization in an electroscope. (*c*) A schematic atom-level view.





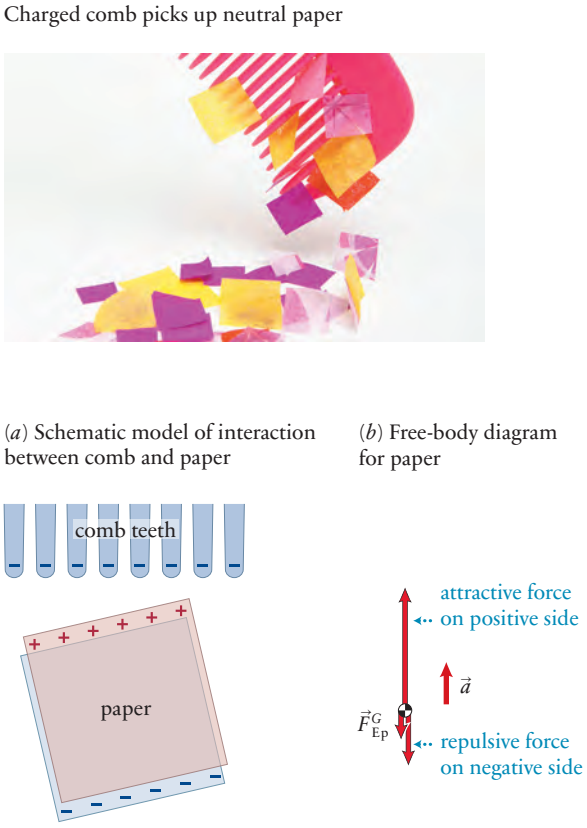


Figure 22.20 Polarization of a neutral atom.

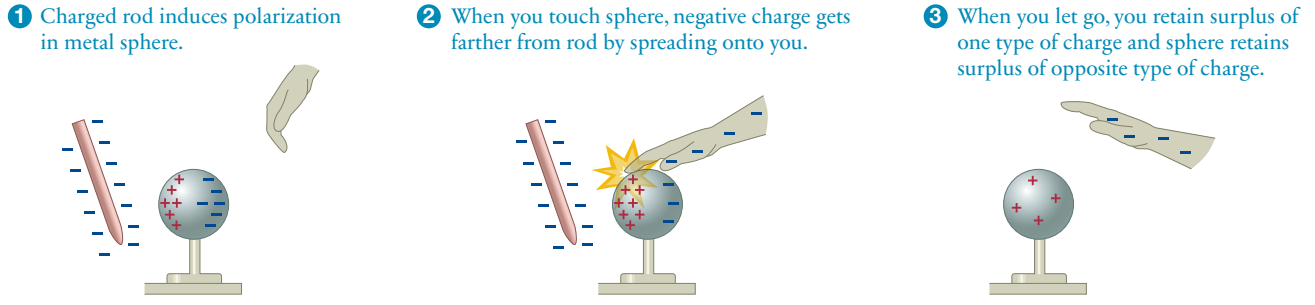
CONCEPTS

Figure 22.21 Polarization of a neutral insulator (bits of paper) by a charged comb. In (*a*), a single bit of paper is modeled as two offset sheets with opposite charges.

of two overlapping parts that have the same shape but carry opposite charges, the positively charged part is pulled a bit toward the comb and the negatively charged part is pushed away, as shown in **Figure 22.21*a***. This leaves the central part of the paper neutral but creates a sliver of surplus positive charge on the side facing the comb and an equal amount of surplus negative charge on the opposite side, and so the paper is polarized.



22.14 In an atom, what limits the separation between the electron cloud and the nucleus in the presence of an external charge? Why, for example, isn't the electron cloud in Figure 22.20*b* pulled all the way to the location of the external positive charge?

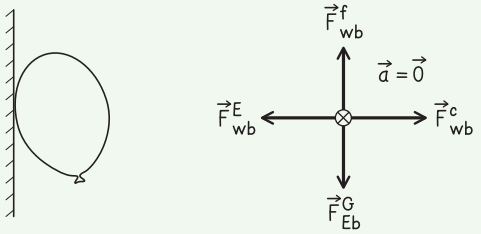
The polarization of atoms is responsible for the attraction between charged and neutral objects. In Figure 22.21, for example, the positively charged side of the paper is closer to the comb than the negatively charged side. Because the electric force magnitude decreases with increasing distance, the magnitude of the attractive force exerted on the positive side is greater than the magnitude of the repulsive force exerted on the negatively charged side (Figure 22.21*b*). Consequently, the vector sum of the electric forces exerted by the comb on the neutral piece of paper points toward the comb and the paper is pulled toward the comb.

22.15 (*a*) When a positively charged object is brought near a neutral piece of paper, is the vector sum of the forces exerted by the charged object on the paper attractive or repulsive? (*b*) Describe what would happen when a negatively charged comb is brought near an electroscope if protons, not electrons, were mobile in metals. (*c*) Can you deduce from the experiment illustrated in Figure 22.19 which charge carriers—electrons or protons—are mobile in metals?

Figure 22.22 illustrates how you can exploit polarization to charge neutral conducting objects. A negatively charged rod brought near a metal sphere induces polarization in the sphere. To get as far away as possible from the negative charge on the rod, the electrons in the metal of the sphere move to the right surface. Thus the surface of the sphere nearer the rod becomes the positive pole, and the surface farther from the rod becomes the negative pole. When you touch the metal, the electrons can move into your body, thereby getting even farther away from the negative charge on the rod. In essence, you have become the negative pole, while the sphere is the positive pole. If you remove your hand from the sphere, the sphere is left with a deficit of electrons (they stayed inside you!) and so carries a positive charge—it has become charged without ever touching a charged object. (Likewise, you now have a surplus of negative charge and carry a negative charge, which is spread so thin that it is hardly noticeable.) This process is called **charging by induction.**

Figure 22.22 Polarization can be exploited to charge neutral conducting objects.

CONCEPTS



Self-quiz

1. You can use a positively charged object to charge a neutral object (*i*) by conduction (in the absence of grounding) or (*ii*) by induction (with grounding). For each process, which type of charge (positive, negative, or neither) does the neutral object acquire?
2. Because we observe two types of electric interactions, attractive and repulsive, we postulate two types of charge. Do you think there are also two types of mass? Why do you think this? Do you think there are two types of magnetic pole? Why do you think this?
3. Is the statement *A plastic comb that has been passed through the hair a few times carries a negative charge* a physical law or a definition? What are some of the differences between a law and a definition?
4. A balloon rubbed in your hair or on your clothes sticks to a wall. If you place the rubbed side of the balloon against the wall, it sticks to the wall immediately. Try this, however: After rubbing the balloon in your hair, place the side of the balloon you did not rub against the wall and notice how the balloon turns until the rubbed side is touching the wall (*a*) Draw a free-body diagram for the balloon sticking to the wall. (*b*) Given that the balloon rotates so that the rubbed area is against the wall, do you think the balloon is an electrical insulator or conductor? (*c*) Was charge created in either the balloon or the wall in order for the sticking to occur? (*d*) Is any charge transferred from the balloon to the wall? Why or why not?
5. Air can act as both an insulator and a conductor. Consider reaching for a metal doorknob after scuffing your feet over a carpet. As your hand approaches the knob, a spark jumps between your hand and the knob. Explain how air acts as both insulator and conductor in this situation.

Answers

1. (*i*) Positive. When the two objects are brought into contact with each other (a necessary condition for conduction), surplus positive charge moves from the charged object to the neutral one. Thus the neutral object acquires the same type of charge as the charged object. (*ii*) Negative. Because the objects don't touch during charging by induction, charge carriers of the same type as the charged object escape from the neutral object during grounding.
2. Mass is the quantity responsible for gravitational interactions. Because all gravitational interactions are attractive, we can assume there is only one type of mass. Magnetic poles are responsible for magnetic interactions, which can be attractive or repulsive. Therefore there must be two types of magnetic pole (called north and south).
3. Definition. A law arises from observable phenomena and is found to be true in all cases that have been tested or observed (see Section 1.1). A definition cannot be tested. There is no test that allows us to observe that the charge on a comb passed through hair is negative. All we can do is show that the charged comb behaves in a fashion similar to other objects whose charge we call negative.
4. (*a*) See **Figure 22.23**. (*b*) Insulator. Because the only portion of the balloon that is attracted to the wall is the rubbed area, we know that the charge created by the rubbing does not spread out over the balloon surface. (*c*) No. Electrical charge can never be created. The surplus charge on the balloon was transferred from your hair or clothing. (*d*) No. If change were transferred, the balloon and the wall would repel each other.

Figure 22.23

5. Scuffing your feet on the carpet transfers charge from the carpet to you. Before you get near the knob, the air insulates your charged body from the knob. As you move nearer and nearer to the knob, the magnitude of the electric force between the charge carriers in your hand and those in the knob increases until the forces are so great that the air molecules are ionized, thereby producing a conducting pathway between your hand and the knob. Now the ionized air acts as a conductor for the jumping charge.

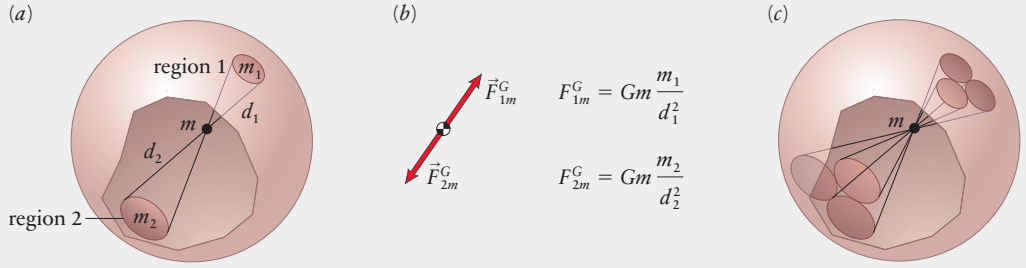
22.5 Coulomb's law

Quantitative experiments with electrical charge are difficult to carry out because objects lose their charge and because charge carriers on objects tend to rearrange themselves in the presence of other charged objects. In the 18th century, however, the English clergyman and scientist Joseph Priestley carried out a remarkable experiment: He charged a hollow sphere and showed that no electric force was exerted on a small piece of charged cork placed inside the sphere. Remembering that Newton had proven that no gravitational force exists inside a hollow sphere (see the box "Zero gravitational force inside a spherical shell" and **Figure 22.24**, below) because the gravitational force decreases with the square of distance, Priestley proposed that the electric force, too, decreases as $1/r^2$.

In 1785, Charles Coulomb, a French physicist, provided direct evidence for an inverse-square law by measuring how the electric force between two charged spheres changes as the distance between the spheres changes. The basic apparatus for Coulomb's experiment is shown in **Figure 22.25**. A small dumbbell is suspended from a long fiber. When spheres A and B are charged, the electric force between them twists the fiber. The amount of twist is a measure of the magnitude of the force between the two spheres

Zero gravitational force inside a spherical shell

A consequence of the inverse-square dependence on distance of the gravitational force is that a uniform spherical shell exerts *no force at all* on a mass placed anywhere inside it. This result is very important in electrostatics because it provides a strong test of the law describing the electric force between charged objects.



Consider the uniform spherical shell in Figure 22.24*a*. A particle of mass m is placed off-center inside the shell. To determine the force exerted by the shell on the particle, consider first the force exerted by region 1, defined as a very small region of the shell surface. Let the mass of this region be m_1 and its distance from the particle be d_1, which means the magnitude of the gravitational force exerted by this region on the particle is Gm_1m/d_1^2. Extending the cone defined by the particle and region 1 to the opposite side of the shell gives us a small region 2, of mass m_2 and at distance d_2 from the particle. The magnitude of the gravitational force exerted by this region on the particle is Gm_2m/d_2^2. If the particle is closer to region 1 than to region 2, the area of region 2 must be greater than the area of region 1 (because of how we defined region 2 as being an extension of the cone formed by region 1 and the particle), which means region 2 contains more mass: $m_2 > m_1$.

Because the mass of the shell is distributed uniformly over the shell, the mass of each of our two regions is proportional to its area: $m_1/m_2 = a_1/a_2$. Because they are marked out by similar cones, the areas of the two regions are proportional to the squares of the distances to the particle: $a_1/a_2 = d_1^2/d_2^2$, which means that

$$\frac{m_1}{m_2} = \frac{d_1^2}{d_2^2}.$$

Rearranging terms, we get $m_1/d_1^2 = m_2/d_2^2$ *regardless* of the position of the particle, and so we see that the forces cancel: The two regions exert forces of equal magnitude in opposite directions on the particle (Figure 22.24*b*). We can now apply the same arguments to other pairs of small regions on either side of the particle, each yielding equal and opposite forces on the particle (Figure 22.24*c*). The vector sum of all the forces exerted on the particle by all the small regions making up the spherical shell is thus zero.

Figure 22.24

QUANTITATIVE TOOLS

(see also Section 15.7). A similar arrangement was used a few years later by Cavendish to study gravitational interactions (see Section 13.5).

Coulomb also devised a method for systematically varying the "quantity of charge" q on a metal sphere. He found that when a charged metal sphere is brought into contact with an identical uncharged metal sphere, the final charge is the same on each sphere—both exert a force of equal magnitude on a third charged object. In other words, each sphere gets half the original charge. By sharing charge among several identical metal spheres, Coulomb could produce spheres whose charge was one-half, one-quarter, one-eighth, and so on of the original charge (**Figure 22.26**).

By thus varying the charges on spheres A and B of his apparatus, Coulomb found that the **electric force** is proportional to the charge on each sphere. We can summarize these findings in one equation, called **Coulomb's law,** which gives the magnitude of the electric force exerted by two charged particles separated by a distance r_{12} and carrying charges q_1 and q_2:

$$F_{12}^E = k\frac{|q_1|\ |q_2|}{r_{12}^2}. \tag{22.1}$$

As we shall see in Chapter 27, the interaction between charged particles becomes more complicated when the particles are not at rest. For this reason the force in Coulomb's law is sometimes called the *electrostatic* force and the branch of physics that deals with stationary distributions of charge is called *electrostatics*.

If the positions of the two charged particles are given by the vectors $\vec{r}_1$ and $\vec{r}_2$, respectively, then the distance between them is $r_{12} = |\vec{r}_2 - \vec{r}_1|$. The value of the constant of proportionality k depends on the units used for charge, force, and length. The absolute-value signs around the charges in Eq. 22.1 are necessary because q_1 and q_2 can be negative but the *magnitude* F_{12}^E of the electric force must always be positive.

Coulomb's law bears a striking resemblance to Newton's law of gravity (Eq. 13.1):

$$F_{12}^G = G\frac{m_1 m_2}{r_{12}^2}. \tag{22.2}$$

Why these two laws have the same mathematical form remains a mystery. The main differences between the two are that mass is always positive but electrical charge can be positive or negative, which means that the gravitational force is always attractive but the electric force can be attractive or repulsive.

The derived SI unit of charge, called the **coulomb** (C), is the quantity of electrical charge transported in 1 s by a current of 1 ampere, a quantity and unit we shall define in Chapter 27. One coulomb is equal to the magnitude of the charge on about 6.24×10^{18} electrons. Conversely, the magnitude of the charge of the electron is

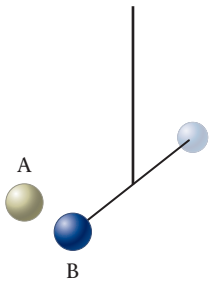
$$e = 1/6.24 \times 10^{18}\ \text{C} = 1.60 \times 10^{-19}\ \text{C}. \tag{22.3}$$

The charge on any object comes in only whole-number multiples of this elementary charge:

$$q = ne \quad (n = 0,\ \pm 1,\ \pm 2,\ \pm 3, \ldots). \tag{22.4}$$

This means that an object can have charge $q = 0$, $q = +7e$, $q = -4e$, and so forth, but not, for instance, $+1.2e$. Because the elementary charge is very small, the fact that charge exists only as whole-number multiples of the elementary charge isn't noticeable under ordinary circumstances. For example, running a comb through your hair easily gives the comb a surplus of about 10^{12} electrons, and the quantity of electrons flowing through

Figure 22.25 Schematic diagram of Coulomb's apparatus for measuring the electric force between two charged spheres.



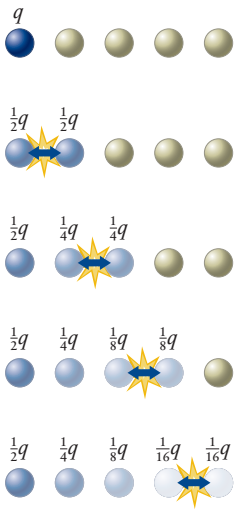


Figure 22.26 By successively allowing a charged sphere to touch an initially uncharged neighbor, we can distribute an amount of charge in ever-lessening amounts over a number of spheres.

a 100-W light bulb each second is about 10^{19}. These are such large numbers that the fact that charge comes in only whole-number multiples of the elementary charge normally remains unnoticed.

Using the coulomb as the unit of charge, we can determine the value of k in Eq. 22.1 experimentally by measuring the force between two known charged particles separated by a known distance:

$$k = 9.0 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2. \tag{22.5}$$

The value of this constant shows how large a unit the coulomb is: Two particles, each carrying a charge of 1 C, separated by 1 m exert on each other a force of 9 billion newtons—equal to the gravitational force exerted by Earth on several dozen loaded supertankers! It is very difficult to build up a charge of this magnitude on all but very large objects because things get ripped apart by the enormous forces. The largest accumulations of charge we know of occur in the atmosphere: Large clouds that accumulate a charge of about 50 C discharge through the air to Earth, causing lightning.

EXAMPLE 22.2 Gravity versus electricity

Compare the magnitudes of the gravitational and electric forces exerted by the nucleus of a hydrogen atom—a single proton ($m_p = 1.7 \times 10^{-27}$ kg)—on an electron ($m_e = 9.1 \times 10^{-31}$ kg) when the two are 0.50×10^{-10} m apart.

❶ **GETTING STARTED** For simplicity, I assume I can treat the proton and electron as particles. I also assume they are at rest so that I can use the principles of electrostatics.

❷ **DEVISE PLAN** I can use Eq. 22.2 to calculate the magnitude of the gravitational force and Eq. 22.1 to calculate the magnitude of the electric force.

❸ **EXECUTE PLAN**

$$F_{pe}^G = G\frac{m_p m_e}{r_{pe}^2}$$

$$= (6.7 \times 10^{-11} \text{ N} \cdot \text{m}^2/\text{kg}^2)\frac{(9.1 \times 10^{-31} \text{ kg})(1.7 \times 10^{-27} \text{ kg})}{(0.50 \times 10^{-10} \text{ m})^2}$$

$$= 4.1 \times 10^{-47} \text{ N}$$

and

$$F_{pe}^E = k\frac{|q_p|\,|q_e|}{r_{pe}^2}$$

$$= (9.0 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2)\frac{(1.6 \times 10^{-19} \text{ C})(1.6 \times 10^{-19} \text{ C})}{(0.50 \times 10^{-10} \text{ m})^2}$$

$$= 9.2 \times 10^{-8} \text{ N}.$$

The electric force exerted by the proton on the electron is $(9.2 \times 10^{-8} \text{ N})/(4.1 \times 10^{-47} \text{ N}) \approx 10^{39}$ times greater than the gravitational force exerted by the proton on the electron. ✔

❹ **EVALUATE RESULT** Table 7.1 gave the electromagnetic interaction for two protons as 36 orders of magnitude stronger than the gravitational interaction. Here we considered a proton and an electron—and found the electric force to be 39 orders of magnitude greater. An electron has about 3 orders of magnitude less mass than a proton, so it makes sense that the gravitational force on it is 3 orders of magnitude less.

EXAMPLE 22.3 Comb electricity

(*a*) A 0.020-kg plastic comb acquires a charge of about -1.0×10^{-8} C when passed through your hair. What is the magnitude of the electric force between two such combs held 1.0 m apart after being passed through your hair? (*b*) If two identical 0.020-kg combs carry one surplus electron for every 10^{11} electrons in the combs, what is the magnitude of the electric force between these combs held 1.0 m apart?

❶ **GETTING STARTED** Both parts of the problem require me to calculate the magnitude of the electric force between the combs. If I treat the combs as particles, I can use Eq. 22.1 to calculate this force.

❷ **DEVISE PLAN** To calculate the magnitude of the electric force between two charged objects, I need to know the charge on each object and their separation distance. I know these data for part *a*: $q_1 = q_2 = -1.0 \times 10^{-8}$ C and $r_{12} = 1.0$ m, where the subscripts 1 and 2 denote the two combs. For part *b* I am given only the separation distance, and so I need to determine the charge on each comb.

I am given the fraction of electrons added, and I know the charge on one electron. So, to determine the charge on each comb, I need to determine how many electrons each comb contains. The number of electrons in each comb is equal to the number of protons in the comb: $N_e = N_p$. I am given the mass of the comb and I know that the mass is determined by the protons and neutrons in all the atoms making up the comb (the electrons contribute very little). Given that the protons and neutrons have almost identical mass ($m_p = m_n = 1.7 \times 10^{-27}$ kg), I can determine the number N of protons and neutrons by dividing the mass of

QUANTITATIVE TOOLS

the comb by m_p. Given that most atoms contain roughly equal numbers of protons and neutrons, I can say that the number of protons is $N_p \approx N/2$.

3 EXECUTE PLAN (*a*) Substituting the values given into Eq. 22.1, I get

$$F_{12}^E = k\frac{|q_1|\ |q_2|}{r_{12}^2}$$
$$= (9.0\times10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(1.0\times10^{-8}\ \text{C})(1.0\times10^{-8}\ \text{C})}{(1.0\ \text{m})^2}$$
$$= 9.0\times10^{-7}\ \text{N}. \checkmark$$

(*b*) The number of protons plus neutrons in the comb is

$$N = \frac{0.020\ \text{kg}}{1.7\times10^{-27}\ \text{kg}} = 1.2\times10^{25},$$

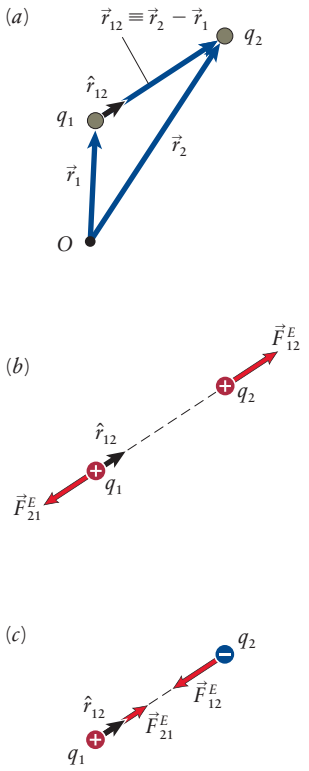
and so $N_p \approx N/2 = 6\times10^{24}$. The number of electrons is equal to the number of protons, and so there are 6×10^{24} electrons in each comb to begin with. Adding one surplus electron for every 10^{11} electrons means adding $(6\times10^{24})/(1\times10^{11}) = 6\times10^{13}$ electrons to each comb; these electrons carry a combined charge of $(6\times10^{13})(-1.6\times10^{-19}\ \text{C}) = -9.6\times10^{-6}\ \text{C}$. The magnitude of the repulsive electric force between the combs is then

$$F_{12}^E = k\frac{|q_1|\ |q_2|}{r_{12}^2}$$
$$= (9.0\times10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(9.6\times10^{-6}\ \text{C})(9.6\times10^{-6}\ \text{C})}{(1.0\ \text{m})^2}$$
$$\approx 1\ \text{N}. \checkmark$$

4 EVALUATE RESULT My answer to part *a* is a force too small to be felt, which is what I expect based on experience (two combs passed through hair don't exert an appreciable force on each other). In contrast, my answer to part *b* is phenomenally large for an electric force. The magnitude of the initial acceleration acquired by the combs would be $a_1 = F_{21}^E/m_1 = (1\ \text{N})/(0.020\ \text{kg}) = 50\ \text{m/s}^2$, or about five times the acceleration due to gravity! Even though the fraction of electrons removed—one in 100 billion—is very small, the factor k in Eq. 22.1 is so great that the resulting force is also great. Indeed, I learned in Table 7.1 that the electromagnetic interaction is 36 orders of magnitude stronger than the gravitational interaction, so my answer is not unreasonable.

22.16 Two identical conducting spheres, one carrying charge $+q$ and the other carrying charge $+3q$, are initially held a distance d apart. The spheres are allowed to touch briefly and then returned to separation distance d. Is the magnitude of the force they exert on each other after the touching greater than, smaller than, or the same as the magnitude of the force they exerted on each other before the touching?

Like the gravitational force, the electric force is *central;* that is, its line of action is along the line connecting the two interacting charged particles. Consider, for example, the two particles carrying charges q_1 and q_2 shown in **Figure 22.27a**. The vector $\vec{r}_{12} \equiv \vec{r}_2 - \vec{r}_1$ gives the position of particle 2 relative to particle 1; this vector points from particle 1 to particle 2. We can define a unit vector pointing in this direction by dividing the vector $\vec{r}_{12}$ by its magnitude:



$$\hat{r}_{12} \equiv \frac{\vec{r}_2 - \vec{r}_1}{r_{12}}. \tag{22.6}$$

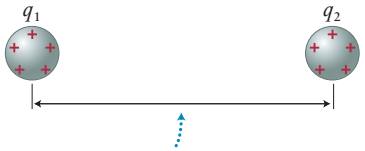
Depending on the algebraic sign of the charges, the electric force can be attractive or repulsive. For like charges ($q_1q_2 > 0$), the force is repulsive. In this case, the force $\vec{F}_{12}^E$ exerted by particle 1 on particle 2 points in the same direction as the unit vector $\hat{r}_{12}$ (Figure 22.27*b*). For opposite charges ($q_1q_2 < 0$), the force is attractive, and so $\vec{F}_{12}^E$ points in the direction opposite the direction of $\hat{r}_{12}$ (Figure 22.27*c*). In either case, $\vec{F}_{12}^E$ can be written in the form

$$\vec{F}_{12}^E = k\frac{q_1q_2}{r_{12}^2}\hat{r}_{12}. \tag{22.7}$$

Because $r_{12} = r_{21}$ and because $\hat{r}_{21}$ points in the direction opposite the direction of $\hat{r}_{12}$, the force $\vec{F}_{21}^E$ exerted *by* particle 2 *on* particle 1, which

Figure 22.27 (*a*) Position vectors for two charged particles. (*b*) Repulsive forces exerted on each other by two particles carrying like charges. (*c*) Attractive forces exerted on each other by two particles carrying opposite charges.

points in the direction opposite the direction of $\vec{F}_{12}^E$, is obtained by simply switching the indices 1 and 2 in Eq. 22.7:



$$\vec{F}_{21}^E = k\frac{q_2q_1}{r_{21}^2}\hat{r}_{21} = k\frac{q_1q_2}{r_{12}^2}(-\hat{r}_{12}) = -\vec{F}_{12}^E, \tag{22.8}$$

as we would expect for an interaction pair (see Eq. 8.15). Equation 22.7 is the vectorial form of Eq. 22.1.

22.17 Using your knowledge about work and potential energy, determine whether the potential energy of a closed system of two charged particles carrying like charge increases, decreases, or stays the same when the distance between the two is increased. Repeat for two particles carrying opposite charge.

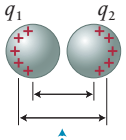


Figure 22.28 The reason Coulomb's law does not apply in a strict sense to macroscopic charged objects. The law is approximately correct if the objects are far apart relative to their radii.

(*a*) Charged spheres separated by a distance large compared to the sphere radii

Distance between centers of charge distributions same as distance between sphere centers

(*b*) Charged spheres separated by a distance small compared to the sphere radii

Charge repulsion causes distance between centers of charge distributions to differ from distance between sphere centers.

Before going on, I should mention a limitation to Coulomb's law. Strictly speaking, it is applicable only to charged particles. This is so because the distance r_{12} is well defined only when the size of the charged objects is negligibly small compared with their separation distance. When the charged objects are not particles, the distance r_{12} is not equal to the center-to-center distance. You can see why with the help of Figure 22.28. In **Figure 22.28*a***, the charge is distributed uniformly over the surface of each of two widely separated metal spheres. The way in which a collection of charge carriers is spread out over a macroscopic object is called a **charge distribution.** Because the charge distributions over the metal spheres in Figure 22.28*a* are uniform, the center of each charge distribution coincides with the center of the sphere, and so r_{12} is well defined. When we bring the spheres close together, as in Figure 22.28*b*, the like charge carriers repel one another and move to the far side of each sphere. Now the centers of the charge distributions no longer coincide with the spheres' centers, so r_{12} (the center-to-center distance of the two charge distributions) is not simply the distance separating the centers of the two conductors.

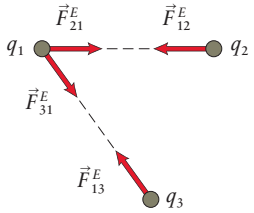
22.18 (*a*) Is the magnitude of the electric force between the two conducting spheres in Figure 22.28*b* greater or smaller than that obtained from Coulomb's law, which assumes the charge is concentrated at the center of each sphere? (*b*) Is the answer to part *a* the same if the charge on one of the conductors is negative instead of positive?

22.6 Forces exerted by distributions of charge carriers

Coulomb's law deals only with *pairs* of charged objects. To calculate the force exerted by an assembly of objects carrying charges q_2, q_3, q_4, . . . on an object 1 carrying a charge q_1, we take the vector sum of all the forces exerted on object 1 by each of the other charged objects independently:

$$\Sigma\vec{F}_1^E = \vec{F}_{21}^E + \vec{F}_{31}^E + \vec{F}_{41}^E + \cdots, \tag{22.9}$$

where each term is given by Coulomb's law:



$$\Sigma\vec{F}_1^E = k\frac{q_2q_1}{r_{21}^2}\hat{r}_{21} + k\frac{q_3q_1}{r_{31}^2}\hat{r}_{31} + k\frac{q_4q_1}{r_{41}^2}\hat{r}_{41} + \cdots. \tag{22.10}$$

In other words, we calculate the force exerted by object 2 on object 1, then calculate the force exerted by object 3 on object 1, and so forth, and then add the forces. This means that if we know the details of some distribution of charged objects, we can calculate the force exerted by this distribution of charged objects on a single charged particle. For distributions that contain large numbers of charged objects, the summation can be

accomplished via an integration. We will limit our discussion here to simple cases involving only a few charged objects.

22.19 **Figure 22.29** shows how a charged particle 1 interacts with two other charged particles 2 and 3. Determine the direction of the vector sum of the electric forces exerted on particle 2.

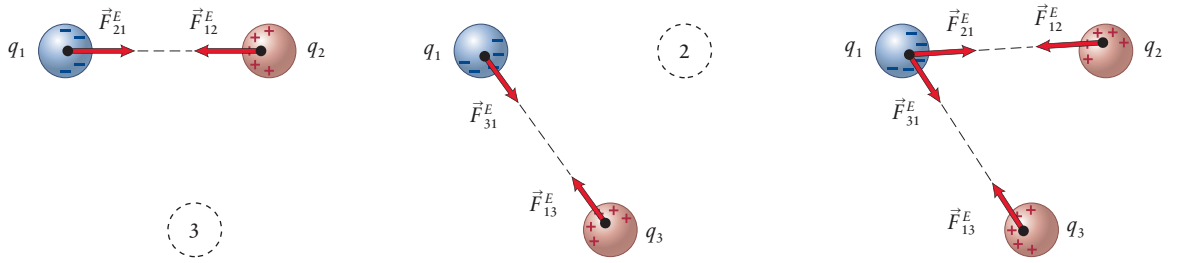


Figure 22.29 Forces exerted by two charged particles 2 and 3 on charged particle 1.

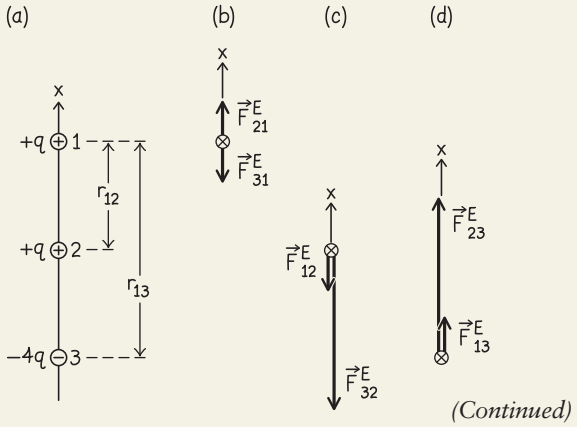
The basic limitation of Coulomb's law continues to apply when we are analyzing collections of charged objects: Eq. 22.10 is valid only for charged *particles*, not for charged extended bodies. Suppose, for example, that we replace each charged particle in Figure 22.29 by a conducting sphere carrying the same charge as each particle. Let us first consider just the interaction between spheres 1 and 2. When these oppositely charged spheres are placed near each other, the charge carriers on the two spheres rearrange themselves to be as close as possible to each other (**Figure 22.30***a*). A similar type of rearrangement takes place when just spheres 1 and 3 are placed near each other (Figure 22.30*b*). When all three spheres are placed near one another, the positive charge on sphere 3 pushes the positive charge on sphere 2 up and pulls the negative charge on sphere 1 down (Figure 22.30*c*). Consequently, the forces that the spheres exert on one another are not the same as the forces exerted by the individual pairs (compare the forces in Figures 22.29 and 22.30).

Figure 22.30

(*a*) Sphere 1 interacts with just sphere 2 (*b*) Sphere 1 interacts with just sphere 3 (*c*) Sphere 1 interacts with both spheres



EXAMPLE 22.4 Electric tug of war

You are given three charged particles. Particles 1 and 2 carry charge $+q$ and particle 3 carries charge $-4q$. (*a*) Determine the relative values of the separation distances r_{12} and r_{13} when the three particles are arranged along a straight line in such a way that the vector sum of the forces exerted on particle 1 is zero. (*b*) With the particles arranged this way, are the vector sums of the forces exerted on particles 2 and 3 also zero?

❶ **GETTING STARTED** Particle 2 exerts a repulsive force on particle 1; particle 3 exerts an attractive force on particle 1. In order for the two forces exerted on particle 1 to cancel, particles 2 and 3 must be on the same side of particle 1. Because the magnitude of the charge on particle 2 is smaller than that of the charge on particle 3, the distance r_{12} must be shorter than the distance r_{13}.

❷ **DEVISE PLAN** I choose my x axis vertically up along the line defined by the particles (**Figure 22.31***a*). To determine the relative values of the separation distances r_{12} and r_{13} when the vector sum of the forces exerted on particle 1 is zero, I draw a free-body diagram for particle 1 (Figure 22.31*b*). The magnitude of each force exerted on this particle is given by

Figure 22.31

(Continued)

QUANTITATIVE TOOLS

Eq. 22.1, and so by setting the sum of the x components of the forces equal to zero, I have an expression containing r_{12} and r_{13} and I can manipulate the expression to get the relative values of r_{12} and r_{13}.

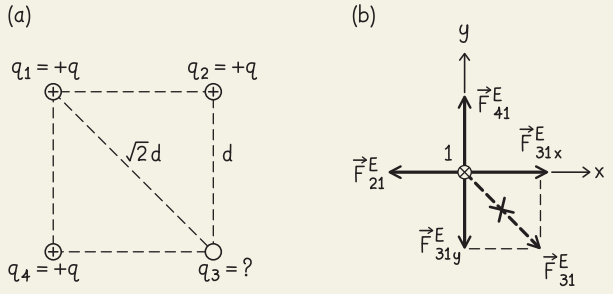
❸ **EXECUTE PLAN** (*a*) The x components of the two forces in Figure 22.31*b* must add to zero, so

$$\begin{aligned}\Sigma F_{1x} &= F_{21x}^E + F_{31x}^E \\ &= +k\frac{|q_1||q_2|}{r_{12}^2} - k\frac{|q_1||q_3|}{r_{13}^2} = k\frac{qq}{r_{12}^2} - k\frac{(q)(4q)}{r_{13}^2} \\ &= +k\frac{q^2}{r_{12}^2} - k\frac{4q^2}{r_{13}^2} = 0.\end{aligned}$$

I therefore must have $\dfrac{q^2}{r_{12}^2} = \dfrac{4q^2}{r_{13}^2}$,

or $r_{13}^2 = 4r_{12}^2$, and so $r_{13} = 2r_{12}$. ✔

(*b*) The forces exerted by particles 1 and 3 on particle 2 both point in the negative x direction (Figure 22.31*c*) and so cannot sum to zero. The forces exerted by particles 1 and 2 on particle 3 both point in the positive x direction (Figure 22.31*d*) and so cannot sum to zero. ✔



❹ **EVALUATE RESULT** My answer for part *a* makes sense because the force exerted by each particle is inversely proportional to the square of the separation distance, and this force varies directly with the quantity of charge. Because the charge on particle 3 is four times greater than that on particle 2, the square of the separation distance r_{13} must be four times r_{12}, and so $r_{13} = 2r_{12}$, as I found.

EXAMPLE 22.5 Electrostatic equilibrium

Consider four charged particles placed at the corners of a square whose sides have length d. Particles 1, 2, and 4 carry identical positive charges. In order for the vector sum of the forces exerted on particle 1 to be zero, what charge must be given to particle 3, which is in the corner diametrically opposite particle 1?

❶ **GETTING STARTED** I begin by making a sketch of the situation (**Figure 22.32*a***). Because particles 1, 2, and 4 all carry identical positive charge, I write $q_1 = q_2 = q_4 = +q$. The separation between neighboring particles on the square is d. The separation between particles 1 and 3 is $\sqrt{2}d$.

Figure 22.32

❷ **DEVISE PLAN** To determine the charge needed on particle 3, I must determine the electric force magnitude F_{31}^E needed to yield a zero vector sum of forces exerted on particle 1. I should therefore draw a free-body diagram for particle 1 and work out the vector sum.

❸ **EXECUTE PLAN** In my free-body diagram (Figure 22.32*b*), I choose my y axis pointing up and x axis pointing to the right. The force $\vec{F}_{21}^E$ is repulsive and so points in the negative x direction; the force $\vec{F}_{41}^E$ is repulsive and points in the positive y direction. To make the vector sum of the forces exerted on 1 zero, $\vec{F}_{31}^E$ must be such that its components cancel $\vec{F}_{21}^E$ and $\vec{F}_{41}^E$. Along the x axis, I therefore have

$$\Sigma F_{1x} = F_{21x}^E + F_{31x}^E + F_{41x}^E = -F_{21}^E + F_{31}^E \cos 45° + 0 = 0,$$

so $F_{21}^E = F_{31}^E \cos 45°$. Substituting the Coulomb's law expressions for these two force magnitudes, I have

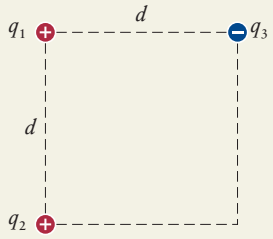
$$k\frac{|q_2||q_1|}{d^2} = k\frac{|q_3||q_1|}{(d\sqrt{2})^2}\cos 45°$$

$$\frac{q^2}{d^2} = \frac{|q_3|q}{2\sqrt{2}d^2}$$

$$|q_3| = 2\sqrt{2}\,q.$$

From Figure 22.32*b*, I also know that $\vec{F}_{31}^E$ must be an attractive force, so

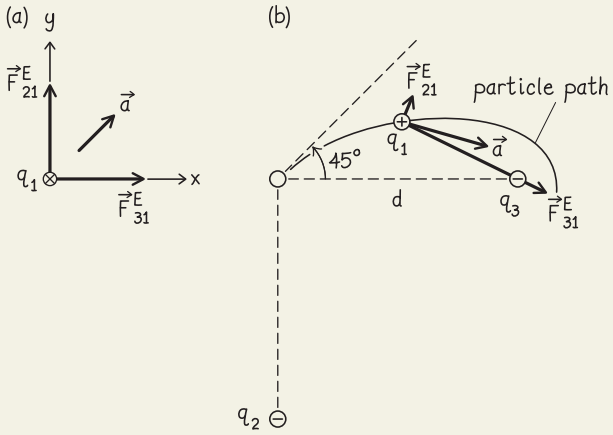
$$q_3 = -2\sqrt{2}q. \checkmark$$



❹ **EVALUATE RESULT** My result indicates that the charge on particle 3 is greater than q. This makes sense because the attractive force exerted by this particle must balance the forces exerted by particles 2 and 4, which are both closer to particle 1. To obtain my answer I solved only for the x component of $\vec{F}_{31}^E$ and did not consider the y component. However, my free-body diagram shows that the magnitudes of the components along the y axis are the same as those along the x axis, so analyzing the y components would have given me the same result.

QUANTITATIVE TOOLS

EXAMPLE 22.6 Electric trajectory



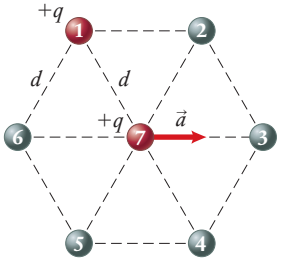
Consider the arrangement of charged particles shown in Figure 22.33. The charge magnitudes are the same in all three cases, but q_1 and q_2 are positive and q_3 is negative. Sketch the trajectory of particle 1 if it is released while particles 2 and 3 are held fixed. Ignore any gravitational force exerted by Earth on the particle.

Figure 22.33 Example 22.6

❶ **GETTING STARTED** I begin by drawing a free-body diagram for particle 1, choosing the x axis to the right and the y axis up (Figure 22.34*a*). Because the charges on the two particles have the same magnitude and because the separation distances are the same, the magnitudes F_{21}^E and F_{31}^E are the same.

Figure 22.34

❷ **DEVISE PLAN** The direction in which particle 1 accelerates is determined by the vector sum of the forces exerted on it, and I can determine this direction from my free-body diagram. As the particle moves along its trajectory, however, the forces exerted on it change in both direction and magnitude, and so I must consider these changes in formulating my answer.



❸ **EXECUTE PLAN** Because the magnitudes F_{21}^E and F_{31}^E are the same, the vector sum of the two forces exerted on particle 1 bisects the angle between the two forces, and so the initial acceleration of 1 (which points in the same direction as the vector sum of forces) points up and to the right at an angle of 45°, as illustrated in Figure 22.34*a*. As particle 1 moves in the direction indicated in Figure 22.34*a*, $\vec{F}_{21}^E$ and $\vec{F}_{31}^E$ change in both direction and magnitude. The magnitude of $\vec{F}_{21}^E$ decreases because the distance between 1 and 2 increases, and the magnitude of $\vec{F}_{31}^E$ increases because the distance between 1 and 3 decreases. The direction of the acceleration of particle 1 is the same as the direction of the vector sum of these two forces. The resultant path of motion is qualitatively illustrated in Figure 22.34*b*. ✔

❹ **EVALUATE RESULT** My sketch makes sense: Particle 1 first moves up and to the right because it is repelled by particle 2 and attracted by particle 3. As it moves away from 2 and approaches 3, the effect of the attraction increases and so the trajectory curves and heads toward 3.

22.20 Seven small metal spheres are arranged in a hexagonal pattern as illustrated in Figure 22.35. Spheres 1 and 7 carry equal amounts of positive charge; the other spheres are uncharged. (*a*) To give sphere 7 an acceleration $\vec{a}$ that points to the right, what (single) other sphere must be charged? There may be more than one possibility. (*b*) What are the sign and magnitude of that charge?

Figure 22.35 Checkpoint 22.20.

Chapter Summary

Electric interactions (Sections 22.1, 22.2, 22.5)

Concepts An **electric interaction** is a long-range interaction between objects that carry a surplus **electrical charge.** The electric force is sometimes called the *electrostatic* force because interactions between charged objects become more complicated for objects that are not at rest (see Chapter 27).

There are only two types of charge: **positive charge** and **negative charge.** Objects that carry like charges repel each other; objects that carry opposite charges attract each other. Any microscopic object that carries electrical charge, such as an electron or ion, is called a **charge carrier.**

The SI unit of charge is the **coulomb** (C), which is the magnitude of the charge carried by about 6.24×10^{18} electrons. It is also equal to the amount of charge transported in 1 s by a steady current of 1 ampere (see Chapter 27).

Quantitative Tools **Coulomb's law** states that if particle 1 carrying charge q_1 and particle 2 carrying charge q_2 are a distance r_{12} apart, the **electric force** $\vec{F}_{12}^{E}$ exerted by particle 1 on particle 2 is

$$\vec{F}_{12}^{E} = k\frac{q_1 q_2}{r_{12}^2}\hat{r}_{12}, \tag{22.7}$$

where the unit vector $\hat{r}_{12}$ points from particle 1 to particle 2 and the constant k is

$$k = 9.0 \times 10^9\ \mathrm{N \cdot m^2/C^2}. \tag{22.5}$$

The **elementary charge** e is the smallest observed amount of charge and is equal to the magnitude of the charge carried by one electron:

$$e = 1.60 \times 10^{-19}\ \mathrm{C}. \tag{22.3}$$

The charge q carried by any object comes in whole-number multiples of e:

$$q = ne \quad (n = 0, \pm 1, \pm 2, \pm 3, \ldots). \tag{22.4}$$

Movement of charge carriers (Sections 22.3, 22.4)

Concepts Charge carriers can flow through an **electrical conductor** but cannot readily flow through an **electrical insulator.** Charge carriers can be transferred from one nonconductor to another only by bringing the nonconductors into contact with each other, and the carriers remain near the spot at which they were deposited.

We **ground** an object by connecting it electrically to Earth. Grounding permits the exchange of charge carriers with Earth, a huge reservoir of charge carriers. A charged, conducting object that is grounded will retain no surplus of either type of charge, assuming no other nearby electrical influences.

An **ion** is an atom or molecule that has lost or gained one or more electrons.

According to the principle of **conservation of charge,** electrical charge can be created or destroyed only in identical positive-negative pairs, with the result that the charge of a closed system always remains constant.

Polarization, which is the separation of charge carriers in an object, allows neutral objects to interact electrically.

Charging by induction is a method of using a charged object to charge a neutral object without the two objects touching each other.

Forces due to multiple charges (Section 22.6)

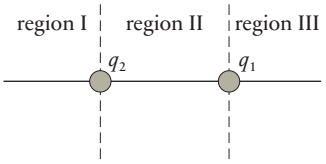
Quantitative Tools The electric force exerted on a charged particle 1 by any number of other charged particles 2, 3, . . . is

$$\Sigma\vec{F}_1^E = k\frac{q_2q_1}{r_{21}^2}\hat{r}_{21} + k\frac{q_3q_1}{r_{31}^2}\hat{r}_{31} + \cdots. \qquad (22.10)$$

Questions and Problems

For instructor-assigned homework, go to Mastering Physics

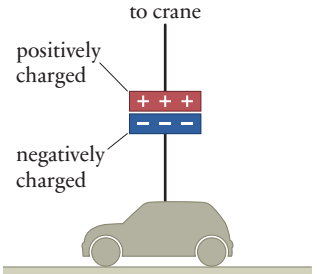
Dots indicate difficulty level of problems: • = *easy,* •• = *intermediate,* ••• = *hard;* CR = *context-rich problem.*



22.1 Static electricity

1. A piece of tape is pulled from a spool and lowered toward a 100-mg scrap of paper. Only when the tape comes within 8.0 mm is the electric force magnitude great enough to overcome the gravitational force exerted by Earth on the scrap and lift it. Determine the magnitude and direction of the electric force exerted by the tape on the paper at this distance. •
2. A baseball bat is placed on a table such that the narrow end of the bat hangs over the edge. Two freshly pulled strips of tape are hung from opposite sides of the overhanging end of the bat. The strips repel each other so that they hang in the air in an inverted V shape, with an angle of about 50° between the strips. Describe at least three things you could do to reduce the angle between the hanging strips. •
3. A plastic spring with spring constant $k = 450$ N/m has a relaxed length of 0.100 m. The spring is positioned vertically on a table, and a charged plastic 1.00-kg sphere is placed on the top end of the spring. Another charged object is suspended above the sphere without making contact. If the length of the spring is now 0.0950 m, what are the magnitude and direction of the electric force exerted on the sphere? ••

22.2 Electrical charge

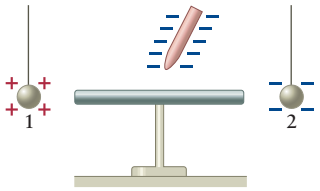


4. Two small objects carry the same amount of charge, and the magnitude of the electric force exerted by one object on the other is 0.10 N when they are held 30 mm apart. If the force magnitude increases when the objects are released and free to move, are the objects of the same charge or opposite charge? •
5. How might the results from electrostatic experiments with tape strips described in Section 22.2 differ from those actually observed if there were three types of electrical charges in the universe? ••
6. If you must do positive work to bring a charged balloon toward a negatively charged sphere, is the charge on the balloon positive or negative? ••
7. Suppose you have three identical, electrically neutral pieces of tape, A, B, and C. (*a*) Describe how you could make two of them repel each other. (*b*) Is it possible for all three to repel one another? ••
8. Suppose that in Figure P22.8, $|q_2| > |q_1| > 0$ but these particles may carry charges of the same or opposite type. A third particle carrying charge q_3 is to be placed in this system along the axis such that the vector sum of electric forces on the third particle is zero. In which region—I, II, or III—might this be possible if (*a*) q_1 and q_2 have the same sign and (*b*) q_1 and q_2 have opposite signs? (*c*) Under what circumstances can the third particle be placed in region I and have the vector sum of electric forces exerted on it be zero? ••

Figure P22.8

9. A salvage yard operator wants to make an electric force linkage for his wrecker crane as a safety device, so that when a vehicle being lifted is too massive, it will break the linkage before the force exerted by the vehicle topples the crane. His plan is to attach two metal plates to the crane cable as shown in Figure P22.9 and connect the plates to the crane's power system. There is to be a positive charge on one plate and a negative charge on the other, so that the two stick together because of the attractive electric force. Discharge is prevented by spraying a layer of plastic on each plate. He needs to know what diameter to make the plates so that they come apart when the vehicle being lifted has a mass greater than 2000 kg. On the micro level, the electric force is between surface atoms carrying positive charge on one plate and surface atoms carrying negative charge on the other plate. The electric force for each atom pair has a magnitude of 2.3×10^{-12} N, and each atom occupies an area of 3×10^{-21} m^2. (*a*) Before doing any calculations, estimate the necessary plate surface area. Which is this surface area comparable to: that of a pinhead, a fingernail, a music compact disc, a dinner plate, or a manhole cover? (*b*) Calculate the necessary area. How accurate was your estimate as to which object the plate area is comparable to? •••

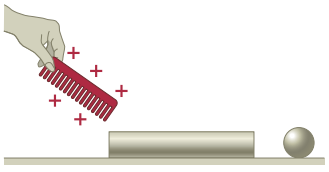
Figure P22.9



22.3 Mobility of charge carriers

10. Which of the following phenomena are due to the electric interaction: (*a*) dissolution of salt in water, (*b*) surface tension in water, (*c*) the elliptical orbit of comets, (*d*) the binding of protons in an atomic nucleus, (*e*) "traction" between tires and pavement. •
11. In an airplane, the body of the aircraft gets charged if friction occurs between it and the air, which contains dust particles. As there is no possibility of grounding through a copper wire on the ground, the aircraft contains sharp wicks. Explain their role in protecting the aircraft from damage due to accumulation of excessive charge. •
12. You have two rods A and B, both made of a nonconducting material. Initially, neither rod is charged. A sphere carrying 100 units of surplus positive charge is placed close to the left end of rod A. One end of rod B is touched to the right end of rod A for some time interval and then removed. What is the final charge on rod B? •
13. Some survivors of lightning strikes have reported feeling their hair standing on end shortly before the strike. What causes the hair to behave in this way? •
14. A closed system consists of a neutron and a positron. The neutron eventually decays. After decay, what are the most likely particles in the system, and what is the charge in the system? (Use the principle of conservation of charge.) ••
15. Two identical 500-mg paper clips, 1 and 2, dangle from two strings, the top ends of which are tied to the same nail. The clips are charged in such a way that the two strings hang with an angle of 32.0° between them. (*a*) Draw a free-body diagram for clip 1, which is to the left of clip 2. (*b*) What are the magnitude and direction of the electric force exerted by one clip on the other? (*c*) If the two clips were brought in contact with each other for an instant and then released, might they discharge into each other and no longer repel? ••
16. A metal sphere is grounded and an electrically charged rod is held close to it. The sphere acquires a charge q. The grounding wire is removed, and the sphere is brought in contact with another uncharged identical metal sphere. (*a*) What is the charge on each sphere after they are separated? (*b*) One of the two spheres is grounded again, and the procedure is repeated. What is the charge on each sphere now? (*c*) What is the maximum charge that can be put on each sphere? ••
17. At separation distance r_1, charged Ping-Pong balls A and B repel each other with an electric force of magnitude 0.40 N. At separation distance r_2, charged Ping-Pong balls A and C repel each other with a force of magnitude 1.4 N. Maintaining the separation distances r_1 and r_2, how should you arrange B and C around A (*a*) to create the maximum electric force exerted on A and (*b*) to create the minimum electric force exerted on A? ••
18. A metal sphere is grounded via a single wire. One end of a plastic rod is given a positive charge and held near the sphere. (*a*) If the ground wire is removed while the rod and sphere are near each other but have not touched, is there an electric force between the two? Why or why not? (*b*) If the rod end is brought in contact with the sphere and then the ground wire is removed, is there an electric force between rod and sphere after they are separated? Why or why not? •••

22.4 Charge polarization



19. If you rub a balloon with hair and bring it close to a stream of water in a wash basin, the water gets attracted toward the balloon. Can you predict the charge on the stream of water? •
20. Three small pieces of electrically neutral paper are placed far apart from one another on a table. One piece is given a negative electric charge, one is given a positive charge, and one is left neutral. They all look identical, and in order to tell which is which, a student runs a comb through her hair and waves the comb over each piece. She observes that one is strongly attracted to the comb; she labels this A. She observes that another is weakly attracted to the comb; she labels this B. The last piece, which is repelled by the comb; she labels C. Which piece is positive, which is negative, and which is neutral? •
21. The electrically neutral metal rod in Figure P22.21 stands between two charged pith balls, and then a negatively charged rubber rod is scraped along the center of the metal rod. Draw the free-body diagram for each ball after the rubber rod is taken away. •

Figure P22.21

22. A charged sphere with 1×10^8 units of negative charge is brought near a neutral metal rod. The half of the rod closer to the sphere has a surplus charge of 1×10^4 units. What is the magnitude of the charge on the half of the rod farther from the sphere? Is this charge positive or negative? •
23. Near one end of an electrically neutral aluminum rod lying on a table made of nonconducting material, you hold a comb that is also made of a nonconducting material but carries a positive charge (Figure P22.23). Does a small steel sphere located near the other end of the rod roll toward the rod, roll away from the rod, or stay where it is if the sphere is (*a*) electrically neutral and (*b*) positively charged? ••

Figure P22.23

24. Two metal rods A and B are initially lying end to end on a wooden table and are touching each other. A sphere carrying surplus positive charge is brought close to the middle of rod A. While the sphere is still in place, the rods are pulled apart by someone wearing gloves made of a fabric that is an electrical insulator. Then the sphere

is moved far away. (*a*) Do the two rods attract each other, do they repel each other, or is there no electric force between them? (*b*) Describe the surplus charge on each rod as positive, zero, or negative. ••

25. You have three pairs of spheres. Pair A consists of two conducting spheres, pair B of two nonconducting spheres, and pair C of one nonconducting sphere and one conducting sphere. If the same charge q is added to all spheres uniformly and in each pair the two spheres are separated by the same distance d, rate the magnitude of the electric force between each pair's spheres when q is (*a*) positive on both spheres, (*b*) negative on both, and (*c*) positive on one sphere in the pair and negative on the other. ••

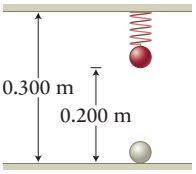
26. Metal sphere A is hung from the ceiling by a long, thin string and given a positive charge. An identical sphere B is suspended nearby with an identical string and given a *negative* charge that has the same magnitude as the charge on A. The two spheres are 50 mm apart when in equilibrium. If an identical sphere C carrying no surplus charge is placed between them, does the distance between A and B increase, decrease, or remain the same? ••

27. You are an astrophysicist working on a problem involving Saturn's rings and trying to figure out why the smaller ice chunks in the rings stick to larger chunks. You hypothesize that as the chunks come out of the shadow of Saturn into the sunlight, the outside of the larger chunks heats up sooner than the center and this temperature difference creates a nonuniform distribution of the charged particles in the larger chunks. (Charge polarization due to temperature differences is known as the "thermoelectric effect.") Then, even though the chunk is electrically neutral, it has a charge separation. The small ice chunks presumably heat up uniformly all the way through and hence are not affected. Explain why small chunks gradually stick to larger ones. •••

22.5 Coulomb's law

28. By rubbing object A against B, if 10 electrons get transferred from A to B, calculate the electric force between the two objects if separated 10 cm apart. •

29. Two electrons are separated by 1.50 nm. What is the magnitude of the electric force each electron exerts on the other? Is this force attractive or repulsive? •



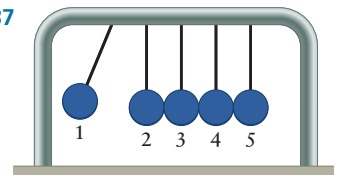
30. Two particles carrying charges q_1 and q_2 are separated by a distance r and exert an electric force of magnitude F^{E} on each other. If q_1 is doubled and q_2 is halved, what distance between them can keep the magnitude F^{E} constant? •

31. A particle carrying a -4.0-μC charge is located at the origin of an xy coordinate system. What are the components of the electric force exerted on a particle carrying a $+1.0$-μC charge if that particle is located (*a*) at $x = 10$ m, $y = 0$ and (*b*) at $x = 0$, $y = -6.0$ m? •

32. (*a*) By what distance do two objects carrying 1.0 C of charge each have to be separated before the electric force exerted on each object is 1.0 N? (*b*) How much charge should be placed on each of two small objects separated by 1.0 m so that the electric force exerted on each is 1.0 N? •

33. In a chamber 0.300 m high, sphere 1 carrying charge $q_1 = 1.00$ μC is suspended by a spring above a sphere 2 that carries charge q_2 and sits on the floor of the chamber (Figure P22.33). The relaxed length of the suspended spring is 70.0 mm, its spring constant is 30.0 N/m, and the mass of sphere 1 is 5.00 g. If sphere 1 comes to rest 0.200 m above the floor (and above sphere 2), what is the value of q_2? ••

Figure P22.33



34. Two identical 9.60-g metal spheres (small enough to be treated as particles) are hung from separate 300-mm strings attached to the same nail in a ceiling. Surplus electrons are added to each sphere, and then the spheres are brought in contact with each other and released. Their equilibrium position is such that each string makes a 13.0° angle with the vertical. How many surplus electrons are on each sphere? ••

35. Suppose two particles carry a positive charge of 1.00 C for every kilogram of their mass. Compare the gravitational force and the electric force they exert on each other at a given separation. ••

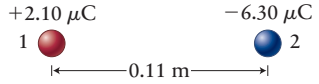
36. Two identical metal spheres, one carrying a 12.0 μC charge and the other carrying a -32.0 μC charge, are initially 50 mm apart. They are brought in contact with each other and then moved back to their original positions. What is the numerical value of the ratio $F_{\mathrm{i}}^{E}/F_{\mathrm{f}}^{E}$, where F_{i}^{E} is the magnitude of the electric force between the spheres before they are brought in contact and F_{f}^{E} is the magnitude of that force after they are brought together and then moved back to their initial positions? ••

37. The device in Figure P22.37 is a so-called Newton's cradle. When you raise steel sphere 1 and then release it, its momentum is transferred to the other four steel spheres, and this momentum transfer causes sphere 5 to rise. When it falls, momentum is again transferred through the row of spheres, and sphere 1 rises and falls, and so on. Imagine modifying the device by positioning a charged wire in such a way that every time each end steel sphere rises, it touches the wire and acquires 10 units of charge. You lift sphere 1 and allow it to touch the wire for the first time and acquire 10 units of charge. You release the sphere and it hits the others, transferring its momentum and causing sphere 5 to rise. Sphere 5

Figure P22.37

touches the charged wire, descends, hits the row of spheres, and transfers its momentum so that sphere 1 rises again and touches the wire for the second time. If the net charge distributes uniformly over all balls, how many units of charge does sphere 1 carry (*a*) just before it touches the wire this second time and (*b*) just before it touches the wire after one more round of this momentum-transfer motion? ••

38. Two 1.00-kg spheres carry identical charges and are placed a distance d from each other. (*a*) How large should the charge on each sphere be so that the repulsive electric force between them balances the attractive gravitational force between them? (*b*) What is the smallest mass that can balance in this way, given that the smallest possible charge is $e = 1.602 \times 10^{-19}$ C? (*c*) Why doesn't the distance between the balls affect this calculation? ••



39. A charged oil drop that has a mass of 5.00×10^{-12} kg and carries 10 elementary charges is centered 50 mm below the center of an oppositely charged nonconducting sphere that has a radius of 5.0 mm. What uniformly distributed charge should the sphere be given so that the electric force it exerts on the drop causes the drop to float in the air for an instant? Treat the drop as a particle. ••

40. In the Bohr model, a hydrogen atom consists of an electron orbiting a one-proton nucleus. Furthermore, the angular momentum (see *Principles*, Chapter 11) of the electron is quantized, i.e., it equals $n\hbar$, where n is an integer and $\hbar$ a fundamental constant. Derive an algebraic expression for the relationship between the radius of the electron's orbit R_{orbit} and the fundamental constant $\hbar$. ••

41. You scrunch up three same-size sheets of aluminum foil to form three balls 1, 2, and 3, and stick each one onto the end of a wooden stake (which allows you to transport the balls without touching them). You place the stakes holding balls 1 and 2 an arm's length apart and then give each ball charge q. Call the electric force exerted by ball 1 on ball 2 $\vec{F}_{12}^{E}$. You then place charge $-2q$ on ball 3 and bring it first in contact with ball 1. Then you move it away from ball 1 and bring it in contact with ball 2. (*a*) Once you have moved ball 3 far away from balls 1 and 2, what is the magnitude, in terms of F_{12}^{E}, of the electric force between balls 1 and 2? (*b*) Has the direction of $\vec{F}_{12}^{E}$ changed? ••

42. (*a*) Draw and label the electric force exerted on each of the charged spheres in Figure P22.42 and compute their magnitudes. The centers of the spheres are separated by 0.11 m. (*b*) Repeat part *a*, drawing to the same scale, if the charge on the left sphere is $-6.30\ \mu$C. ••

Figure P22.42

43. Sphere A carries 6.0 nC of charge. It is placed 100 mm from sphere B, which carries 3.0 nC of charge. Assume the spheres are much smaller than their separation distance. (*a*) What is the magnitude of the electric force exerted on A? (*b*) Draw a figure showing the charges and the electric force vectors on each sphere. (*c*) Draw and label $\vec{r}_{\text{AB}}$ on your diagram. ••

44. You have two marbles, one carrying a uniformly distributed charge $q_{\text{p}} = +1.0\ \mu$C and the other carrying a uniformly distributed charge $q_{\text{n}} = -0.50\ \mu$C. (*a*) What is the magnitude of the electric force between them when they are held 100 mm apart? (*b*) What happens when the marbles are released and so are free to move? (*c*) If the marbles are metallic and share charge when they come in contact with each other, what is the magnitude of the electric force between them when they are again moved 100 mm apart, assuming no charge is transferred either to or from the surroundings of the two-marble system? ••

45. Two charged particles 3.0 m apart exert on each other an attractive electric force of magnitude 8.0×10^{-3} N. If the charge on the two particles sums to 6.0 μC, what is the charge on each particle? ••

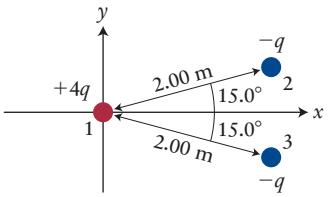
46. A charged particle of 40-nC is located at the origin of the coordinate system. A second charged particle of 50 nC is located at (x, y) = (0, 2m) and another charged particle of 50 nC is located at (x, y) = (2m, 2m). Find the magnitude and direction of the electric force exerted by the first charged particle (*a*) on the second charged particle, and (*b*) on the third charged particle. ••

47. The electric force between two identical positively charged ions is 3.7×10^{-9} N when they are 0.50 nm apart. How many electrons are missing from each of the original atoms? ••

48. Two particles with identical positive charges separated by 2.5 cm are released from rest on a nonconducting, low-friction track. Immediately after release, one particle, which has a mass of 10 mg, has an acceleration of magnitude 5.0 m/s^2, while the other particle has an acceleration of magnitude 9.0 m/s^2. Find (*a*) the mass of the second particle and (*b*) the charge on each particle. ••

49. Two identical lightweight conducting balls are suspended by thin strings of identical length from a common point. One ball is given a charge q, and both are constrained in their motion by only the tension in the strings, gravity, and air resistance. Determine q in terms of m, the mass of each ball; ℓ, the length of each string; d, the final distance between the balls; and any necessary constants. •••

50. Suppose you want to use a repulsive electric force to launch a rocket. (*a*) How much charge do you need to create enough repulsion to bring a 100,000-kg rocket to escape speed (11,200 m/s) while the rocket travels 100 mm? Assume that two identical charged objects, one mounted on the rocket, are separated by an average distance of 1.0 m for the whole launch. (*b*) If each elementary charge requires adding mass equivalent to the mass of one hydrogen atom to the rocket, how much additional mass would be required? •••



51. Two identical metal spheres carrying the same charge hang by insulating strings from the same point. The balls repel each other so that they hang in the air some distance apart. If you touch one of the spheres and let it go, what will the new equilibrium distance between the spheres be? •••

52. (*a*) Prove that the repulsive electric force between two charged particles is a maximum when each particle carries charge $q/2$, where q is the sum of the charges carried by the two particles. (*b*) Explain why this is *not* true for the attractive electric force between charged particles. •••

22.6 Forces exerted by distributions of charge carriers

53. Particle 1 carrying charge $+4q$ is fixed at the origin of a rectangular coordinate system, particle 2 carrying charge $-q$ is fixed 15.0° above the positive horizontal axis, and particle 3 carrying charge $-q$ is fixed 15.0° below the positive horizontal axis (Figure P22.53). Particles 2 and 3 are both 2.00 m from the origin. You must add two charged particles to the system in such a way that the vector sum of the electric forces exerted on particle 1 is zero. What quantity of which type of charge must each added particle carry, and at what locations must you place the particles? •

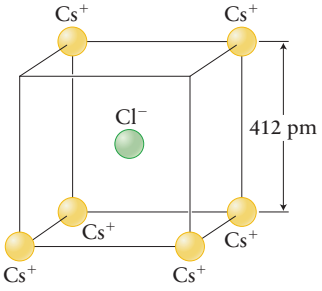


Figure P22.53

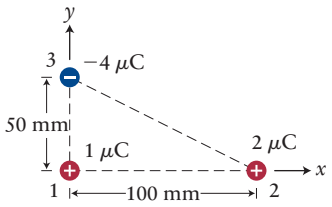
54. Two charges of equal magnitude, 2 μC, are separated by a 2 cm distance. Compare the electric force if the separation is increased to 6 cm. •

55. Cesium chloride (CsCl) is a crystalline salt that forms in a cubic lattice structure, which you can imagine as a cube with Cs^+ ions at the eight corners and a Cl^- ion at the center. The edge length of the cube is 412 pm. Suppose that at the edge of a crystal, two cesium atoms have been stripped from adjacent corners of a cube, as shown in Figure P22.55. What is the vector sum of the electric forces exerted on the chloride ion by the six Cs^+ ions remaining in the cube? •

Figure P22.55

56. Two particles carrying charges $q_1 = -4\ \mu C$ and $q_2 = 12\ \mu C$ are located 5 m apart. Choose a coordinate system where the first particle is at the origin, and the second is at $x = 5$ m. In this coordinate system, an electron sits at (2 m, −3 m). (*a*) Draw a diagram showing the vectors you need in order to determine the direction of the separate electric forces exerted on the electron by the particles. (*b*) Calculate the vector sum of these two forces. ••

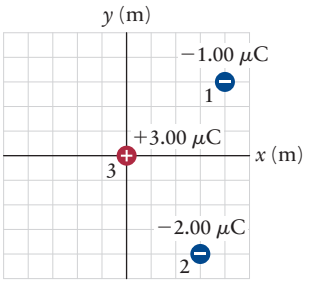
57. Particle 1, carrying charge q, particle 2, carrying charge $2q$, and particle 3, carrying charge $-q$, are located at the vertices of an equilateral triangle of side ℓ in the xy plane. Particle 1 is located at $(-\ell\ /2,0)$, particle 2 is located at $(\ell\ /2,0)$, and particle 3 is located on the positive y axis. Find the direction of the electric force exerted on a fourth charged particle carrying charge q located at the midpoint between particles 2 and 3. ••



58. Four charged particles are located at the vertices of a square of side length 1m in the xy-plane. Particles 1, 2, and 3 ($q1 = 5.00\ \mu C$, $q2 = -4.00\ \mu C$, and $q3 = -3.00\ \mu C$) are located, respectively, at (0,0), (1 m, 0) and (0, 1 m). Determine the position of particle 4, carrying the same charge as particle 1, such that the total electric force on particle 1 is zero. ••

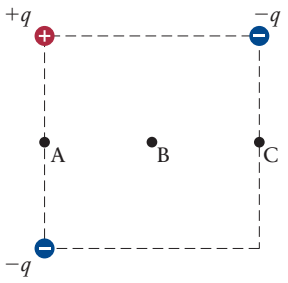
59. Four negatively charged particles each carry a charge q_n and form a square of side length d. A positively charged particle carrying a charge q_p is at the square's center. If the arrangement is in equilibrium (the vector sum of the electric forces on each particle is zero), what is the numerical value of the ratio q_p/q_n? ••

60. Particle 1 carrying 2.0 μC of charge is fixed at the origin of a rectangular coordinate system, particle 2 carrying $-1.0\ \mu C$ is fixed 45° above the positive horizontal axis 2.0 mm from the origin, and particle 3 carrying $-1.0\ \mu C$ is fixed 45° below the horizontal axis 2.0 mm from the origin. Where in the system should you place a particle 4 carrying $-2.0\ \mu C$ so that the vector sum of the electric forces exerted on particle 1 is zero? ••



61. For the charge distribution in Figure P22.61, what is the ratio of the magnitude of the electric force exerted by particle 2 on particle 1 to the magnitude of the electric force exerted by particle 3 on particle 1? ••

Figure P22.61

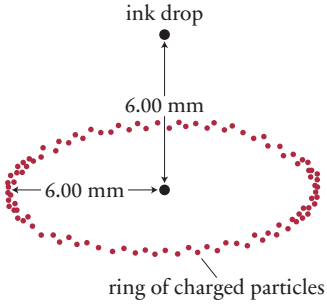


62. For the charge configuration shown in Figure P22.62, what is the vector sum of the electric forces exerted on particle 3? ••

Figure P22.62

63. Two particles, each carrying charge $-q$, are fixed at opposite corners of a square, and a third particle, carrying charge $+q$, is fixed at a third corner (Figure P22.63). (*a*) Draw an arrow representing the vector sum of the forces exerted on a particle carrying charge $+q$ as it is placed first at position A, then at position B, and then at position C. (*b*) Sketch the trajectory of this particle if it is released at each of these three positions. ●●

Figure P22.63



64. Two particles are located on the x axis of a Cartesian coordinate system. Particle 1 carries a charge of +2.0 nC and is at $x = -30$ mm, and particle 2 carries a charge of −2.0 nC and is at $x = 30$ mm. What are the magnitude and direction of the vector sum of the electric forces exerted by these two particles on particle 3, which carries a charge of $+5.0\ \mu$C and is located on the positive y axis 80 mm from the origin? ●●

65. Two identical charged dice having $+5\ \mu$C of charge, each having mass 3 g, stay in static equilibrium on the surface of a table with a separation of 12 m among them. Calculate the coefficient of static friction. ●●

66. Conducting spheres 1, 2, and 3 are placed at three corners of a square. Spheres 1 and 2 at opposing corners are very small and oppositely charged, and the magnitude of the charge on negatively charged sphere 1 is twice the magnitude of the charge on positively charged sphere 2. Sphere 3 is much larger than the other two and electrically neutral. (*a*) Draw the three spheres, showing the approximate distribution of charge on sphere 3. (*b*) Sketch a free-body diagram for sphere 2. ●●

67. You are working as an engineer designing ink-jet printers. Your boss has come across a printer design that involves a charged drop of ink experiencing a force exerted by 100 small, fixed charged particles. As shown in Figure P22.67, the particles are arranged in a ring of radius 6.00 mm, and each carries a charge of 1.00 nC. The ink drop is released at a point 6.00 mm away from the plane of the ring and along the central axis running perpendicular to the plane of the ring. Your boss gives up on calculating the initial force exerted on the charged drop, but you take one look at the setup and realize you can do the calculation in less than a minute. (*a*) Explain how you can do the calculation so quickly, even though it involves 100 separate forces. (*b*) Determine the magnitude and direction of the initial force exerted on a drop that carries a charge of 8.00 nC. (*c*) If the printer adds to each drop of ink a charge equal to 1.00 C per kilogram of ink mass, what is the initial acceleration of each drop? ●●●

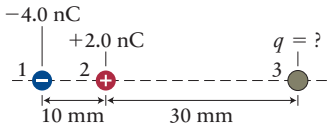
Figure P22.67

68. A 0.160-kg hockey puck modified to hold $+50\ \mu$C of charge is placed at one end of an ice hockey rink that is 61 m long. At the other end of the rink is a device capable of generating a charge of −0.10 C, but only for a short time interval. The coefficient of kinetic friction between ice and puck is $\mu_k = 0.015$. The puck is given a tiny nudge (just enough to get it moving but at a speed of nearly 0, which means you can ignore static friction), and then the charge generator is turned on for 100 ms. (*a*) Is the puck able to reach the generator? (*b*) If so, what is the puck's speed when it arrives at the generator? (For both parts, assume the 100-ms time interval is short enough to allow you to assume that the distance between the puck and the charge generator is constant.) ●●●

69. Two particles 1 and 2, each carrying 3.0 nC of charge, are located 6 cm apart. Where along the symmetry axis between particles 1 and 2 should a particle 3 carrying a charge of +2.0 nC be located if it experiences an upward electric force of 1.2×10^{-5} N? ●●●

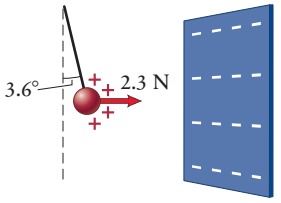
70. Figure P22.70 shows strips of transparent tape repelling each other. Use information given on the packaging of a roll of transparent tape to estimate what fraction of the atoms in either strip lose an electron in order to produce the repulsive effect. (Assume that the material of the tape is mostly carbon and hydrogen atoms present in a 1:2 ratio.) ●●●

Figure P22.70



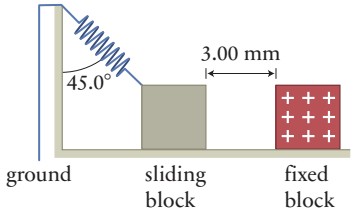
Additional Problems

71. Compare the ratio of electric force to gravitational force among two electrons and two protons, respectively, separated by 1 nm apart. Comment on the obtained different rations. ●



72. How many Coulombs of charge are contained due to the electrons present in 1 kg of liquid ammonia? •
73. A 10 μC negatively charged balloon having a total mass of 5 g that remains floated on top of a charged plastic board above 15 cm. Estimate the charge on the plastic board. •
74. Three identical metallic beads A, B, and C possess charges q_1, q_2, and q_3, respectively. All the three beads are affixed on a meter scale where A lies at 0, B lies at 60 cm, and C at 100 cm. In this configuration, if all the three beads attain electrostatic equilibrium, then find the charge ratios of q_2 to q_3. •
75. Particles A, B, and C, with charges 12.0 μC, 8.0 μC, and -6.0 μC, respectively, are evenly spaced along a line, in that order, with spacing 2.0 m. What is the magnitude and direction of the electric force exerted (*a*) on A, (*b*) on B, and (*c*) on C? •
76. A proton is composed of two up (*u*) quarks ($q = +2/3e$) and one down (*d*) quark ($q = -1/3e$). What is the electric force between two up quarks separated by 1×10^{-16} m inside a proton? ••
77. Three charged particles are arranged along a line as in Figure P22.77. If particle 2 experiences zero electric force, what is the charge on particle 3? ••

Figure P22.77



78. Four identical charged particles are constrained along an *x* axis. Identify one possible configuration of the particles that would leave one of them at rest at the origin when the others are fixed in place. No two charged particles can be at the same location. ••
79. (*a*) A particle carrying charge $+q$ is located at the center of a square with sides of length ℓ. Given four particles, two carrying charge $+q$ and two carrying charge $-q$, how should you place them at the four corners of the square, with one particle at each corner, such that the vector sum of the electric forces exerted on the center particle is zero? (*b*) If you leave the corner particles in the arrangement determined in part *a* but move the center particle to the midpoint of one side of the square, what are the magnitude and direction of the vector sum of the forces exerted on this particle? ••
80. A small charged sphere hanging from a thin string next to an oppositely charged plate experiences a 2.3-N attractive electric force (Figure P22.80). If the string makes an angle of 3.6° with the vertical, what is the mass of the sphere? ••

Figure P22.80

81. The accelerometer in a certain video game controller is constructed as shown in Figure P22.81. A block made of material that is an electrical conductor is grounded by a small stretched spring and is constrained to sliding along a rail. The net force on this block is zero. A nonconducting, positively charged block is fixed in position on the rail. When the magnitude of the electric force between the blocks is 0.100 N, the spring makes a 45.0° angle with the wall and is stretched 3.00 mm from its equilibrium position. What is the spring constant? Ignore friction. ••

Figure P22.81

82. An anti-hydrogen atom, A, is composed of one positron orbiting one antiproton just as a regular hydrogen atom is composed of one electron orbiting one proton. The difference is that each antiparticle has the usual mass but an opposite charge of its regular counterpart. Atom A is placed in a closed container with a neutron. What is the most likely charge of the system after the neutron decays? (Hint: Use charge conservation.) ••
83. All life on Earth is based on one of many two-polymer systems, each made up of a protein and a nucleic acid. In a cell, these polymers are, for the most part, charge-balanced, with the nucleic acid in any pair carrying a negative charge and the protein carrying an equal amount of positive charge. Consider a distribution of eight of these polymers, where the eight proteins sit together near the center of the cell and the nucleic acids are spread out along the circumference of a circle with the radius equal to one-quarter of the cell diameter, centered on the proteins. If seven of the eight nucleic acids are at $\pi/4$, $\pi/2$, $3\pi/4$, π, $3\pi/2$, $7\pi/4$, and 2π rad, where on the circle must you place the eighth acid to give the system a balanced charge distribution? (Hint: Begin by making a sketch.) ••
84. In a simplistic model of the hydrogen atom, the electron orbits the proton in a circle of radius 53 pm. What is the orbital period of the electron, in seconds, if the force responsible for the proton-electron attraction is (*a*) gravitational and (*b*) electric? ••

85. (*a*) About how many electrons are there in a copper penny, which has a mass of about 0.003 kg? (*b*) If you could isolate these electrons, how much charge would you have? (*c*) Estimate the magnitude of the electric force it would require to bring one more electron to within 1.0 nm of these electrons, assuming they are combined to form one small charged object. (*d*) Based on this force magnitude, do you think it would be possible to combine this amount of negative charge? ●●

86. Earth exerts an electric force on small charged objects located near its surface. The effect can be modeled by assuming Earth is a particle at the center of Earth carrying a charge of -6.76×10^5 C. (*a*) What is the magnitude of the electric force exerted by Earth on an electron at its surface? Is this force attractive or repulsive? (*b*) How does this force magnitude compare with the magnitude of the gravitational force exerted by Earth on the electron? (*c*) How much negative charge would you have to put on a penny in order for the repulsive electric force exerted by Earth on the penny to cancel the attractive gravitational force exerted by Earth on the penny? (*d*) How many electrons would you have to add to the penny to achieve this? ●●

87. Four particles, each carrying a charge of magnitude 3.0 nC, are located at the corners of a square of side 50 mm. Two particles have positive charges and two have negative charges. (*a*) Determine the position of each particle so that the vector sum of the electric forces on each particle is directed toward the center of the square. (*b*) Determine the magnitude of the vector sum of the electric forces exerted on each particle. ●●

88. A small sphere 1 carrying charge q is fixed a few meters above the Moon's surface next to a spaceship. An astronaut holds a charged sphere 2 a couple of meters above sphere 1, almost but not quite directly over sphere 1. Sketch the trajectory for sphere 2 when the astronaut drops it if the charge on sphere 2 is (*a*) q, (*b*) $9q$, and (*c*) $-q$. ●●●

89. Someone has challenged you in a friendly bet that, given a set of six charged spheres with three carrying positive charge and three carrying negative charge, you can't place any three of them in a line (a board with a groove in it serves the purpose) and have them be in translational equilibrium. You determine which of the three spheres are the positively charged ones and call them 1, 2, and 3. By comparing the electric force exerted by sphere 1 on sphere 3 with the electric force exerted by sphere 2 on sphere 3, you rank 1 as smaller than 2, placing them in the groove several hundred millimeters apart, temporarily blocking them from moving. You can release them only when the third sphere is in place, but there are so many things to consider! ●●● CR

90. While assembling part of an electric generator, you realize that two pieces were not properly labeled. One piece is a nonconducting block, and the other is a conducting block, but without labels you don't know which is which. Because you had counted on the parts being properly labeled, you do not have a multimeter, batteries, or other standard electrical tools. All you have is your wool sweater, some nonconducting styrofoam "peanuts" used in packaging, and some string. You are about to go for help when you realize that your knowledge of static electricity should be enough. ●●● CR

91. Working on a system to collect solar energy, you are trying to move some charged particles through the open interior of a uniformly charged ring. A colleague vaguely remembers Newton's and Priestley's argument that no electrostatic force is exerted on a charged particle inside a uniformly charged sphere. He suggests that the same must be true for a charged ring, and so you can send the charged particles through any part of the ring interior without the particles feeling an electric force and being deflected by it. You are skeptical, wondering if there might at least be a restriction on the path over which you send the particles such that they experience no electric force. ●●● CR

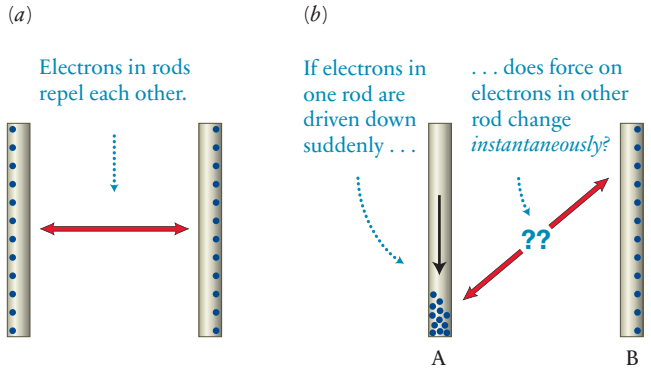
CONCEPTS

QUANTITATIVE TOOLS



In this chapter we revisit an issue we discussed briefly in Chapter 7: the long-range nature of electric and gravitational interactions. How does one charged object "reach out" and affect another charged object? What are the invisible "springs" that pull us—and everything around us—toward Earth's surface? You can describe these long-range interactions by saying that every charged object and every object that has mass has a "sphere of influence" surrounding it. The modern word for this sphere of influence is *field*. Fields are not imaginary. That sensation you felt when, while reading the beginning of Chapter 22, you held a piece of plastic food wrap near your face was the sensation of a field created by the charged particles in the wrap. The closer the wrap is to your skin, the stronger the sensation.

The concept of field is important for two reasons. First, it is impossible to describe the interaction between moving charged particles without it. Second, as you will soon see, it is often easier to deal with fields than with distributions of charge because frequently more is known about fields than about the way charge is distributed.

23.1 The field model

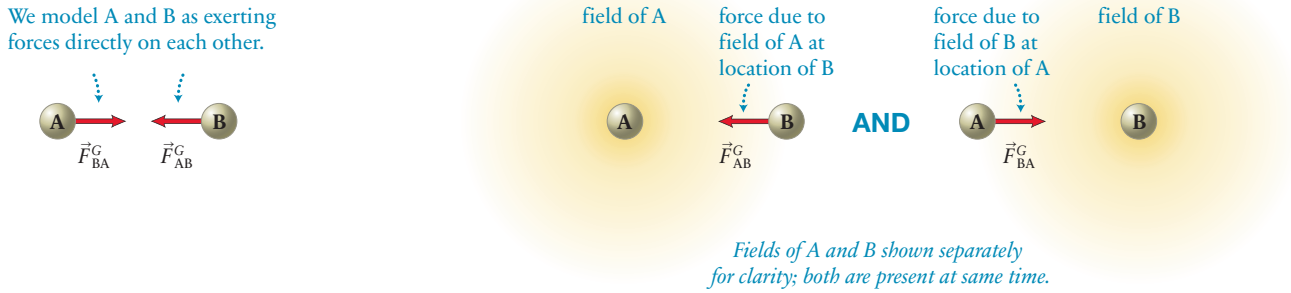
Newton's law of gravity and Coulomb's law describing the electric force between charged particles successfully account for the magnitudes of the gravitational and electric forces between stationary objects. However, they do not address the fundamental puzzle of how objects separated in space can interact without any mediator of the interaction (such an interaction is called *action at a distance*). Worse, they share a fundamental flaw: Both imply that the action of one object on another is instantaneous everywhere throughout space. Consider, for example, the two metal rods in **Figure 23.1**. Even if both are electrically neutral, their electrons interact. Suppose you quickly drive the electrons in rod A down to the bottom, as in Figure 23.1*b*. According to Coulomb's law, doing this will instantly change the force exerted by the electrons in A on those in B, regardless of how far apart the rods are. This means that it would be possible—in principle—to be standing at one position in space and instantly detect a change that occurs at some far distant position.

Figure 23.1 Newton's and Coulomb's laws imply that forces are exerted instantaneously across a distance—but experiments show that they are not.

The idea that an object can directly and instantly influence another object regardless of their separation was troubling in the 19th century but became untenable in the early 20th century when it was demonstrated experimentally that the interaction between charged objects is not instantaneous. The principle illustrated in Figure 23.1, for example, is what makes possible the transmission of radio signals from a transmitting antenna (rod A) to a receiving antenna (rod B). We know from many experiments that such transmission is not instantaneous. As just one example, a radio signal takes about 2.5 s to travel from Earth's surface to the surface of the Moon. In other words, the picture conveyed by Newton's law of gravity and Coulomb's law—that one object directly and instantly affects other objects regardless of the distance between them—cannot be correct.

Instead we must adopt another model of long-range interactions, a model in which interactions take place through the intermediary of an **interaction field** (or simply a **field**). In the field model, an interacting object fills the space around itself with a field. When an object A is placed in the field of an object B, A can "feel" the presence of B's field. Instead of the two objects interacting directly as illustrated in **Figure 23.2*a***, it is the field created by each object that acts on the other object (Figure 23.2*b*). The stronger the field, the greater the magnitude of the force resulting from the interaction.

In Figure 23.1, the electrons in rod B feel the field set up by the electrons in rod A. When the electrons in A accelerate, their motion causes a disturbance in A's field, and this disturbance propagates outward through space like the ripples on the surface of a pond. Only when these ripples in the field reach rod B can the motion of A's electrons be detected by those in rod B. In Chapter 30 we shall study the propagation of disturbances in fields due to accelerating charge carriers. For now, we shall concentrate on fields created by stationary objects.



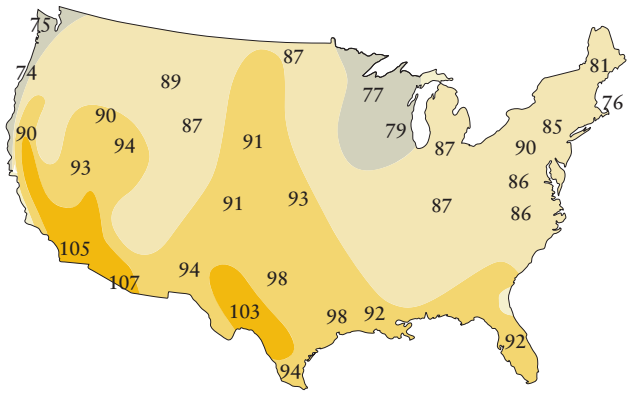
The field model applies equally well to gravitational and electric interactions, with each interaction having its own type of field. The space around any object that has mass is filled with a *gravitational field*, and the space around any electrically charged object is filled with an *electric field*. Gravitational fields exert forces on objects that have mass, and electric fields exert forces on objects that either carry a charge or can be polarized. Let's begin by developing the concept of gravitational field.

Before we attempt to obtain a physical quantity we can use to describe any gravitational field, we should note a number of things. First, for any object A located in a gravitational field created by an object S (S is called the *source* of the field), the magnitude of the field felt by A depends only on the properties of S and on the position of A relative to S; the field magnitude does not depend in any way on the properties of A.

CONCEPTS

Figure 23.2 The field model for interaction at a distance.

(*a*) Model of direct interaction at a distance (*b*) Field model of interaction at a distance



Second, the field of an object is always there, even when the object is not interacting with anything else. A field therefore must be represented by a set of numerical values that cover all the space outside the field source, with every point of this space having a different numerical value. One field representation you are already familiar with is that of a "temperature field," where the temperature across the surface of a region has a specific value at each location (**Figure 23.3**). Third, for stationary objects the field model must give the same forces as Newton's law of gravity and Coulomb's law. In particular, the field model must still yield forces between the two objects that are equal in magnitude and opposite in direction. It is not immediately obvious that the field model preserves this symmetry in the forces because a field is not something shared by two interacting objects—each object has its own field.

For example, in the gravitational interaction between a ball and Earth, the gravitational force exerted by Earth on the ball is due to Earth's gravitational field and the gravitational force exerted by the ball on Earth is due to the ball's field. These two gravitational fields are very different from each other: Earth's field pulls strongly on, say, a paper clip, while the effect of the ball's field on that paper clip is unmeasurably small. As you will see shortly, however, the symmetry of the interaction is preserved despite the asymmetry in the fields (see Checkpoint 23.3).

What physical quantity can we use to describe the gravitational field of an object? How about the gravitational force exerted by the object? Let's examine this possibility using Earth as our object. As we saw in Section 8.8, the magnitude of the gravitational force exerted by Earth on an object of mass m near Earth's surface is $F^G_{Eo} = mg$. This force is not a good quantity for describing Earth's field because the force depends not only on the source—Earth (which determines g)—but also on the mass m of the object placed in the field. As illustrated in **Figure 23.4**, two objects that have different masses m_1 and m_2 but are placed at the same height above Earth's surface are subject to different gravitational forces m_1g and m_2g. The quantity $g = F^G_E/m$, however—the gravitational force per unit of mass—is the same for any object.* This quantity is determined solely by the properties of Earth and is independent of those of any object that experiences a gravitational force exerted by Earth.

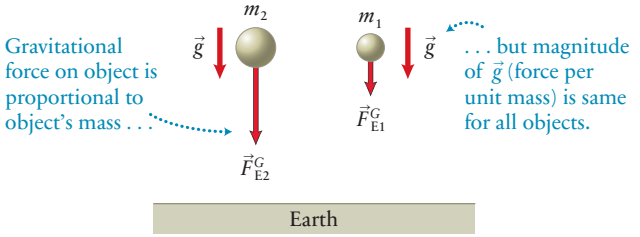


Figure 23.3 The temperature across a region is specified by a set of values, with a specific temperature value for every position in that region. Such a set of values is called a *field*.

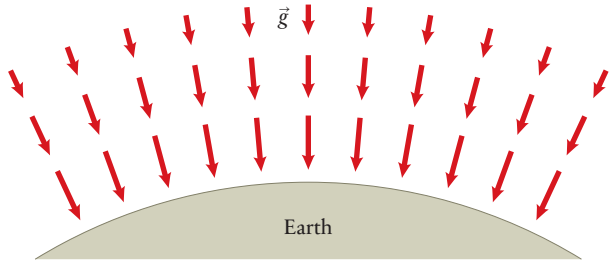
23.1 Two objects 1 and 2, of mass m_1 and m_2, are released from rest far from Earth, at a location where the magnitude of the acceleration due to gravity is much less than $g = 9.8\ \text{m/s}^2$. (*a*) What is the ratio F^G_{E1}/F^G_{E2}? (*b*) For these two objects, is the magnitude of the gravitational force exerted by Earth per unit mass independent of the properties of the objects?



CONCEPTS

Figure 23.4 Comparison between gravitational force and gravitational acceleration on objects of different mass at the same distance from Earth.

*This is so because mass and inertia are equivalent (see Section 13.1), and so the gravitational force per unit of mass is equal to gravitational force divided by inertia, which is gravitational acceleration.

Figure 23.5 Vector field diagram for the gravitational field in a region near Earth.

We can use the gravitational force per unit mass exerted by an object as a measure of the magnitude of the object's gravitational field. For example, near Earth's surface, because $g = 9.8\ \text{m/s}^2$, the magnitude of Earth's gravitational field is 9.8 N/kg; near the surface of the Moon, where $g_{\text{moon}} = 1.6\ \text{m/s}^2$, the magnitude of the Moon's gravitational field is 1.6 N/kg. (Remember that $1\ \text{N/kg} = 1\ (\text{kg}\cdot\text{m/s}^2)/\text{kg} = 1\ \text{m/s}^2$.)

At any given location in the space surrounding a source object S, the magnitude of the gravitational field created by S is the magnitude of the gravitational force exerted on an object B placed at that location divided by the mass of B.

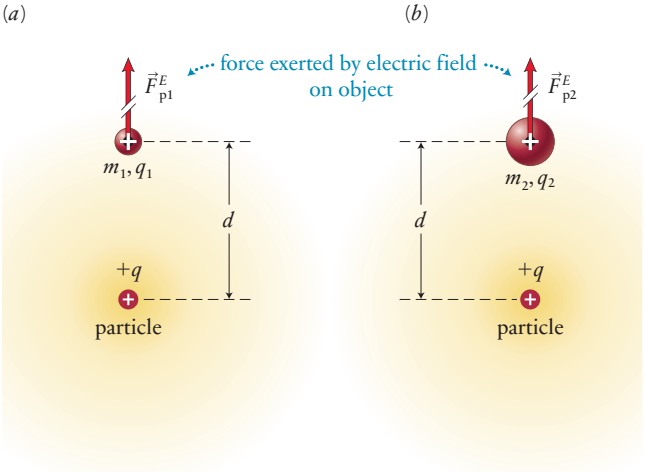
Unlike the temperature field in Figure 23.3, which is a *scalar field*, the gravitational field is a *vector field:* At every position, it has both a magnitude and a direction. **Figure 23.5**, for example, shows a **vector field diagram** representing the gravitational field near Earth. You can determine the magnitude and direction of this field in the space surrounding Earth using a **test particle** (an idealized particle whose mass is small enough that its presence does not perturb the object whose gravitational field we are measuring). Measure, at each location, the gravitational force exerted by Earth on the test particle, and then divide that force by the mass of the test particle to obtain the direction and the magnitude of the gravitational field at that location. As you can see from Figure 23.5, Earth's gravitational field, which can be represented at each position by a vector $\vec{g}$, always points toward the center of Earth, and its magnitude decreases with increasing distance away from Earth. Near Earth's surface, the magnitude of these vectors is $g = 9.8$ N/kg.

23.2 A communications satellite orbits 1.4×10^7 m from Earth's center, at a location where the magnitude of Earth's gravitational field is 2.0 N/kg. (*a*) If the mass of the satellite is $m_s = 2000$ kg, what is the magnitude of $\vec{F}^G_{\text{Es}}$? (*b*) If you place a 0.20-kg ball at the satellite's location, what is the magnitude of $\vec{F}^G_{\text{Eb}}$?

Checkpoint 23.2 illustrates that if you know the gravitational field at a certain position, you can easily calculate the gravitational force exerted by the source of that field on any object at that position by taking the product of the magnitude of the gravitational field at the location of the object and the mass of the object.

23.3 (*a*) Is the magnitude of the gravitational force exerted by Earth on a ball greater than, equal to, or smaller than the magnitude of the gravitational force exerted by the ball on Earth? (*b*) Is the magnitude of Earth's gravitational field at the position of the ball greater than, equal to, or smaller than the magnitude of the gravitational field of the ball at a distance equal to Earth's radius? (*c*) Explain how the answers to parts *a* and *b* can both be correct.

23.2 Electric field diagrams



Let us now apply the same ideas to electric interactions. **Figure 23.6***a* shows object 1 of mass m_1 and charge q_1 a distance d from a particle that carries a charge $+q$. What is the electric field $\vec{E}$ created by the particle at the position of object 1? Before answering this question, answer the next checkpoint, which concerns the interactions of the particle with object 1 and with an object 2 of mass m_2 and charge q_2 (Figure 23.6*b*; $m_2 \neq m_1$ and $q_2 \neq q_1$).

23.4 (*a*) Are the electric forces $\vec{F}^E_{\text{p1}}$ and $\vec{F}^E_{\text{p2}}$ in Figure 23.6 equal? (*b*) What does the quantity $\vec{F}^E_{\text{pi}}/m_i$ represent? (*c*) Is this quantity the same for objects 1 and 2? If not, what quantity is the same for both of these objects?

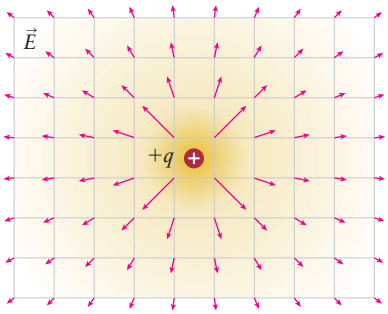
As Checkpoint 23.4 makes clear, the quantity $\vec{F}^E_{\text{pi}}/q_i$—the electric force per unit charge—is determined entirely by the source of the electric field and is independent of the object on which the field exerts a force. So, in analogy to the gravitational field, we can say:

At any given location in the space surrounding a source object S, the electric field created by S is the electric force exerted on a charged test particle placed at that location divided by the charge of the test particle: $\vec{E}_{\text{S}} \equiv \vec{F}^E_{\text{St}}/q_{\text{t}}$.

Figure 23.6 Electric force exerted on two objects of different inertia m and charge q by the electric fields created by two identical charged particles.

CONCEPTS

Like gravitational fields, electric fields are vector fields. There is one difference between the two types of fields, however. Electric interactions can be either repulsive or attractive, and so the direction of the electric force—and hence the direction of the electric field—depends on the sign of the charge. Our rule is that:



The direction of the electric field at a given location is the same as the direction of the electric force exerted on a positively charged object at that location.

23.5 (*a*) If the particle in Figure 23.6 carries a negative charge $q < 0$ and q_1 and q_2 are positive, what are the directions of $\vec{F}^E_{p1}$ and $\vec{F}^E_{p2}$? (*b*) Does the electric field created by the particle point toward or away from the particle? (*c*) If q and q_2 are negative, what are the direction of $\vec{F}^E_{p2}$ and the direction of the electric field created by the particle at the location of object 2? (*d*) If q is positive, does the electric field created by the particle point toward or away from the particle? (*e*) How does the magnitude of the electric field created by a particle that carries a charge $+q$ ($q > 0$) compare with the magnitude of the electric field created by a particle that carries a charge $-q$ of identical magnitude at a distance d from each particle?

Figure 23.7 shows the vector field diagrams for the electric fields of particles that carry positive and negative charges. Because it is impossible to draw electric field vectors at *all* locations, the diagrams show vectors at only certain positions; from these representative vectors you can get an idea of how the electric field looks as a whole. In addition, the drawing is limited to two dimensions, but you should visualize the electric field as spreading out in all three dimensions.

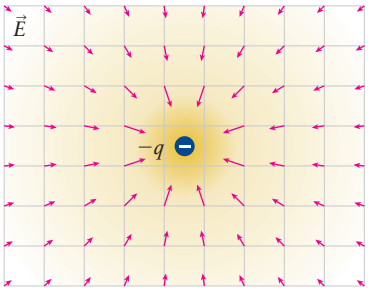


Figure 23.7 Vector field diagrams for positively and negatively charged particles. The lengths of the vectors show that the electric field magnitude decreases with increasing distance from the source.

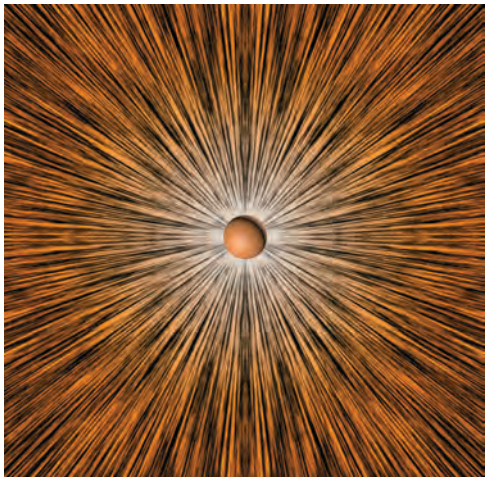
(*a*) Electric field of positively charged particle



Electric field is directed away from positive source . . .

(*b*) Electric field of negatively charged particle

. . . and toward negative source.

Figure 23.8 Electric field pattern created by a small charged object in a solution that contains plastic fibers. The fibers align with the direction of the electric field created by the charged object.

Electric fields can be made visible by putting charged objects in a (nonconducting) liquid that contains small uncharged plastic fibers or grass seed. Each fiber aligns itself in the direction of the electric field at the fiber's location (**Figure 23.8**).

23.6 If you know the electric field $\vec{E}$ at some location, how can you determine the magnitude and direction of the electric force exerted by that field on an object carrying a charge q and placed at that location?

CONCEPTS

23.3 Superposition of electric fields

The concept of electric field becomes especially useful when we consider the combined electric field that results from more than one charged object. Suppose we are interested in the electric field created by two particles that carry charges of equal magnitude but opposite sign. To determine the electric field created by the particles at a point P, we place a test particle* carrying a positive charge q_t at P and measure the vector sum of the forces exerted on it by the two charged source particles (**Figure 23.9** on the next page). The electric field at P is then equal to this vector sum divided by q_t.

*When measuring electric fields, we assume that the charge q_t on the test particle is so small that the particle does not perturb the particles or objects that generate the electric field we are measuring.

Figure 23.9 The electric field due to multiple charged objects (here, a pair of charged particles) is the vector sum of the fields created by the individual objects.

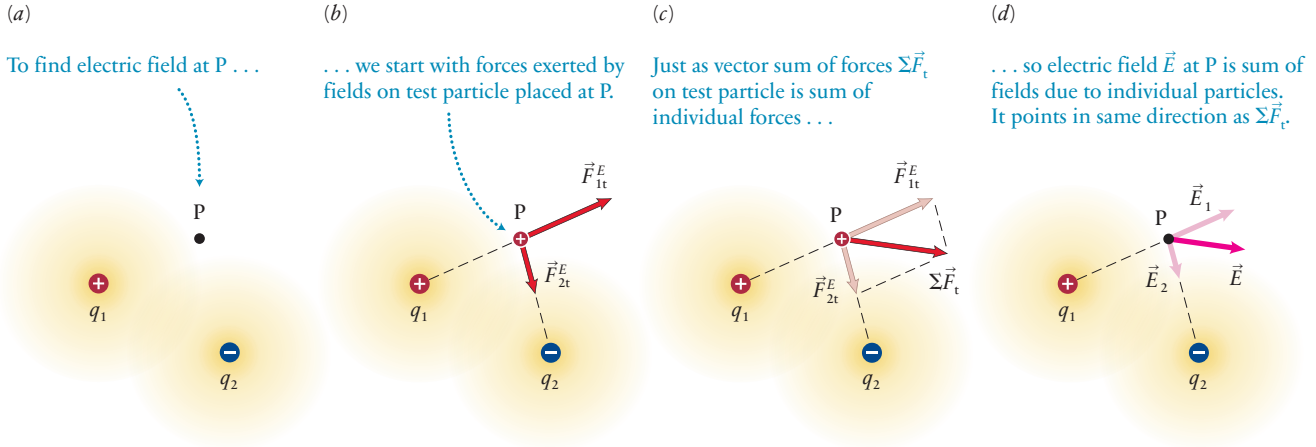


Figure 23.9 illustrates the **superposition of electric fields:**

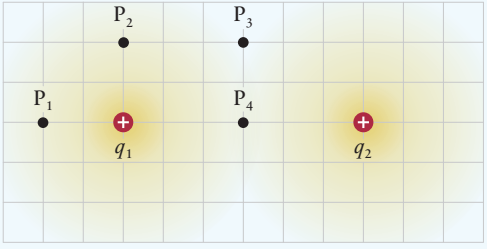
The combined electric field created by a collection of charged objects is equal to the vector sum of the electric fields created by the individual objects.

The superposition principle holds regardless of the number of sources. Because of the vectorial nature of the electric interaction, electric forces add vectorially (Eq. 22.9). Consequently the electric field at P is equal to $(\vec{F}^E_{1t} + \vec{F}^E_{2t})/q_t = \vec{F}^E_{1t}/q_t + \vec{F}^E_{2t}/q_t$, which is the vector sum of the electric fields created by the two sources individually.



The only caveat is the one I pointed out in Figure 22.30. When we deal with conductors, the distribution of charge on the individual conductors in isolation might be different from what it is when the conductors are placed close together.

CONCEPTS

EXERCISE 23.1 Electric field of two positively charged particles

Consider two identical particles 1 and 2 carrying charges $q_1 = q_2 > 0$ (**Figure 23.10**). What is the direction of the combined electric field at points P_1 through P_4?

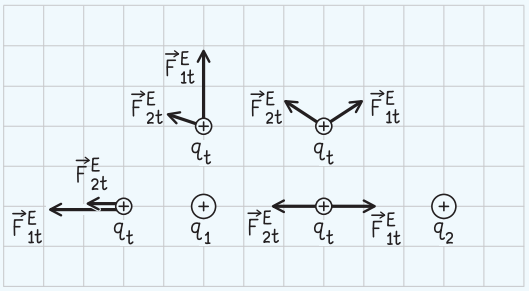


Figure 23.10 Exercise 23.1.

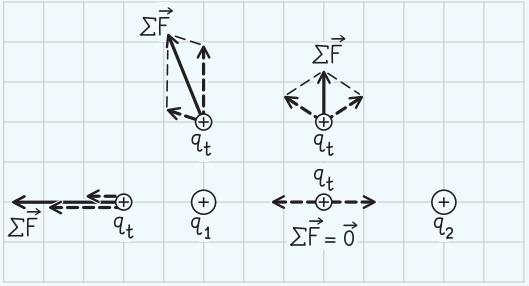


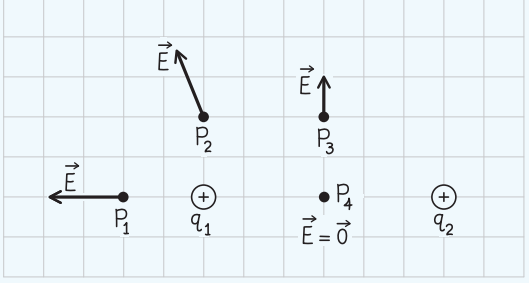
SOLUTION I place a positively charged test particle at each location and determine the vector sum of the (repulsive) forces exerted by 1 and 2 on each test particle. Because $\vec{E} = \Sigma\vec{F}/q_{test}$, the direction of $\vec{E}$ is the same as the direction of $\Sigma\vec{F}$ (**Figure 23.11**).

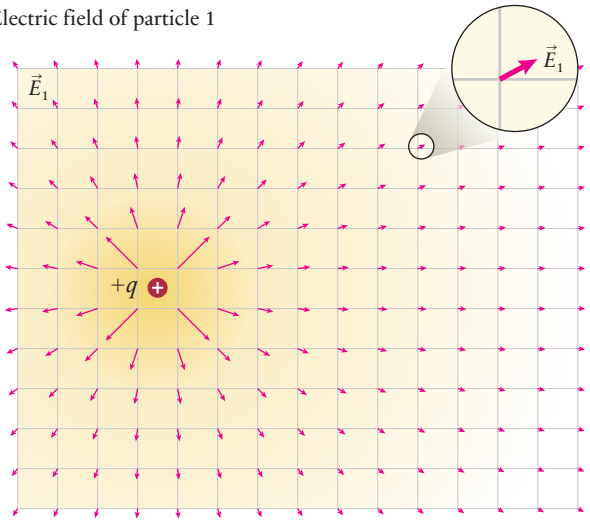
Figure 23.11

(a) Electric forces on test particles

(b) Vector sum of forces on each test particle

(c) Electric field at each tested point





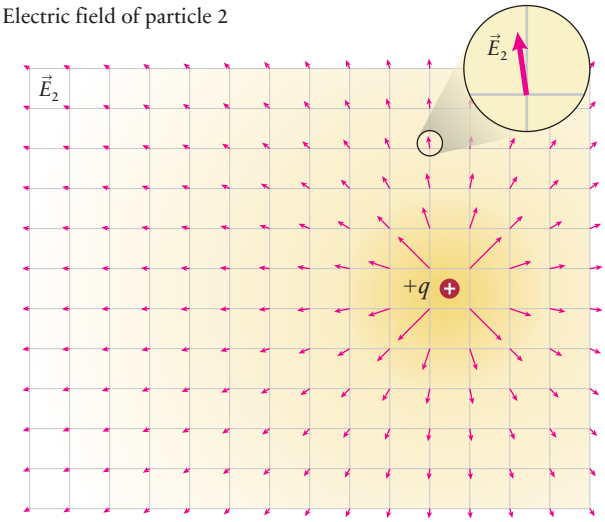


Figure 23.12 Vector field diagrams showing the superposition of the electric fields of the two charged particles of Figure 23.10.

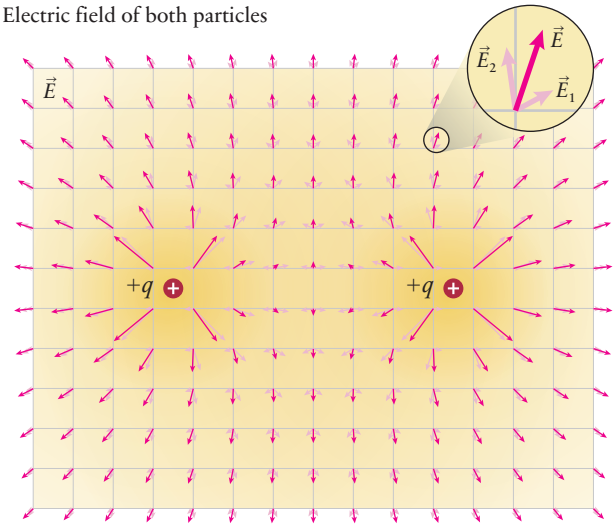
(*a*) Electric field of particle 1

(*b*) Electric field of particle 2

(*c*) Electric field of both particles



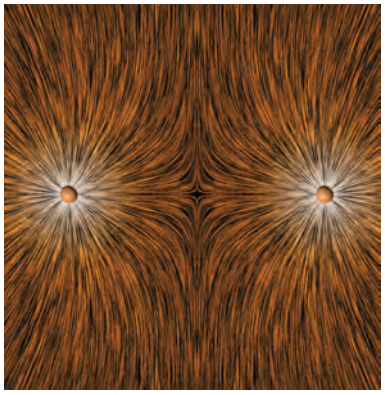


Figure 23.13 Pattern created by two identical charged particles in a liquid containing plastic fibers. Compare with the vector field diagram in Figure 23.12*c*.

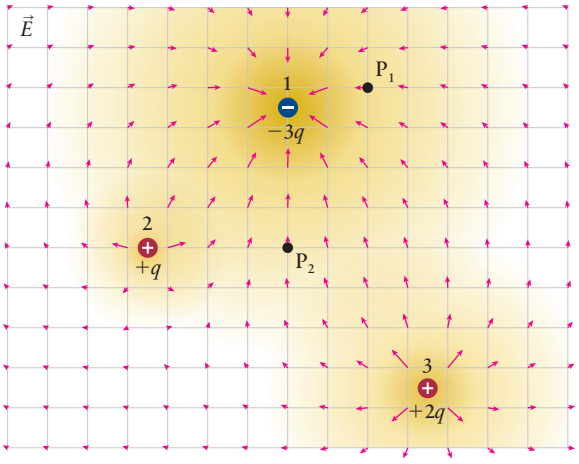


23.7 (*a*) If the charge on particle 2 in Exercise 23.1 is doubled so that $q_2 = 2q_1$, what happens to the direction of the electric field at points P_1 through P_4? (*b*) If the charge on particle 2 is negative so that $q_2 = -q_1$, what is the direction of the electric field at points P_1 through P_4?

Figure 23.11 provides a limited view of the electric field created by the two particles. A more complete view is given in **Figure 23.12**. This diagram is obtained by vectorially adding, for each grid point, the electric field vectors for the individual particles. Note how the pattern of vectors resembles the pattern created by two identically charged particles in a solution of plastic fibers (**Figure 23.13**).

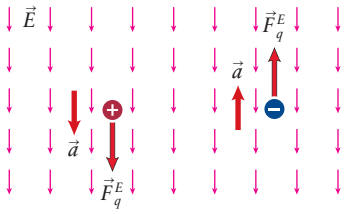
Using the superposition principle, we can determine the electric field produced by any system of charged particles. **Figure 23.14**, for example, shows a vector diagram for the electric field generated by three charged particles. Because every charged object is made up of charged particles—electrons and protons—we can determine the electric field of any object at any position in space. For a real object, the calculation might

Figure 23.14 Vector field diagram of the electric field created by three charged objects.

CONCEPTS

be very tedious or even intractable because of the large number of charged particles, but the basic principle is as given above.

23.8 (*a*) In Figure 23.14, what is the direction of the force $\sum\vec{F}^E$ exerted on a particle carrying a charge $+q$ and placed at P_1? (*b*) How does $\sum\vec{F}^E$ change when the particle at P_1 carries a charge $+3q$? (*c*) Do the magnitude and direction of $\sum\vec{F}^E$ on a charged particle at P_1 change if the $+2q$ charge on object 3 is halved? (*d*) What is the direction of $\sum\vec{F}^E$ exerted on a particle carrying a charge $-q$ and placed at point P_2?



23.4 Electric fields and forces

Before developing additional techniques for determining the electric fields created by systems of charged particles, let us consider this question: What are the forces exerted by an electric field on charged or polarized objects? One of the advantages of working with electric fields is that, for any system of charged particles, once we know the electric field the system creates at some point P in space, we can determine the force exerted by the system on any other charged particle placed at P without worrying about any of the individual source particles in the system anymore.* In Chapter 22 we used the action-at-a-distance model to discuss the forces exerted by charged objects either on other charged objects or on polarized objects. Now we can use the field model to do the same thing. For stationary charged particles, both methods must yield the same result.

When we study the forces exerted by electric fields, it is useful to distinguish between uniform and nonuniform. In a *uniform electric field*, the direction and magnitude of the electric field are the same everywhere. No electric field is ever uniform throughout all space, but as we shall see in Section 23.7 it is possible to create regions of space where the electric field is uniform. In a *nonuniform electric field*, the direction and magnitude of the electric field vary from position to position. (All the electric fields we have considered so far are nonuniform.)

Let us first consider what happens to a charged particle placed in a uniform electric field where the only interaction is electrostatic. Because the electric field is defined as the electric force per unit of charge, the force $\vec{F}_p^E$ exerted by an electric field $\vec{E}$ on a particle carrying a charge q is $\vec{F}_p^E = q\vec{E}$.† Because $\vec{E}$ is the same everywhere, the force $\vec{F}_p^E$ exerted on the particle is constant and so it undergoes a constant acceleration $\vec{a} = \vec{F}_p^E/m = q\vec{E}/m = (q/m)\vec{E}$, where m is the particle's mass.

Figure 23.15 Forces exerted by a uniform electric field on a positively and a negatively charged particle.

A charged particle placed in a uniform electric field undergoes constant acceleration.

If the particle carries a positive charge, $q > 0$, $\vec{F}_p^E$ and $\vec{a}$ point in the same direction as $\vec{E}$. If $q < 0$, $\vec{F}_p^E$ and $\vec{a}$ point in the direction opposite the direction of the electric field (Figure 23.15).

Note from $\vec{a} = (q/m)\vec{E}$ that the magnitude of the acceleration depends on the magnitude of the electric field and on the charge-to-mass ratio q/m of the particle. A large charge q causes a greater force to be exerted on the particle and therefore a greater acceleration; a larger mass m means the particle has greater inertia and therefore the acceleration is smaller.

Because we have already studied motion with constant acceleration, we can apply our knowledge to the motion of charged particles in a uniform electric field. In general, the trajectory of these particles is parabolic, like the trajectory of a projectile fired near Earth's surface, where the gravitational field can be considered uniform over a limited area. In the special case where the initial velocity of a charged particle is parallel to the direction of the electric field, the trajectory is a straight line, like the vertical fall of an object released from rest. The main difference between the motion of projectiles near Earth's surface and the motion of charged particles in an electric field is that Earth's gravitational field is always directed vertically downward, whereas the electric field can be in any direction.

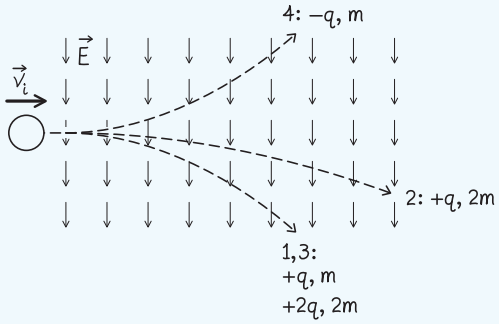
EXAMPLE 23.2 Charged particle trajectories

Four charged particles are fired with a horizontal initial velocity $\vec{v}_i$ into a uniform electric field that is directed vertically downward. The effect of gravity is negligible. The particles have the following charges and masses: particle 1 $(+q, m)$; 2 $(+q, 2m)$; 3 $(+2q, 2m)$; 4 $(-q, m)$. Sketch the four trajectories.

1 GETTING STARTED Because the electric field direction is vertically down, the three positively charged particles experience a downward force and the negatively charged particle experiences an upward force. The magnitude of this force doesn't change as the particles move through the

*This procedure is valid only if the presence of the charged particle at P does not alter the way charge is distributed over the system. We shall refer to the particle or system of particles that creates the electric field at P as being "fixed."

†When dealing with forces exerted by fields, we drop the subscript representing the object that exerts the force (the "by" subscript) because the field is due to *all* objects other than the object on which the force is exerted. The superscript E reminds us that we are dealing with the force exerted by an electric field.



CONCEPTS

electric field because both the field magnitude and the charges on the particles are constant.

2 DEVISE PLAN Because the force exerted on each particle is constant, the particles experience constant accelerations. Because the direction of the force is perpendicular to the direction of the particles' initial motion, they all have a parabolic trajectory. The positively charged particles have a constant downward acceleration; the negatively charged particle has a constant upward acceleration. Because $\vec{a} = (q/m)\vec{E}$, the acceleration magnitude is greatest when q is large and/or m is small.

3 EXECUTE PLAN I draw trajectories that curve down for 1, 2, and 3 and up for 4 (**Figure 23.16**). The magnitude of the electric force exerted on particle 2 is the same as that exerted on particle 1, but the acceleration of particle 2 is smaller because this particle has the greater mass. I indicate this difference in acceleration by making trajectory 1 more curved than trajectory 2. The magnitude of the electric force exerted on particle 3 is twice as great as that exerted on particle 1, but 3's mass is also twice as great, and so the two particles have the same charge-to-mass ratio and therefore the same acceleration and trajectory. The magnitude of the electric force exerted on particle 4 is the same as that exerted on particle 1 but points in the opposite direction, and so trajectories 1 and 4 are identical in shape but curve in opposite directions. ✔

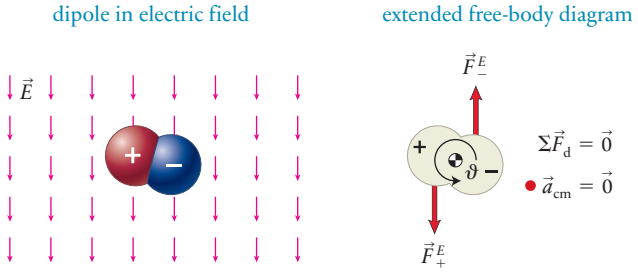


Figure 23.16

4 EVALUATE RESULT My sketch indicates that particles with increasingly positive charge-to-mass ratios curve increasingly downward. Conversely, particles with increasingly negative charge-to-mass ratios curve increasingly upward. This is what I expect because a particle's deflection is a function of both its charge, which determines the magnitude of the force exerted by the electric field on it (greater charge, greater deflection), and its mass, which relates the particle's acceleration to the force exerted on it (greater mass, smaller deflection).

23.9 A water droplet carrying a positive charge is released from rest in a uniform horizontal electric field near Earth's surface. The horizontal electric force is comparable in magnitude to the gravitational force exerted by Earth. Describe the droplet's trajectory.

Figure 23.17 Extended free-body diagram for a permanent dipole placed in a uniform electric field.

In a nonuniform electric field, the force exerted on a charged particle varies from one position to another, so we cannot easily specify the particle's trajectory without knowing more about the electric field. As in a uniform electric field, however:

A positively charged particle placed in a nonuniform electric field has an acceleration in the same direction as the electric field; a negatively charged particle placed in such a field has an acceleration in the opposite direction.

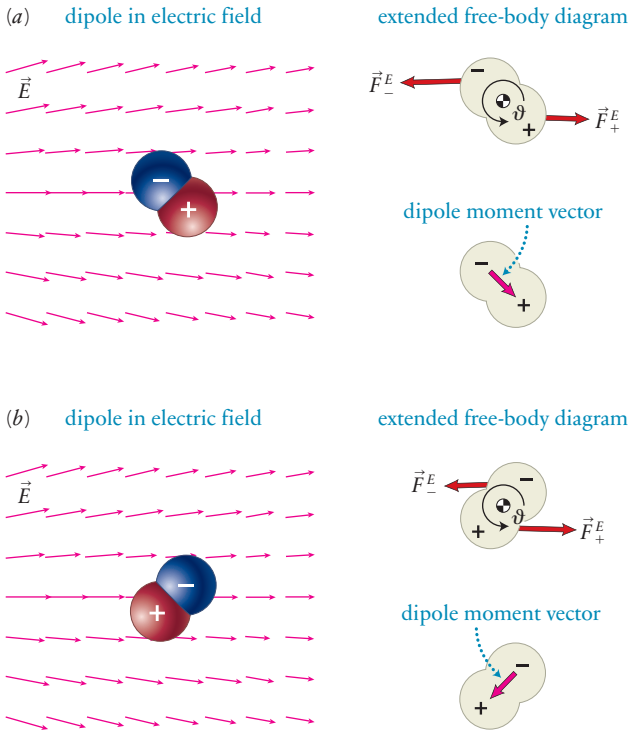
In Chapter 22 we found that charged objects can polarize electrically neutral objects by separating the centers of positive and negative charge in the latter. The resulting configuration of charge—equal amounts of positive and negative charge separated by a small distance—is called an **electric dipole** or simply **dipole.** Many molecules, such as water molecules, are *permanent dipoles;* that is to say, the centers of positive and negative charge are kept separated by some internal mechanism. **Figure 23.17** illustrates the forces exerted on a permanent electric dipole in a uniform electric field. Because the electric field is uniform and the magnitude of the charge on the positive end of the dipole is equal to the magnitude of the charge on the negative end, the forces exerted on the two ends are equal in magnitude but opposite in direction, making their vector sum zero. However, the forces exerted on the two ends cause a torque (see Chapter 12).

23.10 (*a*) What effect does the torque caused by the electric field have on the electric dipole in Figure 23.17? (*b*) Is the torque the same for every orientation of the molecule?

The orientation of an electric dipole can be characterized by a vector, the **dipole moment,** that, by definition, points from the center of negative charge to

CONCEPTS

the center of positive charge, as shown in **Figure 23.18**. As Checkpoint 23.10 illustrates, the electric forces create a torque on the dipole that tends to align the dipole moment with the electric field.

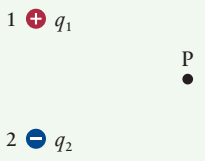


In a nonuniform electric field, the situation is more complicated because the two ends of the dipole are now subject to forces that have different magnitudes as well as different directions. Consider, for example, the nonuniform electric field in Figure 23.18*a*, which is due to a positively charged particle to the left side of the figure. The magnitude of $\vec{F}^E_-$ is greater than the magnitude of $\vec{F}^E_+$ because the negative end of the dipole is closer to the positively charged particle. Thus the vector sum of the forces exerted on the two ends is nonzero, and so the dipole experiences an acceleration whose magnitude and direction depend on its orientation with respect to the electric field. In addition, the forces create a torque about the dipole's center of mass. As in a uniform electric field:

> **A permanent electric dipole placed in an electric field is subject to a torque that tends to align the dipole moment with the direction of the electric field. If the field is uniform, the dipole's center of mass has zero acceleration; if the electric field is nonuniform, the dipole's center of mass has a nonzero acceleration.**

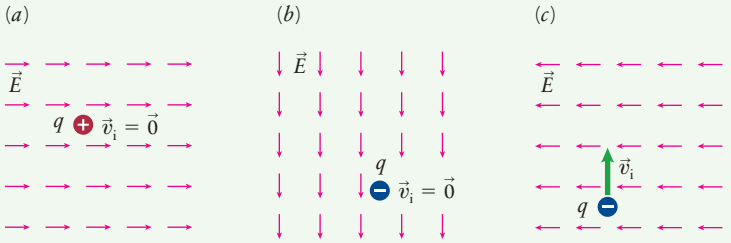
23.11 (*a*) Draw a free-body diagram for the dipole in Figure 23.18*a* and determine the direction of the dipole's center-of-mass acceleration. (*b*) Draw a free-body diagram for the dipole in Figure 23.18*b* and qualitatively describe the dipole's motion.

Figure 23.18 Extended free-body diagrams for permanent dipoles in nonuniform electric fields. The electric field shown is due to a positively charged particle to the left of the figure.



CONCEPTS

Self-quiz



1. Suppose someone discovers that blue and yellow objects attract each other, that two blue objects repel each other, and that two yellow objects repel each other. The strength of this "chromatic interaction" is found to depend on color depth: The deeper the color, the greater the magnitude of the interaction. How would you define the magnitude and direction of the "chromatic field" of an object?
2. (*a*) Does an electrically neutral particle that has mass interact with an electric field? (*b*) Does a charged particle interact with a gravitational field?
3. The two particles in **Figure 23.19** have the same mass, carry charges of the same magnitude ($q_1 = -q_2 > 0$), and are equidistant from point P. (*a*) What is the electric field direction at P? (*b*) At P, what is the direction of the gravitational field due to the two particles? Ignore Earth's gravitational field.

Figure 23.19

4. Can electric and gravitational fields exist in the same place at the same time?
5. What are the directions of the acceleration of each particle in **Figure 23.20**? Describe the resulting motions.

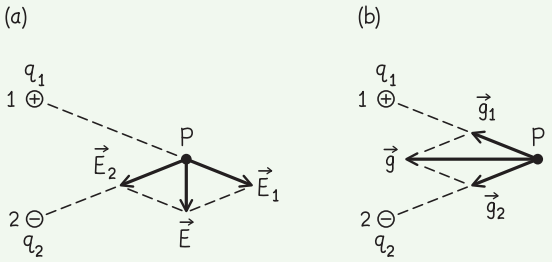


Figure 23.20

Answers

1. The gravitational field is defined as the gravitational force per unit of mass, with the field direction the same as the direction of the force. The electric field is defined as the electric force per unit of charge, with the field direction parallel to that of the force exerted on a positively charged particle. Therefore, the chromatic field can be defined as the chromatic force per unit of color, with the field direction parallel to that of the force exerted on a particle carrying some chosen color.
2. (*a*) No. Uncharged particles don't interact with electric fields. (Remember that a particle has no extent and therefore cannot be polarized.) (*b*) Yes, because any particle or object, charged or uncharged, interacts with a gravitational field.
3. (*a*) The electric field of particle 1 points away from the particle, which means that at P it points to the right and down. The electric field of particle 2 points toward the particle, meaning to the left and down at P. The vector sum of the electric fields at P therefore points straight down (**Figure 23.21a**). (*b*) The gravitational fields of the two particles point toward them from P, and so their vector sum points to the left (Figure 23.21*b*).

Figure 23.21

4. Yes. Consider a charged object near Earth's surface. This object is surrounded by an electric field, but it is also surrounded by Earth's (and to a lesser extent its own) gravitational field. These electric and gravitational fields exist in the same place at the same time.
5. (*a*) Recall from the discussion following Checkpoint 23.4 that the direction of the electric field at a given location is the same as the direction of the electric force exerted on a positively charged particle at that location. In Figure 23.20*a*, therefore, the positively charged particle experiences a force directed to the right. Because its initial velocity is zero, the particle moves in a straight line in the direction of the electric field. (*b*) The negatively charged particle in Figure 23.20*b* experiences an acceleration up the page, opposite the direction of the electric field. This particle moves in a straight line up the page. (*c*) The negatively charged particle in Figure 23.20*c* experiences an acceleration to the right, in the direction opposite the direction of the electric field. Because its initial velocity is perpendicular to the direction of the electric field, the particle travels in a parabolic trajectory up the page and curving to the right.

23.5 Electric field of a charged particle

In Section 23.2 we defined the **electric field** at a certain point P in space as the electric force experienced at P by a test particle carrying a charge q_t divided by the charge of the test particle:

$$\vec{E} \equiv \frac{\vec{F}_t^E}{q_t}. \tag{23.1}$$

The SI unit of electric field is the newton per coulomb (N/C).

Equation 23.1 requires no knowledge of the charge distribution that causes the electric field: It gives a prescription for determining the electric field at a given position in space. We can use Coulomb's law, however, to derive an expression for the electric field created at some point P due to a source particle carrying a charge q_s at position $\vec{r}_s$ (**Figure 23.22**). If we place a test particle carrying a charge q_t at P, Coulomb's law (Eq. 22.7) tells us that the force exerted on the test particle is

$$\vec{F}_{st}^E = k\frac{q_s q_t}{r_{st}^2}\hat{r}_{st}, \tag{23.2}$$

where $k = 9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2$ (Eq. 22.5) is the proportionality constant that appears in Coulomb's law, r_{st} is the distance between the two particles, and $\hat{r}_{st}$ is a unit vector pointing from the source particle to the test particle. If we divide the electric force exerted by the source particle on the test particle by the charge q_t on the test particle, we obtain an expression for the electric field created by the source particle at P:

$$\vec{E}_s = \frac{\vec{F}_{st}^E}{q_t} = k\frac{q_s}{r_{st}^2}\hat{r}_{st}. \tag{23.3}$$

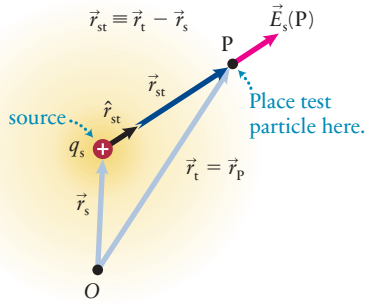
Because the test particle has nothing to do with this electric field, we can omit any reference to it by writing $\vec{r}_{st} = \vec{r}_{sP}$ and referring only to the position of point P:

$$\vec{E}_s(\text{P}) = k\frac{q_s}{r_{sP}^2}\hat{r}_{sP}. \tag{23.4}$$

This expression represents the electric field at P due to a source particle carrying a charge q_s at position $\vec{r}_s$.

As expected, the magnitude of the electric field at P is proportional to q_s, is independent of q_t, and decreases as the inverse square of the distance r_{sP} from the source particle. The direction of the electric field is outward (that is to say, in the direction given by $\hat{r}_{sP}$) when q_s is positive and inward (antiparallel to $\hat{r}_{sP}$) when q_s is negative.

Using the superposition principle, we now can determine the electric field due to a system of particles 1, 2, . . . carrying charges q_1, q_2, ... The combined electric field is the vector sum of the individual electric fields:



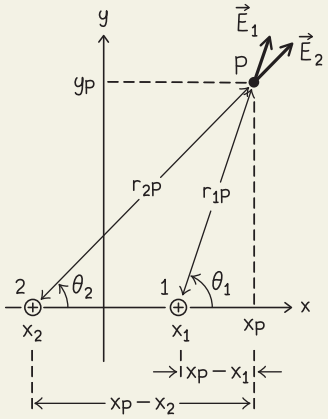
$$\vec{E} = \vec{E}_1 + \vec{E}_2 + \cdots = \Sigma k\frac{q_i\hat{r}_{iP}}{r_{iP}^2}. \tag{23.5}$$

Once the electric field at a certain position is known, the force exerted on any particle carrying charge q placed at that position can be found from

$$\vec{F}_p^E = q\vec{E}. \tag{23.6}$$

(Remember that we omit the "by" subscript on the force when the force is exerted by a field.) If q is positive, the force exerted on the particle is in the same direction as the electric field; if q is negative, the force exerted on the particle is in the direction opposite the direction of the electric field.

Figure 23.22 To determine the electric field at P generated by a charged source particle, we place a test particle at P.



EXAMPLE 23.3 Electric field due to two charged particles

A point P is located at $x_P = 2.0$ m, $y_P = 3.0$ m. What are the magnitude and direction of the electric field at P due to a particle 1 carrying charge $q_1 = +10\ \mu$C and located at $x_1 = 1.0$ m, $y_1 = 0$ and a particle 2 carrying charge $q_2 = +20\ \mu$C and located at $x_2 = -1.0$ m, $y_2 = 0$?

❶ **GETTING STARTED** I begin by making a sketch of the situation (**Figure 23.23**). Each particle carries a positive charge, so the electric field due to each particle points away from the particle.

Figure 23.23

❷ **DEVISE PLAN** To determine the electric field $\vec{E}_P$ at P, I must take the vector sum of $\vec{E}_1$ and $\vec{E}_2$ at P. I can use Eq. 23.4 to calculate the magnitudes E_1 and E_2. To obtain the vector sum of the two fields, I add their x and y components.

❸ **EXECUTE PLAN** The distances from the particles to P are $r_{1P} = \sqrt{(x_P - x_1)^2 + y_P^2} = \sqrt{10\ \text{m}^2} = 3.2$ m and $r_{2P} = \sqrt{(x_P - x_2)^2 + y_P^2} = \sqrt{18\ \text{m}^2} = 4.2$ m. The magnitudes of the electric fields created by the particles at P are thus

$$E_1 = k\frac{|q_1|}{r_{1P}^2} = (9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(1.0 \times 10^{-5}\ \text{C})}{10\ \text{m}^2}$$
$$= 0.90 \times 10^4\ \text{N/C}$$

$$E_2 = k\frac{|q_2|}{r_{2P}^2} = (9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(2.0 \times 10^{-5}\ \text{C})}{18\ \text{m}^2}$$
$$= 1.0 \times 10^4\ \text{N/C}.$$

To calculate $\vec{E}_P$, I take the vector sum of $\vec{E}_1$ and $\vec{E}_2$ at P. In component form, I have

$$E_{Px} = E_{1x} + E_{2x} = E_1\cos\theta_1 + E_2\cos\theta_2$$
$$= E_1\frac{(x_P - x_1)}{r_{1P}} + E_2\frac{(x_P - x_2)}{r_{2P}}$$

$$E_{Py} = E_{1y} + E_{2y} = E_1\sin\theta_1 + E_2\sin\theta_2$$
$$= E_1\frac{y_P}{r_{1P}} + E_2\frac{y_P}{r_{2P}}.$$

Substituting the values given, I have

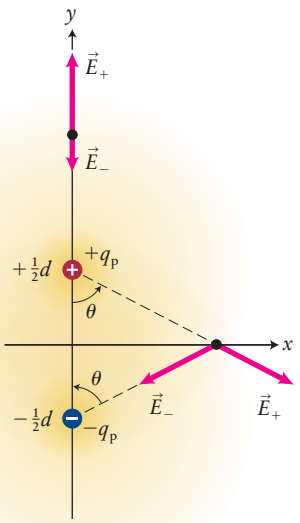
$$E_{Px} = (0.9 \times 10^4\ \text{N/C})\frac{1.0\ \text{m}}{3.2\ \text{m}} + (1.0 \times 10^4\ \text{N/C})\frac{3.0\ \text{m}}{4.2\ \text{m}}$$
$$= +1.0 \times 10^4\ \text{N/C}$$

$$E_{Py} = (0.9 \times 10^4\ \text{N/C})\frac{3.0\ \text{m}}{3.2\ \text{m}} + (1.0 \times 10^4\ \text{N/C})\frac{3.0\ \text{m}}{4.2\ \text{m}}$$
$$= +1.6 \times 10^4\ \text{N/C}.$$

Finally, I write this in vector form as

$$\vec{E}_P = (+1.0 \times 10^4\ \text{N/C})\hat{\imath} + (+1.6 \times 10^4\ \text{N/C})\hat{\jmath}.$$ ✔

❹ **EVALUATE RESULT** Both E_{Px} and E_{Py} are positive, as I expect based on my sketch. The magnitudes of $\vec{E}_1$ and $\vec{E}_2$ are comparable, which is what I would expect: Particle 2 carries twice the charge of particle 1, but the square of its distance to P is greater by a factor of 1.8.



23.12 What is the magnitude of the electric force exerted by the electric field on an electron placed at point P in Figure 23.23? (Assume that the only interaction is electrostatic.) What is the initial acceleration of the electron if it is released from rest from that point? [$e = 1.6 \times 10^{-19}$ C; $m_e = 9.1 \times 10^{-31}$ kg.]

23.6 Dipole field

Next we examine the electric field due to a permanent electric dipole. **Figure 23.24** on the next page shows a dipole that consists of a particle carrying a charge $+q_p$ at $x = 0$, $y = +\frac{1}{2}d$, and another particle carrying a charge $-q_p$ at $x = 0$, $y = -\frac{1}{2}d$, where d is the distance between the two particles. The charge q_p of the positively charged pole is called the *dipole charge*, and the distance d is called the *dipole separation*. Each particle creates an electric field at all positions in space, so the two fields overlap

Figure 23.24 Calculating the electric field due to a dipole.

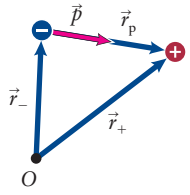
everywhere. We can determine the combined electric field at any position by adding the two fields vectorially. Let us do this for two general locations: anywhere along the x axis and anywhere along the y axis.

Along the x axis, which bisects the dipole, the magnitudes of the electric fields due to the two ends of the dipole are equal:

$$E_+ = E_- = k\frac{q_p}{x^2 + (d/2)^2}. \tag{23.7}$$

The x components of these two electric fields point in opposite directions and so add to zero. The magnitude of the combined electric field is thus equal to the sum of the y components:

$$E_y = E_{+y} + E_{-y} = -(E_+ + E_-)\cos\theta$$



$$= -\left(2k\frac{q_p}{x^2+(d/2)^2}\right)\left(\frac{d/2}{[x^2+(d/2)^2]^{1/2}}\right) = -k\frac{q_p d}{[x^2+(d/2)^2]^{3/2}}. \tag{23.8}$$

The product $q_p d$ is a measure of the strength of the dipole and is the magnitude of the dipole moment introduced in Section 23.4. To specify both the strength and the orientation of the dipole we can write this quantity as a vector, called the **dipole moment:**

$$\vec{p} \equiv q_p \vec{r}_p, \tag{23.9}$$

where $\vec{r}_p \equiv \vec{r}_{-+} = \vec{r}_+ - \vec{r}_-$ is the position of the positively charged particle relative to the negatively charged particle (and so $d = |\vec{r}_p|$). Because q_p is always taken to be positive, the dipole moment $\vec{p}$ points in the same direction as $\vec{r}_p$: along the axis of the dipole (the line that passes through the center of each particle), in the direction from the negative to the positive pole (**Figure 23.25**). Large permanent dipole moments can be caused either by a large dipole separation d or by a large dipole charge q_p. Conceptually you can think of the magnitude of the dipole moment as a measure of how strongly the dipole wants to align itself in the direction of an electric field. The SI unit of dipole moment is C · m.

Figure 23.25 The dipole moment $\vec{p}$ points along the axis of the dipole from the negative to the positive pole.

For distances far from the dipole ($x \gg d/2$), we may ignore $d/2$, and so $[x^2 + (d/2)^2]^{3/2} \to x^3$. Equation 23.8 thus becomes

$$E_y \approx -k\frac{p}{|x^3|} \quad \text{(far from dipole along the positive } x \text{ axis)}. \tag{23.10}$$

The right side of this equation is negative for both positive and negative x, and so anywhere along the x axis the dipole's electric field $\vec{E}$ points in the negative y direction, opposite the direction of the dipole moment. Equation 23.10 also shows that the magnitude of the electric field is inversely proportional to x^3, in contrast to the electric field of a charged particle, which is inversely proportional to x^2 (Eq. 23.4). The reason the electric field of a dipole approaches zero faster as x increases is that the angle between $\vec{E}_+$ and $\vec{E}_-$ in Figure 23.24 approaches 180° as x increases, and so the electric fields of the two poles tend to cancel each other more and more.

Along the y axis, the electric field created by either end of the dipole is directed along the y axis. Thus to determine the y component of the electric field of the dipole at any position along the y axis, we must add the y components of the fields from each particle. For $y > +d/2$:

$$E_y = E_{+y} + E_{-y} = k\frac{q_p}{[y-(d/2)]^2} - k\frac{q_p}{[y+(d/2)]^2}. \tag{23.11}$$

QUANTITATIVE TOOLS

After some algebra, this can be rewritten in the form

$$E_y = k\frac{q_p}{y^2}\left[\left(1-\frac{d}{2y}\right)^{-2}-\left(1+\frac{d}{2y}\right)^{-2}\right] \qquad (y>+d/2). \quad (23.12)$$

For distances far from the dipole, $y \gg +d/2$, so we can use the binomial series expansion, which states that for $x \ll 1$, $(1+x)^n \approx 1+nx$ (see Appendix B). Applying this expansion to the two terms inside the square brackets in Eq. 23.12, we get

$$E_y \approx k\frac{q_p}{y^2}\left[\left(1+2\frac{d}{2y}\right)-\left(1-2\frac{d}{2y}\right)\right]$$

$$= k\frac{q_p}{y^2}\left[\frac{2d}{y}\right] = 2k\frac{q_p d}{y^3} = 2k\frac{p}{y^3} \qquad (y \gg d/2). \quad (23.13)$$

The right side of this equation has the same algebraic sign as y, so the dipole's electric field $\vec{E}$ points in the positive y direction. (Carrying out the same calculation for $y<-d/2$, you can show that the electric field still points in the positive y direction. In between the two charged particles, the electric field points in the negative y direction.) The magnitude of the electric field is inversely proportional to y^3—just as along the x axis, the electric fields of each of the two poles tend to cancel each other more and more as the distance from the dipole increases. One can show that the electric field of the dipole depends on $1/r^3$ for all positions far from the dipole (where r is the distance between the point under consideration and the center of the dipole). The reason is that the electric fields of the positive and negative ends of the dipole partially cancel each other, and this cancellation becomes more complete far from the dipole: The farther you are from the dipole, the smaller the separation between the charged particles appears to be.

23.13 The magnitude of the electric field created by dipole A at a certain point P is E_A. If the dipole is replaced with another dipole B that has its dipole moment oriented in the same direction, the magnitude of the electric field at point P is found to be greater: $E_B > E_A$. Which dipole has the greater dipole moment? For which of these two dipoles is the dipole charge q_p greater?

23.7 Electric fields of continuous charge distributions

So far we have dealt with only charged particles because Coulomb's law applies only to charged particles. However, most charged objects of interest—from charged combs to electrical components—are not particles. Instead, they are extended bodies. Although every macroscopic object consists of very large numbers of charged particles—protons and electrons—it is not practical to calculate the individual field of each of these particles and then add them vectorially. Instead, we shall treat any macroscopic charged object as having a continuous charge distribution and calculate the electric field created by the object by dividing the charge distribution on the object into infinitesimally small segments that may be considered charged source particles carrying a charge dq_s. For the charged macroscopic object shown in Figure 23.26, for example, we can use Coulomb's law to obtain the infinitesimal portion of the electric field at point P contributed by a segment:

$$d\vec{E}_s(\mathrm{P}) = k\frac{dq_s}{r_{sP}^2}\hat{r}_{sP}. \qquad (23.14)$$

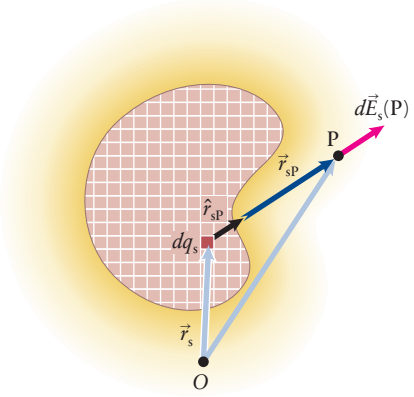


Figure 23.26 To calculate the electric field created at P by a continuous charge distribution, we divide the distribution into infinitesimally small segments that can be treated as charged source particles carrying charge dq_s.

Using the principle of superposition, we can then sum the contributions of all the segments that make up the object. Because the segments are infinitesimally small, this sum corresponds to an integral:

$$\vec{E} = \int d\vec{E}_s = k\int \frac{dq_s}{r_{sP}^2}\hat{r}_{sP}. \tag{23.15}$$

In order to evaluate this integral, we must express dq_s, $1/r_{sP}^2$, and $\hat{r}_{sP}$ in terms of the same coordinate(s). To do so, it is necessary to express the charge on the object in terms of a **charge density**—the amount of charge per unit of length, per unit of surface area, or per unit of volume. For a one-dimensional object, such as a thin charged wire of length ℓ carrying a charge q uniformly distributed along the wire, the *linear charge density*—the amount of charge per unit of length (in coulombs per meter)—is given by

$$\lambda \equiv \frac{q}{\ell} \quad \text{(uniform charge distribution)}. \tag{23.16}$$

For uniformly charged two-dimensional objects, we use the *surface charge density*—the amount of charge per unit of area (in coulombs per square meter). For example, the surface charge density of a flat plate of area A carrying a uniformly distributed charge q is

$$\sigma \equiv \frac{q}{A} \quad \text{(uniform charge distribution)}. \tag{23.17}$$

For a uniformly charged three-dimensional object, we use the *volume charge density:*

$$\rho \equiv \frac{q}{V} \quad \text{(uniform charge distribution)}, \tag{23.18}$$

which gives the amount of charge per cubic meter.

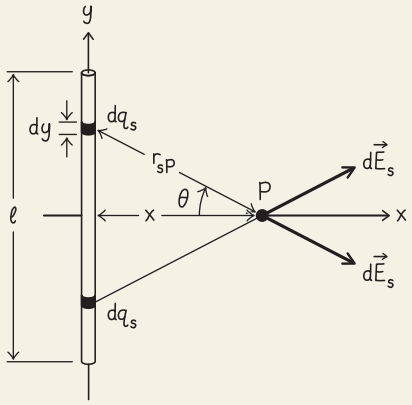
The Procedure box below provides some helpful steps for carrying out the integral in Eq. 23.15, and the next four examples show how to put the procedure into practice.

PROCEDURE: Calculating the electric field of continuous charge distributions by integration

To calculate the electric field of a continuous charge distribution, you need to evaluate the integral in Eq. 23.15. The following steps will help you evaluate the integral.

1. Begin by making a sketch of the charge distribution. Mentally divide the distribution into small segments. Indicate one such segment that carries a charge dq_s in your drawing.
2. Choose a coordinate system that allows you to express the position of the segment in terms of a minimum number of coordinates (x, y, z, r, or θ). These coordinates are the integration variables. For example, use a radial coordinate system for a charge distribution with radial symmetry. Unless the problem specifies otherwise, let the origin be at the center of the object.
3. Draw a vector showing the electric field caused by the segment at the point of interest. Examine how the components of this vector change as you vary the position of the segment along the charge distribution. Some components may cancel, which greatly simplifies the calculation. If you can determine the direction of the resulting electric field, you may need to calculate only one component. Otherwise express $\hat{r}_{sP}$ in terms of your integration variable(s) and evaluate the integrals for each component of the field separately.
4. Determine whether the charge distribution is one-dimensional (a straight or curved wire), two-dimensional (a flat or curved surface), or three-dimensional (any bulk object). Express dq_s in terms of the corresponding charge density of the object and the integration variable(s).
5. Express the factor $1/r_{sP}^2$, where r_{sP} is the distance between dq_s and the point of interest, in terms of the integration variable(s).

At this point you can substitute your expressions for dq_s and $1/r_{sP}^2$ into Eq. 23.15 and carry out the integral (or component integrals), using what you determined about the direction of the electric field (or substituting your expression for $\hat{r}_{sP}$).



QUANTITATIVE TOOLS

EXAMPLE 23.4 Electric field created by a uniformly charged thin rod

A thin rod of length ℓ carries a uniformly distributed charge q. What is the electric field at a point P along a line that is perpendicular to the long axis of the rod and passes through the rod's midpoint?

❶ **GETTING STARTED** I begin by making a sketch of the situation. After drawing a set of axes, I place the rod along the y axis, with the origin at the rod center and point P on the positive x axis (**Figure 23.27**).

Figure 23.27

❷ **DEVISE PLAN** The word *thin* implies that I can treat the rod as a one-dimensional object. Because the rod is uniformly charged, I can thus use Eq. 23.16 to determine the linear charge density along the rod. To determine the electric field at P, I divide the rod lengthwise into a large number of infinitesimally small segments, each of length dy. Each segment contributes to the electric field at P an amount given by Eq. 23.14. For each segment above the x axis there is a corresponding segment below the axis at the same distance from P. The y components of the electric fields $d\vec{E}_s$ due to these two segments add up to zero, so I need to calculate only the x component dE_{sx}. To get the electric field created by the entire rod, I use Eq. 23.15 to integrate my result over the length of the rod.

❸ **EXECUTE PLAN** The charge dq_s on each segment dy is $dq_s = \lambda\, dy = (q/\ell)\, dy$. The x component of the electric field created by each segment at P is thus

$$dE_{sx} = k\frac{dq_s}{r_{sP}^2}\cos\theta = k\frac{q}{\ell r_{sP}^2}\cos\theta\, dy, \tag{1}$$

where θ is the angle between the x axis and the line that connects the segment dy with P. Both θ and r_{sP} depend on the position y of the segment, so I must choose one integration variable and express the others in terms of that variable. I choose θ as the integration variable, which means I must express the factor dy/r_{sP}^2 in Eq. 1 in terms of θ. Using trigonometry, I have

$$\cos\theta = \frac{x}{r_{sP}} \tag{2}$$

and

$$\tan\theta = \frac{y}{x}, \tag{3}$$

where x is the x coordinate of point P. Differentiating Eq. 3 yields

$$dy = x\, d(\tan\theta) = \frac{x}{\cos^2\theta}d\theta. \tag{4}$$

Next I divide Eq. 4 by r_{sP}^2 to obtain the factor dy/r_{sP}^2 I need. I use r_{sP}^2 on the left, but on the right I use Eq. 2 to write r_{sP}^2 in the form $x^2/\cos^2\theta$, yielding

$$\frac{dy}{r_{sP}^2} = \left(\frac{\cos^2\theta}{x^2}\right)\left(\frac{x}{\cos^2\theta}d\theta\right) = \frac{1}{x}d\theta.$$

Substituting this result into Eq. 1 and integrating over the entire rod yield

$$E_x = k\frac{q}{\ell}\int_{-\theta_{max}}^{+\theta_{max}}\frac{\cos\theta}{x}d\theta = \frac{kq}{\ell x}\int_{-\theta_{max}}^{+\theta_{max}}\cos\theta\, d\theta$$
$$= \frac{kq}{\ell x}\sin\theta\Big|_{-\theta_{max}}^{+\theta_{max}} = \frac{2kq}{\ell x}\sin\theta_{max},$$

where θ_{max}, the maximum value of θ, is the angle between the x axis and the line that connects the top end of the rod with P. Substituting $\sin\theta_{max} = y/r_{sP} = \frac{1}{2}\ell/\sqrt{(\ell/2)^2 + x^2}$ finally yields

$$E_x = \frac{kq}{x\sqrt{\ell^2/4 + x^2}};\ E_y = 0;\ E_z = 0. \checkmark$$

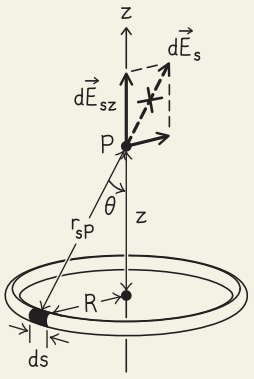
❹ **EVALUATE RESULT** Very far from the rod along the positive x axis, $x \ll \ell$, so the rod looks like a particle. In this case, I can ignore the ℓ^2 term in the denominator and my result becomes identical to Eq. 23.4, the equation for a particle that carries a charge q ($E = kq/r^2$, or using the symbols from this problem, $E_x = kq/x^2$).

When P is very close to the rod, $x \ll \ell$, I can ignore the x^2 term in the denominator and write

$$E_x = \frac{2k(q/\ell)}{x} = \frac{2k\lambda}{x}. \tag{5}$$

In this $x \ll \ell$ case, the distance from P to either end of the rod is much greater than the distance from P to the closest point on the rod (which is the rod midpoint, located at the origin), and thus the rod essentially looks "infinitely long" to an observer at P. Indeed, Eq. 5 shows that my result no longer depends on ℓ.

I also note that the rod's electric field is now inversely proportional to x rather than x^2. I saw in Chapter 17 that the amplitudes of waves that spread out in three dimensions are inversely proportional to x^2, whereas the amplitudes of waves that spread out in two dimensions are inversely proportional to x. My result therefore make sense because the electric field that emanates from a charged particle "spreads out" in three dimensions, but the field that emanates from an infinitely long charged rod spreads out in just two dimensions.



QUANTITATIVE TOOLS

EXAMPLE 23.5 Electric field created by a uniformly charged thin ring

A thin ring of radius R carries a uniformly distributed charge q. What is the electric field at point P along an axis that is perpendicular to the plane of the ring and passes through its center?

1 GETTING STARTED I begin by making a sketch of the situation. I let the ring be in the xy plane, with the origin at the center of the ring, and I place P on the positive z axis (**Figure 23.28**).

Figure 23.28

2 DEVISE PLAN Because the ring is thin, I can use Eq. 23.16 to determine its linear charge density. To determine the electric field at P, I divide the ring into a large number of infinitesimally small segments, each of arc length ds. Each segment contributes to the electric field an amount given by Eq. 23.14. Because all segments are at the same distance from P, all contribute an electric field $d\vec{E}_s$ of the same magnitude. As shown in my sketch, the contribution $d\vec{E}_s$ makes an angle θ with the z axis, and so each segment ds produces a component parallel to the z axis and a component perpendicular to it. For each pair of segments on opposite sides of the ring, the components of $d\vec{E}_s$ perpendicular to the z axis add up to zero, and so I am concerned only with the z components.

To get the electric field created by the ring, I can use Eq. 23.15 to integrate my $d\vec{E}_s$ result over the circumference of the ring.

3 EXECUTE PLAN Each segment carries a charge $dq_s = \lambda\, ds$, where $\lambda = q/2\pi R$ is the linear charge density along the ring. The magnitude of each segment's contribution to the electric field is, from Eq. 23.14,

$$dE_s = k\frac{dq_s}{r_{sP}^2} = k\frac{\lambda\, ds}{r_{sP}^2} = k\frac{\lambda\, ds}{z^2 + R^2}.$$

For the z component of $d\vec{E}_s$, I see from Figure 23.28 that the angle between the vectors $d\vec{E}_{sz}$ and $d\vec{E}_s$ is also θ, and so $\cos\theta = dE_{sz}/dE_s$. Then, combining this expression with the relationship

$$\cos\theta = \frac{z}{r_{sP}} = \frac{z}{\sqrt{z^2 + R^2}},$$

I have

$$dE_{sz} = \cos\theta\, dE_s = \left[\frac{z}{\sqrt{z^2 + R^2}}\right]\left[k\frac{\lambda\, ds}{z^2 + R^2}\right] = k\frac{z\lambda}{[z^2 + R^2]^{3/2}}ds.$$

To determine the electric field created by the ring, I must integrate the contributions around the ring, from $s = 0$ to $s = 2\pi R$. Because k, z, R, and λ are all independent of s, I can move everything out of the integral except ds:

$$E_z = \int dE_{sz} = k\frac{z\lambda}{[z^2 + R^2]^{3/2}}\int_0^{2\pi R} ds = k\frac{z\lambda(2\pi R)}{[z^2 + R^2]^{3/2}}.$$

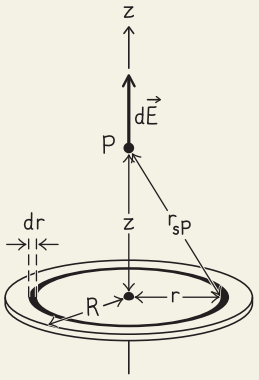
Because $\lambda = q/2\pi R$, the term $\lambda(2\pi R)$ is equal to the charge q on the ring, so I get for the z component of the electric field along the axis perpendicular to the plane of the ring and passing through the ring center

$$E_x = 0;\ E_y = 0;\ E_z = k\frac{qz}{[z^2 + R^2]^{3/2}}. \checkmark$$

4 EVALUATE RESULT Very far from the ring my expression for E_z should become the same as that for a charged particle. Indeed, when $z \gg R$, I can ignore the R^2 term in my result, and so

$$E_z \approx k\frac{qz}{[z^2]^{3/2}} = k\frac{qz}{z^3} = k\frac{q}{z^2},$$

as I expect.



At the center of the ring, $z = 0$ and so my expression yields $E_z = 0$. This result is reasonable because at the center of the ring the electric forces exerted by segments on opposite sides of the ring on a charged test particle add to zero. When the vector sum of these forces is zero, the electric field must be zero also.

EXAMPLE 23.6 Electric field created by a uniformly charged disk

A thin disk of radius R carries a uniformly distributed charge. The surface charge density on the disk is σ. What is the electric field at a point P along the perpendicular axis through the disk center?

1 GETTING STARTED I begin with a sketch, placing the disk in the xy plane, with the disk center at the origin. I let point P lie on the positive z axis (**Figure 23.29**).

Figure 23.29

2 DEVISE PLAN Because of the circular symmetry of the disk, I divide it into a large number of ring-shaped segments, each of radius r and width dr. The charge on each ring is the product of the ring surface area (circumference times width) and the surface charge density: $dq_s = (2\pi r)dr\,\sigma$. The

contribution of each ring to the electric field at P is given by the expression for E_z I obtained for a uniformly charged thin ring in Example 23.5 with $2\pi r\,\sigma\,dr$ substituted for q and r substituted for R. So all I need to do is integrate over the entire disk.

❸ **EXECUTE PLAN** Substituting $q = 2\pi r\,\sigma\,dr$ and $R = r$ into the Example 23.5 expression for E_z and integrating the result over the disk from $r = 0$ to $r = R$, I have

$$E_z = \int dE_z = k\int_0^R \frac{2\pi r\,\sigma z}{(z^2+r^2)^{3/2}}dr.$$

Because σ and z are independent of r, I can move them out of the integral:

$$E_x = 0;\ E_y = 0;$$

$$E_z = k\pi\sigma z\int_0^R \frac{2r\,dr}{(z^2+r^2)^{3/2}}$$

$$= k\pi\sigma z\int_0^R \frac{d(r^2)}{(z^2+r^2)^{3/2}} = k\pi\sigma z\frac{-2}{(z^2+r^2)^{1/2}}\Bigg|_0^R$$

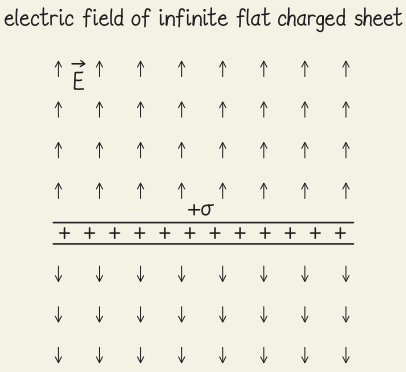
$$= 2k\pi\sigma z\left[\frac{1}{(z^2)^{1/2}} - \frac{1}{(z^2+R^2)^{1/2}}\right]. \checkmark \qquad (1)$$

❹ **EVALUATE RESULT** Let me evaluate my result for $z \gg R$, where, to an observer at P, the disk looks like a particle. For positive z, I can write the E_z in Eq. 1 as

$$E_z = 2k\pi\sigma\left[1 - \frac{z}{(z^2+R^2)^{1/2}}\right]. \qquad (2)$$

From the binomial series expansion (see Appendix B), I get in the case that $z \gg R$,

$$\frac{z}{(z^2+R^2)^{1/2}} = \left(1+\frac{R^2}{z^2}\right)^{-1/2} \approx 1 - \tfrac{1}{2}\frac{R^2}{z^2}.$$



Substituting this result into Eq. 2 and writing $q = \sigma(\pi R^2)$ for the charge on the disk, I get

$$E_z = 2k\pi\sigma\left(\tfrac{1}{2}\frac{R^2}{z^2}\right) = k\frac{\sigma\pi R^2}{z^2} = k\frac{q}{z^2},$$

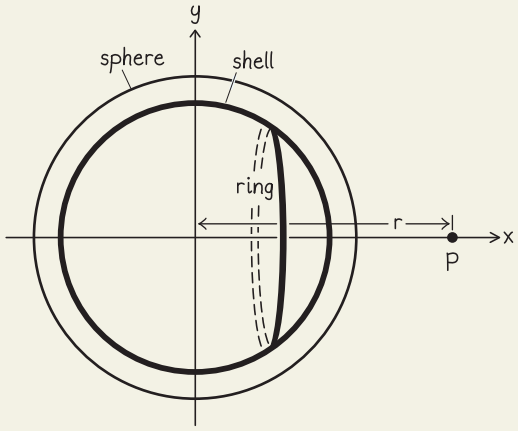
which is the result for a charged particle, as I expect.

I can also evaluate my result for $z \approx 0$, where, to an observer at that location, the disk looks like it has an infinite radius (that is to say, it looks like an infinite flat sheet). In that case, the second term inside the brackets in Eq. 2 is zero and $E_z = 2k\pi\sigma$. This tells me that the electric field of an infinite flat charged sheet is independent of z and constant throughout space, as I have sketched in **Figure 23.30**. (In other words, it is uniform.) While this lack of dependence on z is somewhat counterintuitive, it agrees with what I concluded earlier: The electric field that emanates from a charged particle "spreads out" in three dimensions and its amplitude is inversely proportional to the square of the distance from the particle, whereas the electric field that emanates from an infinitely long charged rod spreads out in just two dimensions and its amplitude is inversely proportional to the distance from the rod. As my sketch shows, the electric field that emanates from an infinite plane can't spread out at all (if the plane is truly infinite), and therefore its amplitude is independent of distance.

Figure 23.30

23.14 (a) Describe the electric field between two infinitely large parallel charged sheets if the charge density of one sheet is $+\sigma$ and that of the other is $-\sigma$. (*b*) Describe the electric field outside the sheets.

EXAMPLE 23.7 Electric field created by a uniformly charged sphere



A solid sphere of radius R carries a fixed, uniformly distributed charge q. Exploiting the analogy between Newton's law of gravity and Coulomb's law, use the result obtained in Section 13.8 to obtain an expression for the magnitude of the electric field created by the sphere at a point P outside the sphere.

❶ **GETTING STARTED** To determine the electric field magnitude at point P, I need to determine the magnitude of the electric force exerted by the sphere on a test particle carrying a charge q_t at P and then divide that force magnitude by q_t.

❷ **DEVISE PLAN** I can follow the same procedure as in Section 13.8 to calculate the gravitational force of a spherical object: I first divide the sphere into a series of thin concentric shells that resemble the layers in an onion and then

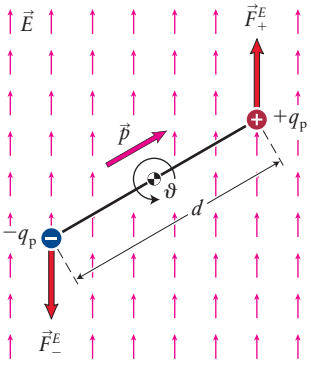
(Continued)

Figure 23.31

divide each shell into a series of vertical rings (**Figure 23.31**). I then calculate the contribution of each ring to the electric field at P and integrate first over each shell and then over the sphere. The expression I get for F^E_{sphere} must be of the same form as that for the gravitational sphere, F^G_{sphere} (Eq. 13.37), because the gravitational force and the electric force are both inversely proportional to the square of the distance between the interacting particles. So all I need to do is replace G in Eq. 13.37 by k, M_{sphere} by q, and m by q_t to obtain the magnitude of the electric force exerted by the sphere on the test particle. To obtain an expression for the electric field, I then divide the result by q_t.

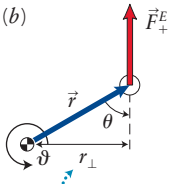
❸ **EXECUTE PLAN** In analogy to Eq. 13.37, I write

$$F^G_{\text{sp}} = G\frac{mM_{\text{sphere}}}{r^2} \rightarrow F^E_{\text{st}} = k\frac{q_t q}{r^2},$$



where r is the distance from the center of the sphere to P. To obtain the magnitude of the electric field, I divide the electric force by q_t:

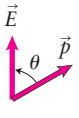
$$E_{\text{sphere}} = k\frac{q}{r^2}. \checkmark$$



❹ **EVALUATE RESULT** Comparing my result with Eq. 23.3 (in scalar form), $E_s = kq_s/r^2_{st}$, shows that outside a uniformly charged solid sphere the magnitude of the electric field is the same as that surrounding a particle carrying the same charge and located at the center of the sphere. The result is independent of the radius R of the sphere and similar to the result obtained in Section 13.8: A solid sphere exerts a gravitational force as if the entire mass of the sphere were concentrated at the center. It makes sense that I obtain a similar result for the charged sphere because the gravitational force and the electric force are both proportional to $1/r^2$.

Figure 23.32 The torque on an electric dipole caused by an electric field tends to align the dipole moment $\vec{p}$ with the direction of the electric field.

(*a*) Electric dipole in electric field



(*b*)

Lever arm $\vec{r}_\perp$ depends on angle θ of dipole with respect to electric field.

(*c*)

Torque on dipole is vector product $\Sigma\vec{\tau} = \vec{p} \times \vec{E}$.

23.15 How does the electric field inside a uniformly charged sphere vary with distance from the sphere center? [Hint: What is the electric field inside a hollow uniformly charged sphere?]

23.8 Dipoles in electric fields

Let us end this chapter by considering the forces exerted by electric fields on dipoles. **Figure 23.32*a*** shows a dipole consisting of two particles that carry charges of equal magnitude but opposite sign connected by a rod of length d; the dipole makes an angle θ with a uniform electric field $\vec{E}$ created by some unseen distant source. As we saw in Section 23.4, the forces exerted by the electric field on the charged ends of the dipole are equal in magnitude but opposite in direction, and so the vector sum of the forces exerted on the dipole is zero. Consequently the acceleration of the center of mass of the dipole is zero. Because the forces are exerted on opposite ends of the dipole, however, they create torques that cause the dipole to rotate counterclockwise about its center of mass. Figure 23.32*b* shows that the force exerted on the positive end causes a counterclockwise torque of magnitude

$$\tau_+ = r_\perp F^E_+ = \left(\tfrac{1}{2}d\sin\theta\right)(q_pE), \qquad (23.19)$$

where $r_\perp$ is the lever arm of the force. The force exerted on the negative end causes an identical torque because the lever arm and the magnitude of the force are the same. The electric field thus causes a torque on the dipole equal to

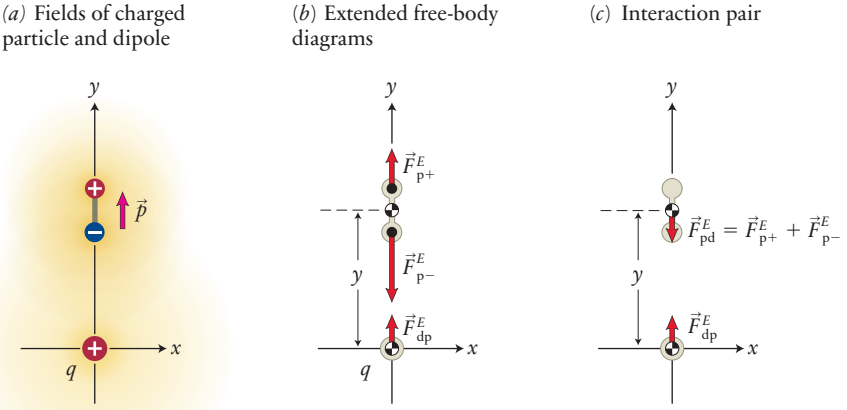
$$\Sigma\tau_\vartheta = 2\left(\tfrac{1}{2}d\sin\theta\right)(q_pE) = (q_pd)E\sin\theta \equiv pE\sin\theta. \qquad (23.20)$$

QUANTITATIVE TOOLS

This can be written in vectorial form as

$$\Sigma\vec{\tau} = \vec{p} \times \vec{E}, \tag{23.21}$$

where $\vec{p}$ is the dipole moment, which by definition points from the negative end of the dipole to the positive end and whose magnitude is given by Eq. 23.9. According to the right-hand rule (see Section 12.4), the vector product $\vec{p} \times \vec{E}$ in Eq. 23.21 gives a torque that points out of the plane of the drawing in Figure 23.32*c*. As we saw in Section 12.8, such a torque indeed causes a counterclockwise rotation. The torque on the dipole is maximum when the dipole moment is perpendicular to the electric field and zero when it is parallel or antiparallel to the electric field.



23.16 Is Eq. 23.20 valid if the center of mass is not halfway between the two charged ends of the dipole?

As we saw in Section 23.4, the vector sum of the forces exerted on dipoles in nonuniform electric fields is not zero. Consider, for example, the situation illustrated in **Figure 23.33*a***. A dipole with its dipole moment $\vec{p}$ aligned along the y axis is placed in the nonuniform electric field generated by a particle carrying a charge q and located at the origin. Because the distance between the negative end of the dipole and the particle is smaller than the distance between the positive end and the particle, the magnitude of the attractive force $\vec{F}^E_{p-}$ on the negative end is greater than the repulsive force $\vec{F}^E_{p+}$ on the positive end. Consequently the vector sum of the forces exerted by the nonuniform field on the dipole is nonzero, and the dipole is attracted to the particle. How does this attraction vary with the position y of the dipole?

To answer this question, we can write an expression for the vector sum of the forces $\Sigma\vec{F}^E_d$ exerted on the two ends of the dipole and examine how this sum varies with y. Alternatively, we can calculate the force $\vec{F}^E_{dp}$ exerted by the dipole on the particle, using our results from Section 23.6. This force and the vector sum of the forces exerted by the particle on the dipole form an interaction pair, and so their magnitudes are the same. Equation 23.13 tells us that, along the dipole axis, the magnitude of the electric field created by the dipole is $2k(p/y^3)$, and so the magnitude of the force exerted by the dipole on the particle is

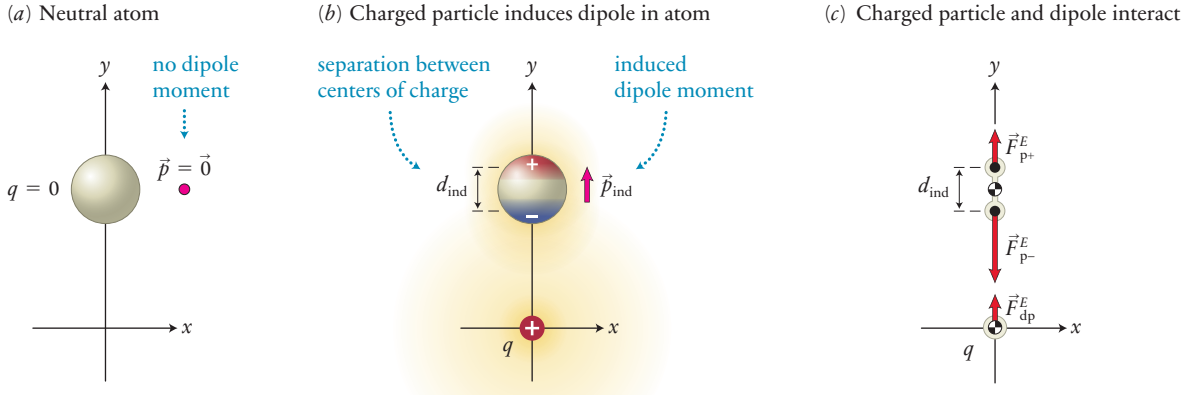
$$F^E_{dp} = qE_d = 2k\frac{pq}{y^3}. \tag{23.22}$$

Figure 23.33 A dipole interacts with a charged particle.

QUANTITATIVE TOOLS

The magnitude of the force exerted by the particle on the dipole, being equal in magnitude to F^E_{dp}, is thus

$$F^E_{pd} = F^E_{p-} - F^E_{p+} = 2k\frac{pq}{y^3}. \tag{23.23}$$



Like the electric field of a dipole, the forces between a charged object carrying charge q and a dipole is inversely proportional to the cube of the distance between them.

23.17 How does doubling each of the following quantities affect the force between a dipole and a particle placed near the dipole and carrying charge q: (*a*) the charge q, (*b*) the dipole separation d of the dipole, (*c*) the dipole charge q_p, (*d*) the distance between the dipole and the charged particle?

As we saw in Chapter 22, electrically neutral objects interact with a charged object because they become polarized in the presence of the charged object. Consider an isolated neutral atom. The centers of the atom's positive and negative charge distributions coincide, and therefore the atom's dipole moment is zero: $d = 0$ and so $\vec{p} = \vec{0}$ (**Figure 23.34*a***). The presence of an external electric field—that is, an electric field created by some other charged object—causes a separation between the positive and negative charge centers and so induces a dipole moment (Figure 23.34*b*). To understand the interaction between charged objects and neutral ones, we must therefore study the interaction between a charged particle and what is called an **induced dipole**. The first question to ask is: How does the magnitude of the induced dipole moment depend on the presence of a charged particle?

When a neutral atom is placed in an electric field $\vec{E}$, it is found that, as long as the electric forces exerted by that field on the charged particles in the atom are not too large, the induced dipole separation d_{ind} in the atom obeys Hooke's law. In other words, the induced dipole separation is proportional to the magnitude of the applied electric force, $F^E_d = cd_{ind}$, with c being the "spring constant" of the atom. We can rewrite this as $d_{ind} = (1/c)F^E_d$, and because d_{ind} is proportional to the magnitude of the induced dipole moment p_{ind} and the magnitude of the force exerted on the dipole is proportional to the magnitude E of the electric field at the

Figure 23.34 A charged particle induces a dipole in an electrically neutral atom.

position of the dipole, the **induced dipole moment** is proportional to the field at the position of the dipole:

$$\vec{p}_{\text{ind}} = \alpha\vec{E} \quad (E \text{ not too large}), \tag{23.24}$$

where α, the **polarizability** of the atom, is a constant that expresses how easily the charge distributions in the atom are displaced from each other. The SI unit of polarizability is $C^2 \cdot m/N$.

23.18 Given that the induced dipole moment $\vec{p}_{\text{ind}}$ points from the negative to the positive end of an induced dipole and the electric field $\vec{E}$ displaces the positive charge center in the direction of the electric field and the negative charge center in the opposite direction, do you expect the polarizability α to be positive or negative?

The electric field of a charged particle is given by Eq. 23.4, so the magnitude of the induced dipole moment is proportional to the inverse square of the distance between the particle and the dipole:

$$p_{\text{ind}} = \alpha E = \alpha\, k\frac{q}{y^2}. \tag{23.25}$$

In contrast, the dipole moment of a permanent dipole is constant.

We can now substitute the induced-dipole result of Eq. 23.25 into Eq. 23.23 to determine the force exerted by a charged particle on an induced dipole:

$$F^E_{\text{pd}} = 2k\frac{p_{\text{ind}}q}{y^3} = \alpha\frac{2k^2q^2}{y^5}. \tag{23.26}$$

This result shows that the interaction between a charged particle and a polarized object depends much more strongly on the distance between them $(1/y^5)$ than does the interaction between two charged objects $(1/y^2)$. You may have noticed this in Chapter 22 when comparing the attraction between two charged strips of tape with the attraction between a charged strip and a neutral object.* As the neutral object approaches the charged strip, the force varies so fast with distance that it is often difficult to prevent the tape from sticking to the neutral object.

23.19 (*a*) How does doubling the charge q_A carried by an object A affect the force exerted by A on another charged particle? (*b*) How does doubling q_A affect the force exerted by A on an induced dipole? (*c*) Explain why your answers to parts *a* and *b* are the same or different. (*d*) Can the force exerted by a charged particle cause a torque on an induced dipole?

*Try it! Pull two strips of transparent tape out of a dispenser, suspend one from the edge of a table and then move the other slowly toward it. Notice how the interaction between the strips varies relatively smoothly as a function of separation. Next, move your hand slowly toward the suspended strip and note how the force increases rapidly.

QUANTITATIVE TOOLS

Chapter Summary

Electric fields (Sections 23.1–23.3, 23.5)

Concepts In the field model of long-range interactions, interacting object A fills the space around itself with a **field** (or **interaction field**). When an object B is placed in this field, the field acts on B. If A and B have mass, the field is a *gravitational field;* if they are charge carriers, it is an *electric field*.

A **test particle** is one whose mass and/or charge is so small that the particle does not perturb the objects generating the field being measured.

The direction of the **electric field** at a given location is the same as the direction of the electric force exerted on a positive test particle at that location.

Quantitative Tools If a test particle located at position P and carrying charge q_t experiences a force $\vec{F}_t^E$, then the **electric field** $\vec{E}$ (N/C) at P is

$$\vec{E} \equiv \frac{\vec{F}_t^E}{q_t}. \tag{23.1}$$

If the source particle is at position $\vec{r}_s$ and carries charge q_s, the electric field it creates at any position P is

$$\vec{E}_s(\mathrm{P}) = k\frac{q_s}{r_{sP}^2}\hat{r}_{sP}, \tag{23.4}$$

where $\hat{r}_{sP}$ is a unit vector pointing from the source particle to P and $k = 9.0 \times 10^9\ \mathrm{N \cdot m^2/C^2}$.

Principle of **superposition of electric fields:** The combined electric field $\vec{E}$ created by a system of particles that carry charges $q_1, q_2, \ldots$ is

$$\vec{E} = \vec{E}_1 + \vec{E}_2 + \cdots = \Sigma k\frac{q_i\hat{r}_{iP}}{r_{iP}^2}. \tag{23.5}$$

Electric dipoles (Sections 23.4, 23.6, 23.8)

Concepts A *uniform electric field* has a constant magnitude and direction at all locations; a *nonuniform electric field* can vary in magnitude and/or direction from one location to another. A uniform electric field gives a charged particle a constant acceleration.

An **electric dipole** consists of equal quantities q_p of positive and negative charge separated by a small distance.

When an electrically neutral object is placed in an electric field, the field causes the object's positive and negative charge centers to separate, producing an **induced dipole.**

Quantitative Tools The **dipole moment** $\vec{p}$ (C · m) of a dipole is

$$\vec{p} \equiv q_p\vec{r}_p, \tag{23.9}$$

where $\vec{r}_p$ is the vector from the center of negative charge to the center of positive charge.

The torque $\Sigma\vec{\tau}$ produced on a dipole by a uniform electric field is

$$\Sigma\vec{\tau} = \vec{p} \times \vec{E}. \tag{23.21}$$

The **induced dipole moment** $\vec{p}_{ind}$ of a neutral atom placed in an external electric field that is not too large is

$$\vec{p}_{ind} = \alpha\vec{E}, \tag{23.24}$$

where α is the **polarizability** of the atom.

For positions far from an electric dipole, the electric field due to the dipole is inversely proportional to the cube of the distance r from the dipole. In particular, at distant points along the bisector axis (x axis)

$$E_y \approx -k\frac{p}{|x^3|}, \tag{23.10}$$

and at distant points along the dipole separation axis ($+y$ axis)

$$E_y \approx 2k\frac{p}{y^3}. \tag{23.13}$$

Electric fields of continuous charge distributions (Section 23.7)

Concepts **Charge density** can be linear (λ, C/m), over a surface area (σ, C/m^2), or throughout a volume (ρ, C/m^3).

Quantitative Tools The electric field due to a set of infinitesimal source particles of charge dq_s is

$$\vec{E} = k\int \frac{dq_s}{r_{sP}^2}\hat{r}_{sP}. \tag{23.15}$$

See the Procedure box on page 828.

Linear, *area*, and *volume charge densities* are

$$\lambda \equiv \frac{q}{\ell} \tag{23.16}$$

$$\sigma \equiv \frac{q}{A} \tag{23.17}$$

$$\rho \equiv \frac{q}{V}. \tag{23.18}$$

A uniformly charged rod of length ℓ carrying charge q oriented along the y axis and centered at the origin produces an electric field

$$E_x = \frac{kq}{x\sqrt{\ell^2/4 + x^2}}$$

along the x axis.

A uniformly charged ring of charge q and radius R oriented with the plane of the ring perpendicular to the z axis and the ring center at the origin produces an electric field

$$E_z = k\frac{qz}{(z^2 + R^2)^{3/2}}$$

along the z axis.

A uniformly charged disk of surface charge density σ and radius R oriented with the disk face perpendicular to the z axis and the disk center at the origin produces an electric field

$$E_z = 2k\pi\sigma\left[1 - \frac{z}{(z^2 + R^2)^{1/2}}\right]$$

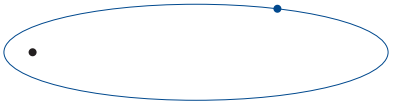
along the z axis.

Outside a solid sphere of radius R carrying a uniformly distributed charge q, the electric field produced by the sphere is

$$E_{\text{sphere}} = k\frac{q}{r^2},$$

where $r > R$ is the distance from the sphere's center. This field is the same as the field that would be produced if all the charge were concentrated at the sphere's center.

Questions and Problems



For instructor-assigned homework, go to Mastering Physics

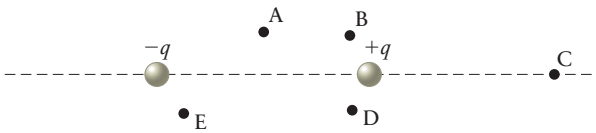
Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

23.1 The field model

1. Compare the magnitudes of the gravitational field that earth feels due to the Sun and the Moon. •
2. Determine the magnitude of Earth's gravitational field for (*a*) a 70.0-kg person standing at Earth's surface, (*b*) a 700.0-kg satellite in orbit 150 km above Earth's surface, and (*c*) the Moon (use 3.844×10^8 m for the center-to-center distance between Earth and the Moon). •
3. Sketch the gravitational field at 15 positions uniformly distributed along the comet orbit in Figure P23.3. ••

Figure P23.3

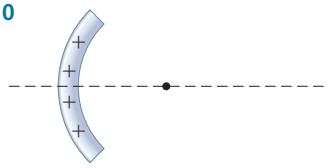
4. Suppose there is an electric field pointing horizontally toward the east at some location near Earth's surface. Does it make sense to add the gravitational and electric *fields* to determine the behavior of a proton at that location? ••



23.2 Electric field diagrams

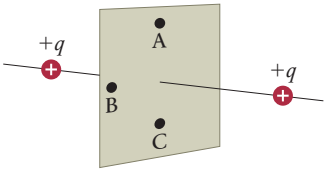
5. The units of the gravitational field are those of acceleration. Is that true of the electric field as well? If not, why not? •
6. Assume an electron is fixed at the origin of a rectangular Cartesian coordinate system. Calculate the magnitude of the electric field at 15 mm on the positive *x*-axis. •
7. The dwarf planet Pluto and its moon Charon have very similar masses. Suppose the masses are equal, and draw a gravitational field diagram for this system of two source objects. ••
8. Draw a vector field diagram for particles carrying charges $+2q$ and $-q$ separated by a distance r. Comment on the significance of the vector diagram. ••

23.3 Superposition of electric fields



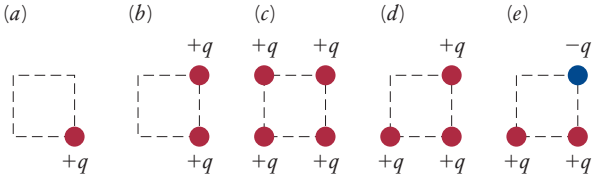
9. The two Ping-Pong balls in Figure P23.9 carry charges that have the same magnitude but opposite signs. Sketch the vectors that represent the electric fields the balls produce at locations A, B, C, D, and E, which all lie in a common plane that includes the line joining the centers of the balls. Use a ruler to estimate that relative distances between locations. •

Figure P23.9



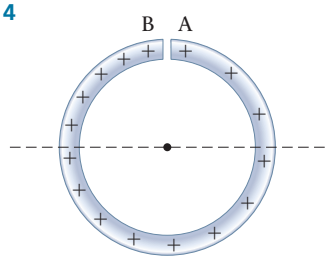
10. Positive charge is distributed uniformly on a plastic rod bent to form a quarter-circular arc (Figure P23.10). What is the direction of the electric field at the center of the circle? •

Figure P23.10



11. Repeat Problem 9 for the case where the positive charge in Figure P23.9 remains $+q$ but the negative charge is changed to $-2q$. ••
12. The two particles in Figure P23.12 carry identical charges. Sketch the vectors that represent the electric fields the particles produce at locations A, B, and C, which all lie in the plane that is midway between the two particles and perpendicular to the line connecting them. ••

Figure P23.12



13. Charged beads are placed at the corners of a square in the various configurations shown in Figure P23.13. Each red bead carries a charge $+q$, and the blue bead carries a charge $-q$. Rank the configurations according to the magnitude of the electric field at the center of the square, smallest magnitude first. ••

Figure P23.13

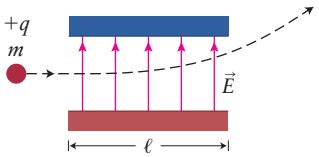
14. The charge on a nonconducting rod increases linearly from end A to end B. The rod is bent in a circle so that ends A and B almost meet very near the top of the circle (Figure P23.14). What is the direction of the electric field at the center of the circle? (Hint: Consider contributions from diametrically opposite segments!) •••

Figure P23.14

23.4 Electric fields and forces

15. The Burj Khalifa in Dubai has 163 floors. Compare the gravitational field in a room on the ground floor and one on the 163rd floor. •
16. A positively charged test particle is placed midway between two fixed, identical positively charged source particles. (*a*) Is the test particle in a stable or unstable equilibrium at that location? (*b*) If the test particle is replaced by a negatively charged test particle, is it in a stable or unstable equilibrium at that location? •
17. A box full of charged plastic balls sits on a table. The electric force exerted on a ball near one upper corner of the box has components 1.2×10^{-3} N directed north, 5.7×10^{-4} N directed east, and 2.2×10^{-4} N directed vertically upward. The charge on this ball is 120 nC. If this ball were replaced with one that has a charge of −50 nC, what would be the force components exerted on the replacement ball? ••
18. An electron traveling horizontally east passes between two horizontal, oppositely charged plates and is deflected downward. Passing through the same space between the plates, in which direction (if any) would each of the following be deflected: (*a*) a proton traveling horizontally east, (*b*) an electron traveling horizontally west, (*c*) a proton traveling horizontally west, and (*d*) a proton traveling horizontally north? ••
19. A 10.0-mg oil drop carrying a charge of +15 μC passes undeflected through a region in which there is a uniform, constant electric field. What is the magnitude and direction of the electric field? ••
20. Each dipole in Figure P23.20 is free to rotate about an axis that is perpendicular to the plane of the page (represented by the dot in the center of each dipole). The dipoles are initially held fixed in a horizontal line as shown but are then released and begin rotating. What is their most likely final orientation if there is a mechanism for energy dissipation? ••

Figure P23.20



21. Suppose two plates lie in parallel horizontal planes, one plate in the *xy* plane at $z = 0$ and the other plate in the plane that is parallel to the *xy* plane at $z = 10$ mm. Between the plates is a constant electric field directed vertically upward (that is, in the positive *z* direction). A proton and an electron are launched in the positive *x* direction with the same initial velocity from position (0, 0, 5.0 mm). If the proton strikes a plate at (200 mm, 0, 10 mm), where does the electron strike? •••

23.5 Electric field of a charged particle

22. Two uniformly charged pellets A and B are held some distance from each other, and then the charge on A is doubled. Which of the following statements is most correct? (*a*) The magnitude of the electric force exerted on A is doubled because the electric field at the position of A is doubled. (*b*) The magnitude of the electric force exerted on A is doubled because the electric field at the position of B is doubled. (*c*) The magnitude of the electric force exerted on B is doubled because the electric field at the position of B is doubled. •
23. What is the magnitude the net force on an electron when placed at the electric field at a distance of 100 mm produced by 5 μC of charge? •
24. A small, charged, spherical object at the origin of a Cartesian coordinate system contains 3.30×10^4 more electrons than protons. Find the magnitude and direction of the electric field at a point that is 3 mm away from the origin. •
25. Consider a hydrogen atom. The Bohr radius of hydrogen atom is 0.529×10^{-8} cm. Calculate the electric field halfway between the electron and the proton. •
26. A positively charged particle initially at rest on the ground moves 4.0 m upward in 2.00 s. If the particle has a charge-to-mass ratio of 10 μC/g and the electric field in this region is constant and uniform, what is the magnitude and direction of the electric field? ••
27. A particle, carrying a positive charge of 4 nC, located at (5cm, 0) on the *x*-axis experiences an attractive force of magnitude 115.2 N due to an unknown charge *q* located at the origin. (*a*) Determine the value of *q*. (*b*) Using the relationship between electric field and electric force and the result from part (*a*), determine the magnitude and direction of the electric field due to the charge *q* at a point located 20 cm away from the 4-nC charge in a direction perpendicular to the line between the two charges. ••
28. A particle at the origin of a Cartesian coordinate system carries a charge of 5.0×10^{-9} C. What are the magnitude and direction of the electric field at (*a*) (4.00 mm, 0), (*b*) (0, 4.00 mm), and (*c*) (−3.00 mm, 4.00 mm)? ••
29. (*a*) Plot the value of the radial component of the electric field due to a positively charged pellet as a function of distance from the pellet center. (*b*) Repeat for a negatively charged pellet. Take each pellet to be a uniformly charged nonconducting sphere having a radius of 18.5 mm and carrying a charge of 1.11 nC. ••
30. A rubber flying ring having a diameter of 20 cm is fixed to the *xy*-plane of the Cartesian coordinate system such that its geometric center lies on the origin. The ring is uniformly charged with +10 μC. (*a*) What is the magnitude of the electric field at 10 cm on the z-axis? (*b*) What is the magnitude of the electric field at the origin? ••
31. A small sphere carrying 6.0 nC of charge is placed 100 mm from a small sphere carrying 3.0 nC of charge. Assume the spheres are tiny relative to the 100-mm separation distance. At what position on the line joining the spheres is the electric field magnitude zero? ••
32. Two beads, one carrying charge +*q* and the other carrying charge +4*q*, are separated by a distance *d* that is much greater than the radius of each bead. (*a*) Is there any location along the line between them where the electric field magnitude is zero? If so, what is that location in terms of *d*? (*b*) Is there any other position where the electric field magnitude is zero? ••
33. In an inkjet printer, tiny drops of ink of inertia *m* are given a charge *q* and then fired toward the paper at speed *v*. They first pass between two charged plates of length ℓ that create a uniform electric field of magnitude *E* between

them (Figure P23.33). The field direction is perpendicular to the plates and to the initial path of the drops. The electric field deflects each drop from its initial horizontal path and is used to control what is printed on the paper. (*a*) Derive an expression for how far in the vertical direction a drop is deflected as it passes between the plates. (*b*) For a drop inertia of 1.5×10^{-10} kg, an electric field strength of 1.2×10^{6} N/C, a plate length of 10 mm, and a drop speed of 20 m/s, calculate the drop charge necessary to result in a deflection of 1.3 mm. (*c*) Is it acceptable to ignore the effects of gravity in this case? ••

Figure P23.33

34. (*a*) What electric field magnitude is needed to balance the gravitational force exerted by Earth on an electron near Earth's surface? (*b*) Relative to the electron's position, where would you have to place a proton in order to create an equivalent electric force on the electron? ••

35. Consider a rectangle with diagonal length $2a$ in the yz plane with the origin at the center of the rectangle. Four beads, each carrying charge q, are placed on the rectangle perimeter, one bead at each corner. Show that the electric field along the x axis is given by

$$E_x = k\left(\frac{4qx}{(x^2 + a^2)^{3/2}}\right)\hat{\imath}. \text{ ••}$$

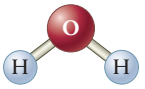
36. A particle carrying a charge of 6.0 μC is located at the origin of a rectangular coordinate system, and a particle carrying a charge of 4.0 μC is located at (0, 5.0 m). What are the magnitude and direction of the electric field at the positions (*a*) (5.0 m, 0), (*b*) (−5.0 m, 0), and (*c*) (0, −5.0 m)? ••

37. Five charged particles are located around a semicircular arc of radius 100 mm, with one particle at each end of the semicircle and the remaining three spaced equally between the two ends. The semicircle lies in the region $x < 0$ of an xy plane, such that the complete circle is centered on the origin. (*a*) If each particle carries a charge of 1.00 nC, what is the electric field at the origin? (*b*) Where could you put a single particle carrying a charge of −5.00 nC to make the electric field magnitude zero at the origin? ••

38. A positively charged particle 1 is at the origin of a Cartesian coordinate system, and there are no other charged objects nearby. You need the electric field magnitude at the position (3.00 nm, 4.00 nm) to be zero, so that no electric force is exerted on any charged object placed at that location. (*a*) Make a plot of all positions where a single additional charged particle 2 (of arbitrary charge) could be placed to make the electric field magnitude zero at (3.00 nm, 4.00 nm). Explain some of the key points of your graph. (*b*) Where would you need to place particle 2 if it carried the same charge as particle 1? ••

39. Three particles carrying equal positive charge q are located at the corners of an equilateral triangle with side length a. What are the magnitude and direction of the electric field (*a*) at the center of the triangle, (*b*) at the midpoint of any side of the triangle, and (*c*) a distance a above the triangle apex? •••

40. Two nonconducting spheres 1 and 2 carry the same charge, and the magnitude of the electric force exerted by each sphere on the other is 0.10 N when they are 50 mm apart. (*a*) What is the magnitude of the charge on each sphere, assuming each has a diameter much smaller than 10 mm? (*b*) What is the magnitude of the electric field 50 mm directly above sphere 1 if sphere 2 is located to the left of sphere 1? (*c*) Would your answers change if each sphere had a radius of 10 mm? •••



41. Three particles carrying charges $2q$, q, and $-3q$ are located at the vertices of an equilateral triangle on the xy-plane. Particles 1 and 2 are located symmetrically on the x-axis and particle 3 is located on the positive y-axis. Find the direction of the electric field at the center of the triangle. (Hint: You need to use only ratios and geometrical considerations.) •••

42. In table salt—sodium chloride, NaCl—the Na^+ and Cl^- ions are arranged in a cubic crystal structure. You can observe in this structure a cube made up of eight ions: four Na^+ and four Cl^- in alternating corners. Each Na^+ has a radius of 99 pm, each Cl^- has a radius of 181 pm, and the ions are spaced as though they were solid balls of these sizes, touching their neighbors. (*a*) For a single cube of this arrangement, what are the magnitude and direction of the electric field at one of the Na^+ ions due to the other seven ions in the cube? (*b*) What are the magnitude and direction of the vector sum of the electric forces exerted on this Na^+ ion by the other seven ions? •••

23.6 Dipole field

43. A water molecule (Figure P23.43) has a dipole moment of 6.19×10^{-30} C·m. If the O–H bonds were ionic bonds (in reality they are polar covalent bonds), the electrons from the two hydrogen atoms would be completely transferred to the oxygen atom. Using the measured dipole moment and the fact that the centers of positive and negative charge are 0.058 nm apart, can you rule out the hypothesis that the O–H bonds are ionic? •

Figure P23.43

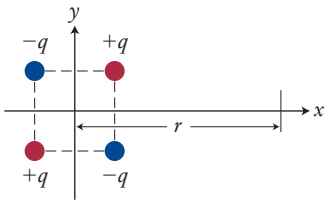
44. Two balls of identical size (ball 1 made up of nylon and ball 2 made up of rubber) were rubbed against each other so that they carry a uniformly distributed charge of magnitude 0.25 nC. After charging, the two balls were stuck to the end of a 15 cm scale. In that situation, calculate the dipole moment of the arrangement. •

45. As Figure P23.43 shows, the water molecule is bent, and the angle formed by the three atoms is 104.5°. Given that the permanent dipole moment of the molecule is 6.186×10^{-30} C·m, determine the dipole moment of each O–H bond. ••

46. A proton located several proton diameters away from a small charged object carrying charge q is subject to an

electric field of magnitude E. As the proton moves a distance d along the x axis away from the object, the electric field magnitude drops to $E/4$. If the charged object had instead been an electric dipole (with a charge of magnitude q on each end) oriented in the z direction, by what factor would the initial electric field magnitude E have dropped as the proton receded by distance d along the x axis? ••

47. Two ping pong balls, 1 and 2, are charged uniformly such that ball 1 gets 0.5 nC charge and ball 2 gets −0.5 nC charge. Calculate the ratio of the magnitudes of the dipole moments produced if they were stuck to the opposite ends of the two sticks of length 200 mm and 400 mm. ••



48. Equation 23.12,

$$E_y = k\frac{q_p}{y^2}\left[\left(1-\frac{d}{2y}\right)^{-2}-\left(1+\frac{d}{2y}\right)^{-2}\right],$$

was derived for the case $y > d/2$. Explain why this equation holds for the case $y < -d/2$. ••

49. An electric *quadrupole* can be constructed by placing four charged objects at the corners of a square (Figure P23.49). The objects are identical except for the charge they carry: The two objects in one diagonally opposed pair each carry charge $+q$, and the other two objects carry charge $-q$. (Note that there is no charge on the quadrupole overall and that the combination of four charges has no dipole moment.) How does the magnitude of the electric field depend on the distance r from the center of the quadrupole? Take the side length for the square to be d and assume $r \gg d$. ••

Figure P23.49

50. A dipole is centered at the origin of a coordinate system, and a small charged sphere is some distance away along the perpendicular bisector of the dipole. The particle carries a uniformly distributed charge of −3.0 nC, and experiences a 200 nN electric force in the positive y direction. (*a*) If the dipole charge is 10 nC and the dipole separation is 20 mm, how far away from the dipole is the sphere? (*b*) How is the dipole moment oriented? ••

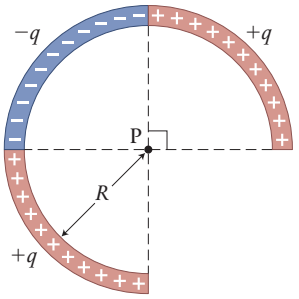
51. Two thin plastic rods, each of length ℓ, are joined end to end. One rod is positively charged with a uniform linear charge density λ, and the other carries a negative charge density $-\lambda$. What is the effective dipole moment of the rod? ••

52. An electric dipole that has dipole separation d is aligned along the y axis of an xy coordinate system, pointed in the positive y direction. (*a*) Show that for x and y much greater than d, the x and y components of the electric field of the dipole are given by

$$E_x = \frac{3kpxy}{(x^2+y^2)^{5/2}};\quad E_y = \frac{kp(2y^2-x^2)}{(x^2+y^2)^{5/2}}.$$

(*b*) Show that this general result includes the special results derived in Section 23.6. •••

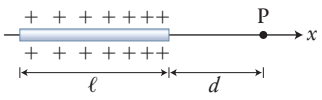
23.7 Electric fields of continuous charge distributions



53. You've been given the task of charging a spherical weather balloon made of a conducting material, and you want to put as much charge on it as possible. An experienced colleague advises you that the air surrounding the balloon becomes conducting when the electric field at the balloon surface reaches 100,000 N/C, causing a spark that discharges the balloon. Because the balloon must stay charged, you cannot allow this air breakdown to occur. By measuring the balloon's shadow, you calculate the balloon diameter to be 3.5 m. This gives you enough information to estimate the maximum charge the balloon can have without causing air breakdown. •

54. A positively charged particle is released from rest along the axis of symmetry of a fixed ring carrying a uniformly distributed negative charge. Describe the motion of the particle. •

55. A 20-cm-long rod, with uniform linear charge density 100 nC/cm, is set up symmetrically on the x axis. What are the magnitude and direction of the electric field at a point located at a distance of 5cm on the perpendicular bisector of the rod in the xy-plane? •



56. In the uniform charge distribution shown in Figure P23.56, each of the three arcs forms one-fourth of the circumference of a ring. The upper right and lower left arcs each carry a positive charge q, while the upper left arc carries a charge $-q$. Determine the electric field at P, the ring center, in terms of q and R. ••

Figure P23.56

57. The thin glass rod of length ℓ in Figure P23.57 has a linear charge density that starts out as zero at the left end of the rod and increases linearly from left to right. The positive charge on the rod is q_{rod}. (*a*) What is the electric field along the rod's axis at position P, which lies a distance d from the right end of the rod? (*b*) What is the approximate expression for the magnitude of the electric field at distances $d \gg \ell$—that is, far enough away to make the rod look small? ••

Figure P23.57

58. You have two disks, 1 and 2, both of radius $R = 25.0$ mm and both made of the same nonconducting material. Disk 1 carries a uniformly distributed charge $q_1 = 1.50\ \mu$C, and the uniformly distributed charge q_2 on disk 2 is unknown. You place disk 1 at $z_1 = 0$ and disk 2 at $z_2 = +32.0$ mm such that the symmetry axis of each disk coincides with the z axis. Using a small charged pith ball, you locate one position on the z axis where the electric force exerted on the pith ball is zero; this position is $z_{E=0} = +88.0$ mm. What is the charge on disk 2? ••

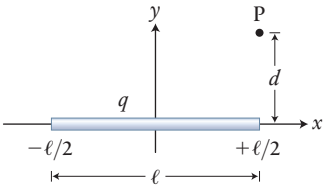
59. What percentage error in the electric field magnitude do you introduce by approximating the charged disk of Figure 23.29 as an infinite charged sheet with the same surface charge density for (*a*) $z = 0.1R$, (*b*) $z = 0.5R$, and (*c*) $z = R$? ••

60. You wish to determine the electric field magnitude along the perpendicular bisector of a 250-mm line along which 30 nC of charge is distributed uniformly. You want to get by with a minimal amount of work, so you need to know when it is sufficient to approximate the line of charge as a charged particle. At what distance along the perpendicular bisector does your error in E reach 5% when you use this approximation? ••

61. For a uniformly charged disk of radius 90 mm, you wish to determine the electric field magnitude along the axis that runs through the disk center and perpendicular to the disk face. You want to get by with a minimal amount of work, so you need to know when you can get by with approximating the disk as an infinite sheet. At what distance along the perpendicular axis does your error in E reach 10% when you use this approximation? ••

62. Three narrow concentric rings of radii 50 mm, 70 mm, and 90 mm are centered about the origin, with the axis of symmetry of each ring oriented along the y axis. The charge on the inner ring is 1.0 μC, that on the middle ring is $-2.0\ \mu$C, and that on the outer ring is 1.0 μC. (*a*) What is the electric field magnitude at (0, 100 mm, 0)? (*b*) What quantity of charge must be placed at (0, −100 mm, 0) to make the electric field magnitude zero at the position calculated in part *a*? ••

63. Two large oppositely and uniformly charged parallel plates are held 10 mm apart. An electron is projected halfway between the plates and parallel to them with an initial speed of 5×10^6 m/s. The electron hits the top plate 35 mm from where it was projected. (*a*) Which plate is negatively charged? (*b*) What are the surface charge densities on the plates? ••



64. A particle of inertia m that carries charge q is held above an infinite sheet on which the surface charge density is σ. The charge on the sheet is of the same type as the charge on the particle. The particle is then released from rest. (*a*) Describe its motion. (*b*) What is its acceleration? (*c*) What is the change in its kinetic energy after it has traveled a distance s? ••

65. A uniformly charged thin rod lies along the x axis from $x = 0$ to $x = +\infty$. (*a*) Derive an expression for the component E_y of the electric field in the positive y direction, and (*b*) show that the electric field at all positions on this axis makes an angle of 135° with the rod. •••

66. One half of a charged thin ring of radius R carries a charge q_1 uniformly distributed over it, and the other half of the ring carries a charge q_2 uniformly distributed over it. For any position along the axis of symmetry of the ring, derive an expression for (*a*) the component of the electric field parallel to the axis and (*b*) the component of the electric field perpendicular to the axis. •••

67. In Figure P23.67, determine the x and y components of the electric field at position P, which is a distance d above one end of a rod of length ℓ carrying uniformly distributed charge q. •••

Figure P23.67

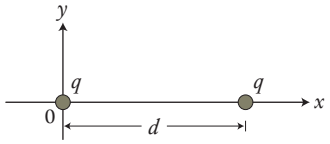
68. A thin rod of length 2ℓ has a linear charge density that is λ_0 at the left end but decreases linearly with distance going from left to right in such a way that the charge on the entire rod is zero. (*a*) What is the magnitude of the electric field along the rod's axis at a position P that is a distance $d > \ell$ to the right of the center of the rod? (*b*) Does your expression simplify to a familiar result for the limiting case $d \gg \ell$? (Hint: The dipole moment of the rod has magnitude $p = 2\lambda_0\ell^2/3$.) •••

69. You place 2.2 μC of charge along a long nonconducting rod. The rod extends from $x = 0$ farther than you can see along the positive x axis. The charge distribution has the form of a decreasing exponential: $q(x) = q_0 e^{-x/\ell}$, where $\ell = 28.6$ mm. Calculate the electric field magnitude 20 mm from the near end of the rod, along its long axis. •••

23.8 Dipoles in electric fields

70. The water molecule is a permanent dipole with a dipole moment of 6.186×10^{-30} C·m. If a single water molecule were oriented such that its dipole moment is along the z axis, what torque is caused on it by the electric force due to an 8500-N/C electric field if that field is in the xz plane and directed 42° above the x axis? •

71. A microwave oven, which fills the oven chamber with oscillating electric fields, works well at heating food that has a high water content. However, it does not work well with frozen food or with food that has a high oil content but low water content. Can you think of a reason for this? (Hint: Water molecules in ice are much more rigidly constrained than they are in liquid, and oil molecules are nonpolar.) •



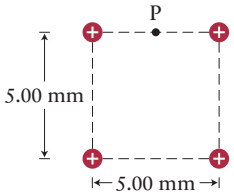
72. The electric force due to a uniform external electric field causes a torque of 8×10^{-9} N·m on an electric dipole oriented at 45° from the direction of the external field. The dipole moment of the dipole is 4.0×10^{-12} C·m. (*a*) What is the magnitude of the external electric field? (*b*) If the two particles that make up the dipole are 5 mm apart, what is the charge on each particle? •

73. Among copper and gold, whose polarizability is higher? Justify your answer. •
74. Two oppositely charged identical metallic spheres, each having a mass of 4 g, lie on a horizontal plane, joined by a tiny insulating rod of length 2 cm. The magnitude of the charge on each sphere is 3 μC. The rod is parallel to a uniform electric field of magnitude 1500 N/C. Calculate the angular frequency ω of small oscillations about the equilibrium orientation. ••
75. A dipole that is free to move is placed near a fixed dipole, with the midpoint of the free dipole on the perpendicular bisector of the fixed dipole. The distance from the free dipole to the fixed one is much greater than the dipole separation d of the fixed dipole. Draw a diagram to illustrate the motion of the free dipole if it is placed with its dipole moment (*a*) in the same direction as the direction of $\vec{p}_{\text{fixed}}$, the dipole moment of the fixed dipole, (*b*) in the direction opposite that of $\vec{p}_{\text{fixed}}$, and (*c*) perpendicular to the direction of $\vec{p}_{\text{fixed}}$. ••
76. In a particular region of space, an electric field has a constant direction but its magnitude increases smoothly along that direction. A dipole is placed in this field, its dipole moment is oriented perpendicular to the field, and it is released from rest. If no dissipative forces are present, describe the dipole's motion, paying particular attention to how it differs from what the motion would be if the electric field were uniform. ••
77. A particle carrying 5.0×10^{-7} C of charge is located on the perpendicular bisector of a small dipole, 300 mm from the center of the line joining the two poles of the dipole. The magnitude of the electric force exerted on the particle is 10.0×10^{-6} N. Draw a diagram showing the dipole and indicating the direction of its dipole moment. On this diagram, show (*a*) the direction of the electric force exerted on the particle and (*b*) the direction of the electric force exerted on the dipole. (*c*) Determine the magnitude of the electric force exerted on the dipole. ••
78. There are two possible alignments of a dipole in an external electric field where the dipole is in equilibrium. (*a*) Draw a field diagram for a uniform electric field and show these two alignments. (*b*) Are both alignments stable? (Consider what would happen in each case if you gave the dipole a slight twist.) (*c*) Based on your answer to part *b* and your experience in mechanics, in which orientation does the dipole have less potential energy? ••
79. In very rare cases, the polarizability of a molecule may be negative. (*a*) Draw a picture showing the resultant charge distribution when such a molecule is placed in the electric field surrounding a positively charged particle. (*b*) Describe the motion of the molecule that would result. ••
80. Two identical particles, each carrying charge q, are a distance r apart. A dipole for which the dipole moment magnitude is p and the dipole separation is $d < r$ is placed on the (imaginary) line joining the two particles in such a way that the center of the dipole coincides with the center of the line joining the two particles. Determine the electric force exerted on the dipole. (Hint: You may wish to use a Taylor series expansion to determine the small difference in the electric forces exerted on the two poles of the dipole.) •••
81. An electrically neutral molecule is collinear with (and located between) two charged particles, one carrying a charge of +3.56 μC and the other carrying a charge of −1.05 μC. The center of the molecule is 2.57 μm from each particle. If the vector sum of the electric forces exerted on the molecule is 45.0 nN, what is the polarizability of the molecule? •••

Additional Problems

82. A plastic flying disc with radius 25 cm is uniformly charged with $\sigma = 8$ nC/m^2. Find the magnitude of the electric field at 30 m on the axial position. •
83. Four particles are located at the corners of a square that is 50 mm on a side. All four particles carry a charge of magnitude 3.0 nC, with positive charge at the lower left corner and negative charge at the other corners. Draw the electric field vectors at the center of the square caused by each of the four source charges, then determine the magnitude and direction of the electric field at the center of the square. •
84. A charge of 2.86 μC is uniformly distributed within a rubber ball having radius 5.6 cm. Calculate the electric field at 10 cm from the center of the rubber ball. •
85. Each of the two particles in Figure P23.85 carries a charge of magnitude q. Determine a position, if one exists, where the electric field magnitude is zero if the charge (*a*) is of the same type on the two particles and (*b*) is positive on one particle and negative on the other. •

Figure P23.85



86. Two uniformly charged plates carrying opposite charges are separated by a distance of 20 mm. The magnitude of the charge density on each plate is 3×10^{-8} C/m^2. An electron is launched with a speed of 2.1×10^6 m/s halfway between the two plates. (*a*) How far does the electron travel before it hits one of the plates? (*b*) What speed does the electron attain before it hits a plate? ••
87. An electrically neutral, linear, polar molecule has positive charge equivalent to the charge on one proton centered 0.30 nm from its center of mass and an equal quantity of negative charge centered 0.10 nm from its center of mass (opposite the positive charge). The two charge centers are collinear with the molecule's center of mass. In an electric field of magnitude 100.0 N/C, what are (*a*) the greatest possible and (*b*) the smallest possible torque experienced by this molecule? ••
88. You have a pair of objects that interact with each other electrically. The objects initially are separated by a distance r and exert a force of magnitude F^{E} on each other. If the separation is increased to $2r$, calculate the new force magnitude between the objects if they are (*a*) charged particles, (*b*) permanent dipoles with their separation along their dipole axis, (*c*) permanent dipoles

with their separation perpendicular to their dipole axis, (*d*) a charged particle and a permanent dipole with the dipole pointing directly away from the charged particle, (*e*) a charged particle and an induced dipole. ••

89. Two infinitely wide charged plates carry opposite charge densities of magnitude $1.77 \times 10^{-6}\ \text{C/m}^2$. A small sphere, of mass m = 2 g, lies between the plates, attached to the positive charged plate by means of an inextensible insulating wire of negligible mass. At equilibrium, the wire forms an angle of 30° with respect to the positively charged plate. Find the magnitude of the charge on the sphere. ••

90. Figure P23.90 shows four charged particles, each having a charge equal to +3.00 μC, arranged in a square. What are the magnitude and direction of the electric field at P, located midway between the top two particles? ••

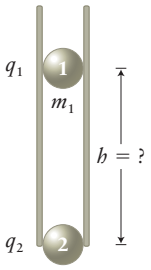


Figure P23.90

91. A uniformly charged rod extends from $y = -150$ mm to $y = +150$ mm along the y axis of an xy coordinate system. The charge on the rod is 30 nC. (*a*) With the goal of eventually calculating the electric field magnitude along the rod's perpendicular bisector, approximate the rod as three charged particles, and draw a picture showing the locations of the three particles you will use for the calculation and the magnitude of the charge on each one. (*b*) What is the electric field magnitude at $x = 200$ mm using this approximation? (*c*) What is the error in your result in part *b*? (*d*) If you were unable to integrate, what could you do to your approximation to make it better? ••

92. A small sphere 1 carrying charge q_1 and having inertia m_1 is constrained to moving inside a narrow vertical tube (Figure P23.92). Fixed at the bottom of the tube is a small sphere 2 carrying charge q_2. (*a*) Determine the equilibrium height h for sphere 1 (ignore friction). (*b*) Show that if sphere 1 is displaced from this equilibrium position by a small amount and then released, it moves in simple harmonic motion with angular frequency $\omega = (2g/h)^{1/2}$. •••

Figure P23.92

93. Your boss is designing a new data storage system that will have a lot of dipoles very close to one another. They will point in the z direction and be closely spaced in the x and y directions. The data reader will detect E_z as it passes some small distance above the sheet of dipoles. You know that Equation 23.13 is valid only for large distances from the dipole, but it is much easier to apply than the exact result. You prefer the easiest calculation possible, but your boss demands 1.00% accuracy at distances only a few dipole separations from one of the source dipoles. ••• CR

94. You are designing a new guidance mechanism for an inkjet printer. You believe that a circular arc of charge, mounted in the xy plane, is needed in order to deflect the ink droplets most efficiently from their original path along the z axis. You want to use a uniformly charged arc of arc length s that subtends an angle 2θ along a circle of radius R through whose center the ink droplets will pass. The amount of charge that can easily be transferred to the arc is q, which limits the magnitude of the electric field that can be attained at the center of the circle. ••• CR

95. A rod of length πR is composed of three nonconducting segments of equal length. The middle segment is electrically neutral, and each end segment carries a uniformly distributed negative charge $-q$. The rod is bent into a semicircle of radius R. Determine the magnitude of the electric field at the center of the semicircular arc. •••

CONCEPTS

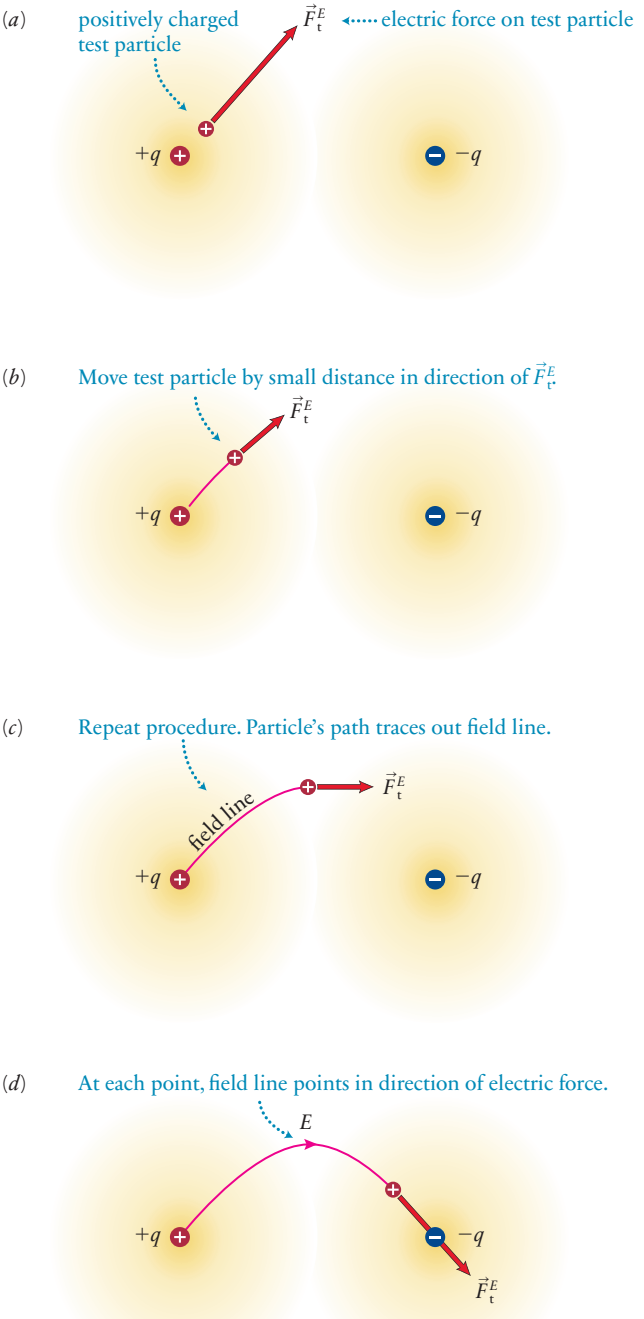
QUANTITATIVE TOOLS

In principle, Coulomb's law allows us to calculate the electric field produced by any discrete or continuous distribution of charged objects. In practice, however, the calculation is often so complicated that the sums or integrals that arise might require numerical evaluation on a computer. For this reason, it pays to search for additional methods to determine the electric field produced by a charge distribution. In this chapter we develop a relationship between an electric field and its source, known as *Gauss's law*, that can be used to determine the electric fields due to charge distributions that exhibit certain simple symmetries. These symmetries appear in many common applications, which makes Gauss's law an important tool in calculating electric fields. As we shall see in Chapter 30, Gauss's law is one of the fundamental equations of *electromagnetism*—the theory that describes electromagnetic interactions and electromagnetic waves.

24.1 Electric field lines

In Chapter 23 we used vector field diagrams to visualize electric fields. Another way to visualize electric fields, which will help us reach some new insights, is to draw **electric field lines.** These lines are drawn so that at any location the electric field $\vec{E}$ is tangent to them. Because the electric field is a vector, we assign to field lines a direction that corresponds with the direction of the electric field.

To draw an electric field line, imagine placing a test particle carrying a positive charge q_t somewhere near a charge distribution. Then move the test particle only a small distance in the direction of the electric force exerted on it. (Remember from Chapter 23 that the electric field points in the same direction as the electric force exerted on a positively charged test particle.) Slowly repeat the procedure to trace out a line (**Figure 24.1**). We label the field lines with the symbol E to remind us that they represent an electric field.



CONCEPTS

24.1 Draw several field lines representing the electric field of an isolated positively charged particle. Repeat for a negatively charged particle.

As Checkpoint 24.1 illustrates, the field line diagrams for a positive and for a negative isolated charged particle are similar, even though the electric fields point in opposite directions. They point radially outward from a positively charged particle and point radially inward toward a negatively charged particle. This direction means that electric field lines always start from a positively charged object and always end on a negatively charged object, never the other way around.

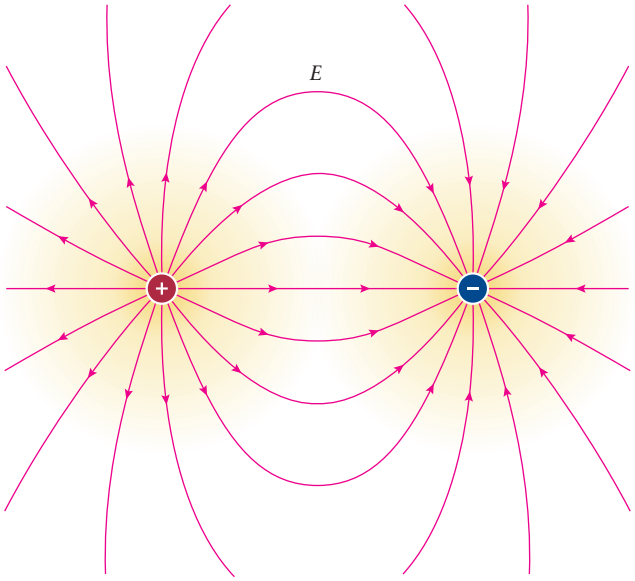
Because an electric field is present everywhere around a charged object, a field line passes through every location in space. In practice, we draw only a finite number of field lines to represent the entire field. **Figure 24.2**, for example, shows the pattern of field lines created by a pair of oppositely charged particles (that is, a dipole).

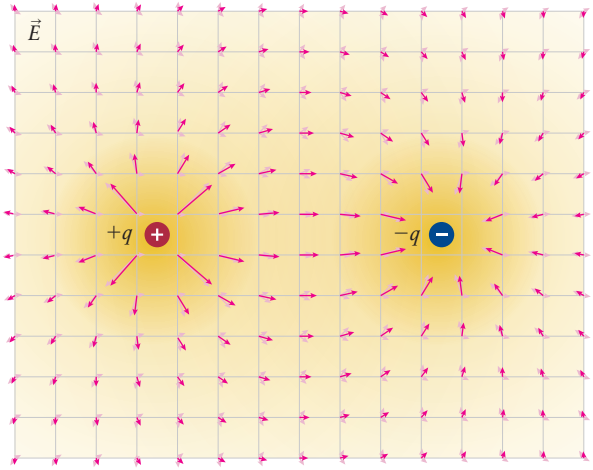
Figure 24.1 Using a positively charged test particle to trace out an electric field line.

Sixteen field lines emanate from the positively charged particle on the left, and 16 field lines terminate on the negatively charged particle on the right. Notice the correspondence between this pattern and the corresponding vector field diagram in **Figure 24.3*a*** and the pattern created by the fibers in Figure 24.3*b*.

The number of field lines that emanate from a positively charged object is arbitrary; we could have chosen some number other than 16 for Figure 24.2. However, in a given field line diagram, the number of

Figure 24.2 Electric field line diagram for an electric dipole.





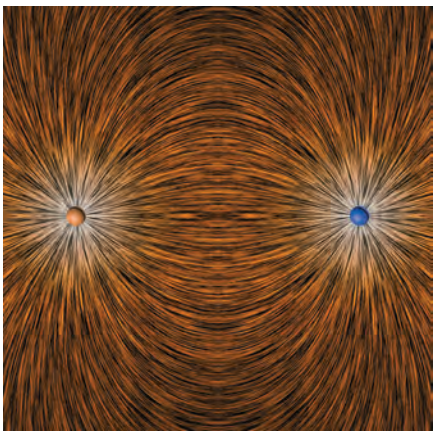


Figure 24.3 Two representations of the electric field of an electric dipole.

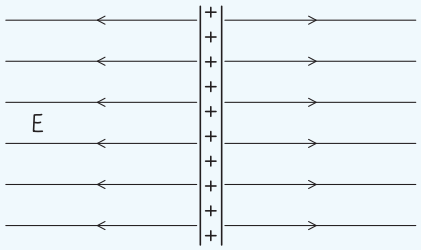
(*a*) Vector field diagram of an electric dipole

(*b*) Pattern created by electric dipole in a suspension of plastic fibers that align with the electric field

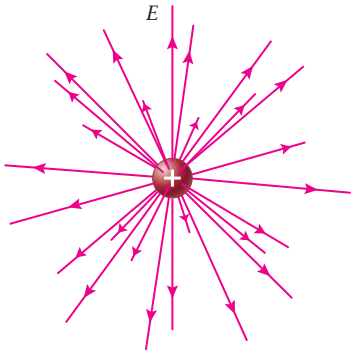
field lines is always proportional to the magnitude of the charge carried by the object. If, for example, 16 field lines emanate from an object that carries a charge $+q$, then 32 lines emanate from an object that carries a charge $+2q$ and eight lines terminate on an object that carries a charge $-q/2$.



The number of field lines that emanate from a positively charged object or terminate on a negatively charged object is proportional to the charge carried by the object.

EXERCISE 24.1 Field lines of infinite charged plate

Draw a field line diagram for an infinite plate that carries a uniform positive charge distribution inside the plate.



SOLUTION I know from Chapter 23 that the electric field produced by a charged plate of infinite area is always perpendicular to the plate (see Figure 23.30). Thus, the field lines must be straight lines perpendicular to the plate. Because the plate is positively charged, I draw the field lines perpendicular to and away from the plate on either side (**Figure 24.4**). ✔

Figure 24.4

Like vector field diagrams, field line diagrams provide an incomplete view of the electric field and are awkward to draw for all but the simplest charge distributions. Both types of diagram are limited by the two-dimensional nature of illustrations. In particular, you should keep in mind that field lines emanate in three dimensions (**Figure 24.5**), not just in the plane of the drawing.

Figure 24.5 Although we generally use two-dimensional representations of field line diagrams, field lines emanate in three dimensions.

CONCEPTS

24.2 (*a*) Is it possible for two electric field lines to cross? (Hint: What is the direction of the electric field at the point of intersection?) (*b*) Can two electric field lines touch?

24.2 Field line density

The most remarkable feature of field lines is this: Even though we take into account only the *direction* of the electric field when drawing field lines, they also contain information about the *magnitude* of the electric field. Figure 24.5 shows that as the distance from the charged object increases, the field lines are spaced farther apart from one another. To see whether there is a quantitative correspondence between field line spacing and electric field magnitude, complete the next checkpoint.

24.3 Imagine a hollow sphere enclosing the charged object in Figure 24.5, centered on the object. (*a*) Given that 26 field lines emanate from the charged object, how many field lines cross the surface of the hollow sphere? (*b*) If the radius of the hollow sphere is R, what is the number of field line crossings per unit surface area? (*c*) Now consider a second sphere with radius $2R$, also centered on the charged object. How many field lines cross the surface of this second sphere? (*d*) How does the number of field line crossings per unit area on the second sphere compare with that on the first sphere? (*e*) How does the electric field at a location on the second sphere compare with the field at a location on the first sphere?

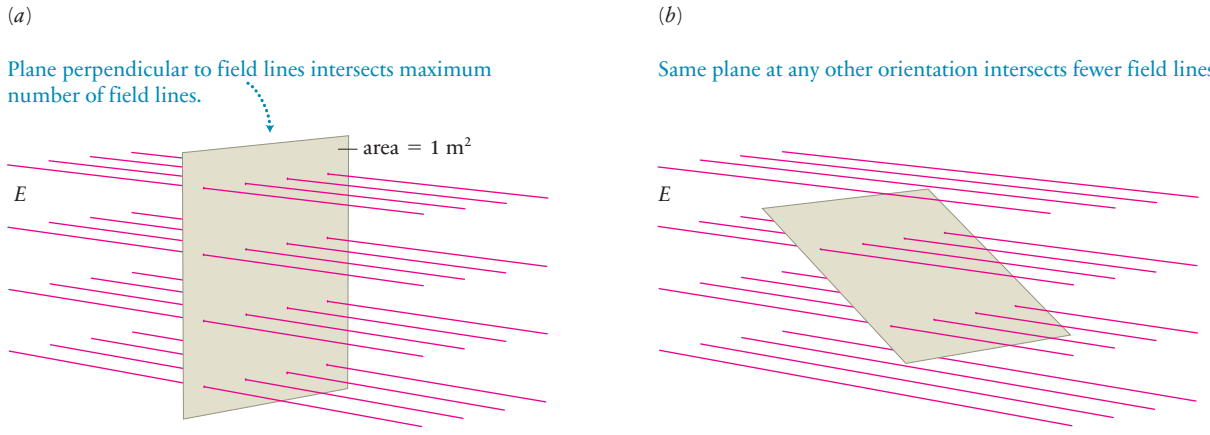
From Checkpoint 24.3, we see that the electric field and the number of field line crossings per unit area both decrease as $1/r^2$. To express this correspondence quantitatively, we define a new quantity, the **field line density:**

The field line density at a given position is the number of field lines per unit area that cross a surface perpendicular to the field lines at that position.

Figure 24.6 illustrates why the surface through which the field lines pass must be perpendicular to the field lines. The field represented by the field lines in the figure is uniform—its magnitude and direction are the same everywhere. As you can see in the figure, the number of field lines that cross the surface depends on the orientation of the surface. The number of field lines that cross the surface is maximum when the surface is perpendicular to the field lines and decreases for any other orientation. We shall see later in this chapter how to account for the orientation of a surface when calculating field line density.

Because the number of field lines in a field line diagram is arbitrary, the field line density is also an arbitrary number, and so you may be wondering why field line density is a useful quantity. As you will see shortly, however, the field line density allows us to draw conclusions about electric field magnitudes. The only condition we make is that, in a given field line diagram, the number of field lines emanating from or terminating on charged objects is proportional to the magnitude of the charge carried by these objects.

24.4 (*a*) In Figure 24.6, for what orientation is the number of field lines that cross the surface a minimum? (*b*) How many field lines cross a plane surface of area 0.5 m^2 placed perpendicular to the field lines in Figure 24.6? (*c*) Using your answer to part *b*, what is the number of field line crossings *per unit area* through the 0.5-m^2 surface? (*d*) How does this compare to the number of field line crossings per unit area for the 1-m^2 surface in Figure 24.6*a*?



For the spherical surfaces of Checkpoint 24.3, the field lines are all perpendicular to the surface because the field lines are radial. The number of field line crossings you calculated per unit area *is* the field line density. These results lead us to conclude:

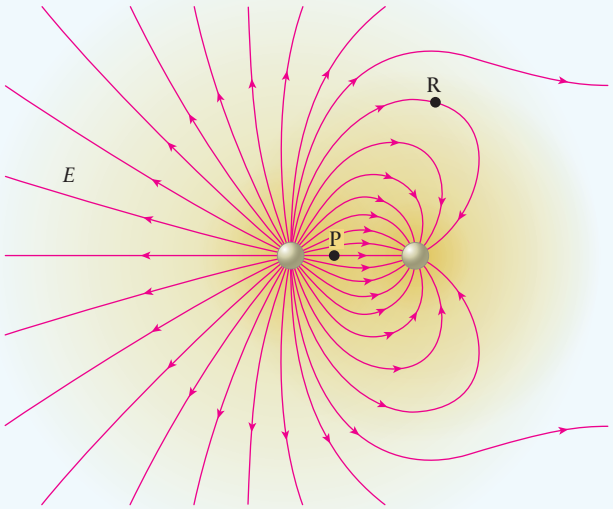
At every position in a field line diagram, the magnitude of the electric field is proportional to the field line density at that position.

The box "Properties of electric field lines" summarizes the properties of electric field lines.

CONCEPTS

Figure 24.6 The number of field lines that cross a given surface depends on the orientation of the surface relative to the field lines.

Properties of electric field lines



When working with electric field lines, keep the following points in mind:

1. Field lines emanate from positively charged objects and terminate on negatively charged objects.
2. At every position, the direction of the electric field is given by the direction of the tangent to the electric field line through that position.
3. Field lines never intersect or touch.
4. The number of field lines emanating from or terminating on a charged object is proportional to the magnitude of the charge on the object.
5. At every position, the magnitude of the electric field is proportional to the field line density.

EXERCISE 24.2 Field strength from field lines

Consider the field line diagram shown in **Figure 24.7**. (*a*) What are the signs of the charges on the two small spherical objects? (*b*) What are the relative magnitudes of these charges? (*c*) What is the ratio of the magnitudes of the electric fields at points P and R? (*d*) Is the electric field zero anywhere in the region shown?

Figure 24.7 Exercise 24.2.

SOLUTION (*a*) Because field lines leave the left object and terminate on the right one, the left object carries a positive charge and the right object carries a negative charge. ✔

(*b*) From Figure 24.7 I see that about twice as many field lines leave the left object as end on the right one. Thus, the charge on the left object is about twice that on the right object.* ✔

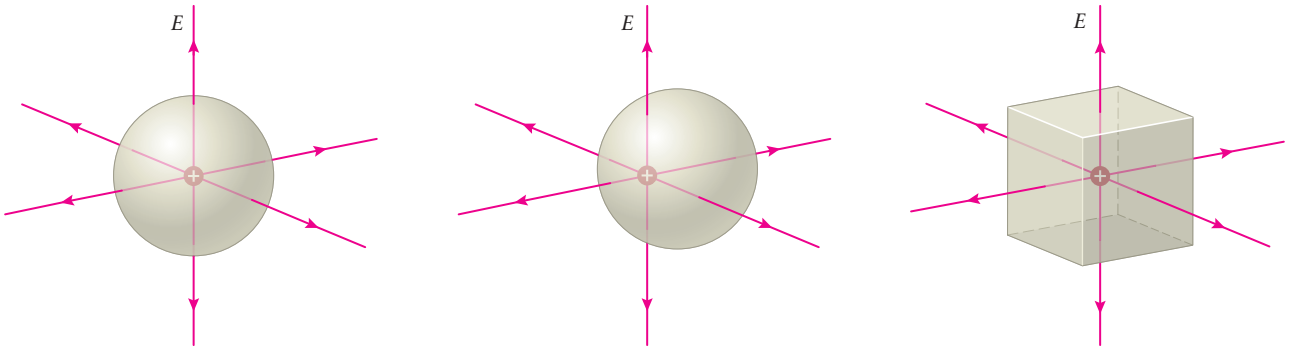
(*c*) The magnitude of the electric field at each position is proportional to the field line density at that position. The field line density is equal to the number of field lines per unit length, which is proportional to the inverse of the distance between adjacent field lines. Measuring with a ruler, I see that the distances between adjacent field lines at points P and R are $d_P \approx 1$ mm and $d_R \approx 6$ mm, so

$$\frac{E_P}{E_R} = \frac{d_R}{d_P} \approx \frac{6\text{ mm}}{1\text{ mm}} = 6. \checkmark$$

(*d*) The absence of field lines on the right suggests that the electric field is small (or even zero). Indeed, if a test particle carrying a positive charge is placed in that region, it is subject to a repulsive force exerted by the positively charged object on the left and an attractive force exerted by the negatively charged object on the right. If the test particle is to the right of the particles and $\sqrt{2}$ as far from the positively charged particle as it is from the negatively charged particle, the vector sum of the two forces is zero and so the electric field at that position is zero. ✔

*If you answered that the magnitude of the charge on the left is four times that on the right to account for three dimensions instead of two, imagine rotating the plane of the cross-section shown in Figure 24.7 around an axis that contains both charges. That cross-section won't change. So, even in three dimensions, the charge magnitude on the left is about twice that on the right.

Note that in Exercise 24.2, half of the field lines leave the area of interest. These field lines either eventually terminate on a negatively charged object (not shown) or continue out to "infinity."



CONCEPTS

24.5 Imagine moving the hollow sphere of radius R of Checkpoint 24.3*a* sideways so that the charged object is no longer at the center of the sphere (but still within it). (*a*) How does the number of field line crossings through the surface of the sphere change as it is moved? (*b*) How does the average number of field line crossings per unit surface area of the sphere change? (*c*) Does the electric field strength at a fixed position on the surface of the sphere change or remain the same as the sphere is moved? (*d*) Are your answers to parts *b* and *c* in contradiction, given the relationship between the electric field magnitude and field line crossings per unit area?

24.3 Closed surfaces

Checkpoint 24.5 leads us to another result that will be important in deriving Gauss's law: Whenever a charged particle is placed inside a hollow spherical surface, the number of field lines that pierce the surface is the same *regardless of where inside the surface the particle is placed*. This is true simply because so long as the charged particle is inside the surface, all the field lines emanating from the particle must go

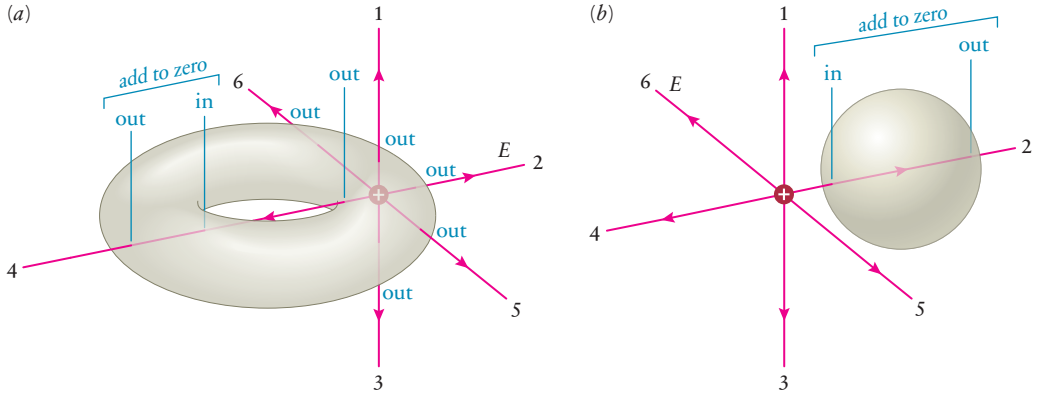
Figure 24.8 Any surface that encloses a positively charged particle is pierced by all the field lines that emanate from that particle, regardless of the shape of the surface and the position of the particle within the surface.

through the spherical surface. In fact, we don't even need to use a spherical surface—a cube-shaped surface or any other surface enclosing the charged particle will do (**Figure 24.8**). In each case, the number of field lines that pierce the surface is equal to the number of field lines that emanate from or terminate on the charged particle enclosed by the surface.

24.6 Suppose eight field lines emanate from an object carrying a charge $+q$. How many field lines pierce the surface of a hollow sphere if the sphere contains (*a*) a single object carrying a charge $+2q$ and (*b*) two separate objects, each carrying a charge $+q$? (*c*) If the sphere is pierced by 20 field lines, what can you deduce about the amount of combined charge on objects inside the sphere?

A surface that completely encloses a volume is called a **closed surface**. Checkpoint 24.6 suggests that a direct relationship exists between the number of field lines that cross a closed surface and the **enclosed charge**—the sum of all charge enclosed by that surface. However, what happens if a field line reenters the closed surface, as illustrated in **Figure 24.9a**? Field line 4 now crosses the closed surface *three* times, so the number of field line crossings is not six but eight. If you look closely at the figure, however, you will discover that not all the crossings are the same. For seven of the crossings the field line goes outward (from the inside of the closed surface to the outside), while for the eighth crossing the field line goes inward. If we assign a value of $+1$ to each outward crossing and a value of -1 to each inward crossing, we obtain $(+7) + (-1) = 6$.

To keep track of the number of inward and outward field crossings, we define a new quantity called the *field line flux*:



> **For any closed surface, the *field line flux* is the number of outward field lines crossing the surface minus the number of inward field lines crossing the surface.**

In calculating the field line flux for any closed surface, we assign a value of $+1$ to each outward field line crossing the surface and a value of -1 to each inward field line crossing the surface.

24.7 (*a*) If more than one field line reenters the donut in Figure 24.9*a*, what happens to the field line flux? (*b*) Are there any closed surfaces enclosing a charged particle through which the field line flux is different from that through a simple sphere around that particle?

CONCEPTS

Figure 24.9 The number of field lines exiting a closed surface minus the number entering it is always equal to the number of field lines generated inside the surface.

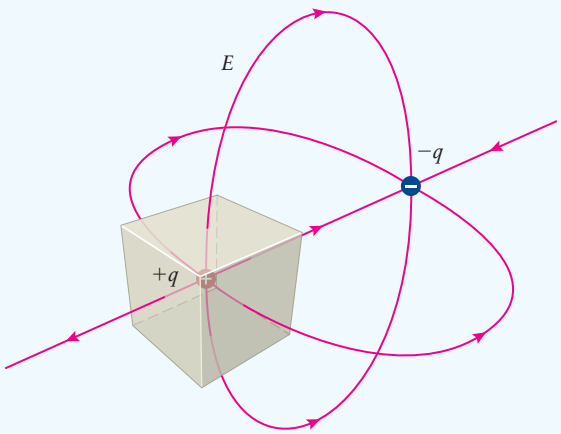
The field line flux through any closed surface is always equal to the number of field lines that originate from within that surface minus the number of field lines that terminate on charged objects within that surface. So far, we have drawn an arbitrary number of field lines, but we can make our statement more precise:

The *field line flux* through a closed surface is equal to the charge enclosed by the surface multiplied by the number of field lines per unit charge.

What about charged objects outside the closed surface? To see what effect such charged objects have, complete the following checkpoint.

24.8 (*a*) What is the field line flux through the closed spherical surface in Figure 24.9*b* due to a charged particle outside the sphere? (*b*) Does your answer to part *a* change if we move the particle around (but keep it outside the volume enclosed by the surface)?

Checkpoint 24.8 demonstrates a very important point:



The field line flux through a closed surface due to charged objects outside the volume enclosed by that surface is always zero.

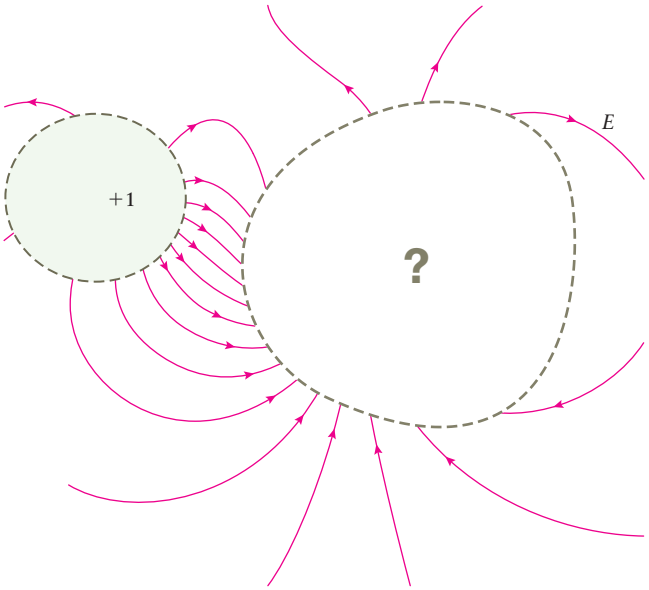
This means that if we know the field line flux through a closed surface, then we can determine the charge enclosed by that surface, regardless of the distribution of charge outside the surface. This statement is a form of Gauss's law, which we shall describe mathematically in Section 24.7.

EXAMPLE 24.3 Flux of an electric dipole

Consider the three-dimensional dipole field line diagram shown in **Figure 24.10**. Six field lines emanate from the positively charged end, and six terminate on the negatively charged end. (*a*) What is the field line flux through the surface of the cube that encloses the positively charged end shown in the figure? (*b*) What is the field line flux through the surface of a similar cube that encloses the negatively charged end?

Figure 24.10 Example 24.3.

SOLUTION (*a*) Six field lines emanate from the positively charged particle. Each line crosses the surface of the cube in the outward direction and thus contributes a value of +1 to the field line flux. The field line flux is +6. ✔



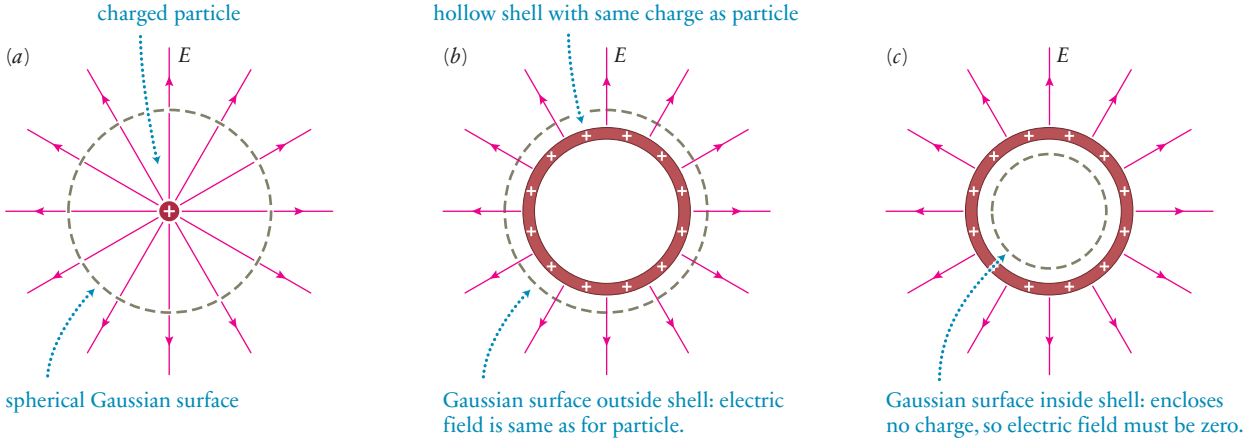
(*b*) Six field lines terminate on the negatively charged particle, so there are again six field line crossings. However, these field lines are directed inward and so the field line flux is −6. ✔

24.9 What is the field line flux through the surface of a rectangular box that encloses *both* ends of an electric dipole?

The relationship between the field line flux through a closed surface and the enclosed charge is important because it can help us determine one from a knowledge of the other. For example, in the next section we shall use this relationship to derive two important theorems about isolated conducting objects.

24.10 Consider the two-dimensional field line diagram in **Figure 24.11**, part of which is hidden from view. (*a*) If the object in the top left carries a charge of +1 C, what is the charge enclosed in the region that is hidden? (*b*) What is the field line flux through a surface that encloses the entire area represented by the diagram?

Figure 24.11 Checkpoint 24.10: What is the charge inside the dashed region?



24.4 Symmetry and Gaussian surfaces

The relationship between field line flux and enclosed charge allows us to reach several important conclusions about charged objects and their electric fields without having to do any calculations. To apply this relationship

CONCEPTS

Figure 24.12 Using spherical Gaussian surfaces to examine the electric fields of a charged particle and a uniformly charged spherical shell. The electric fields, Gaussian surfaces, and charged shell are spherical and are shown here in cross section.

in a given situation, we first need to select a closed surface. This surface need not correspond to a real object—any surface, real or imagined, will do. We'll refer to these closed surfaces as **Gaussian surfaces.** The choice of surface is dictated by the symmetry of the situation at hand. As a rule of thumb, we choose a surface such that the electric field is the same (and possibly zero) everywhere along as many regions of the surface as possible, because such a choice makes it easy to determine the field line flux through the surface.

Consider, for example, the charged particle shown in **Figure 24.12*a***. As we have seen, the field lines for the particle radiate outward from it. (The figure shows only a two-dimensional cross section of the three-dimensional situation.) The field is symmetrical in all three dimensions—it has the same magnitude at the same distance from the center in any direction. Therefore, if we draw a spherical Gaussian surface that is concentric with the particle, the magnitude of the electric field is the same at all locations on the sphere. In other words, the field line density is the same all over the surface of the sphere. As we have seen in the preceding section, the field line flux through the Gaussian surface is proportional to the charge enclosed by the sphere.

Now suppose we replace the charged particle by a spherical shell that carries the same charge as the particle and still fits within our Gaussian surface (Figure 24.12*b*). If the charge is uniformly distributed over the shell, then the electric field should still be the same in all directions. Like the charged particle, the charged shell has *spherical symmetry* (see the box "Symmetry and Gauss's law"): Reorienting the spherical shell by rotating it over an angle about any axis does not change the charge configuration and so should not change the electric field at a given location. This means that the field lines should again be straight lines radiating uniformly outward. Also, the field line flux through the Gaussian surface should still be the same because the surface encloses the same amount of charge. The only way that the field line fluxes through the Gaussian surfaces in Figures 24.12*a* and *b* can be uniform *and* equal in magnitude is if the electric fields are the same at every position on the spherical Gaussian surface. Because this argument holds for a spherical Gaussian surface of any radius, we can conclude:

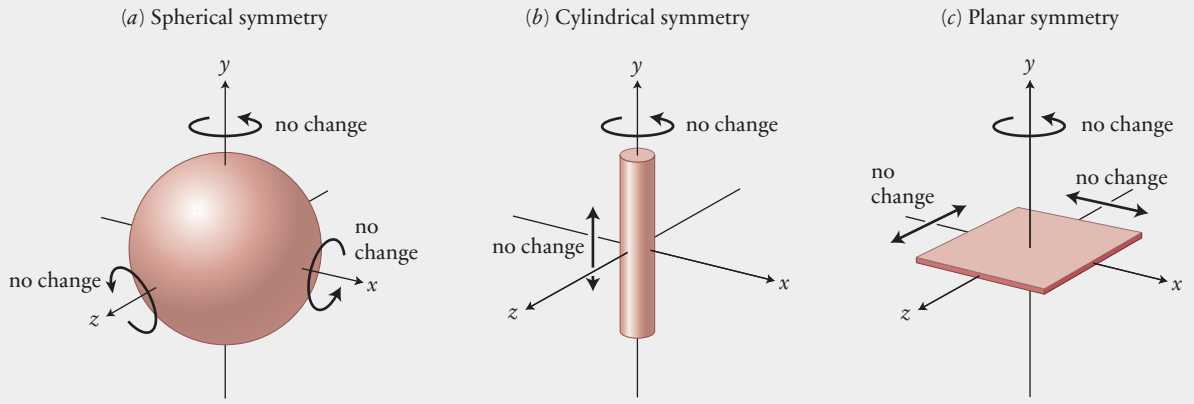
> **The electric field outside a uniformly charged spherical shell is the same as the electric field due to a particle that carries an equal charge located at the center of the shell.**

This means that a uniformly charged shell exerts a electric force on a charged particle outside the shell as if all the shell's charge were concentrated at the center of the shell. Because a sphere may be viewed as a collection of shells, we can extend this statement to uniformly charged spheres.

Let us now turn our attention to the electric field in the space enclosed by the shell. We draw a spherical Gaussian surface that fits within the shell (Figure 24.12*c*). This Gaussian surface encloses no charge, so the field line flux through the Gaussian surface is zero. Because the electric field can only be radially outward by symmetry, the electric field must be zero everywhere on the Gaussian surface. Because we can vary the radius of the Gaussian surface from zero to the inner radius of the shell without changing this argument, we can conclude:

> **In the absence of other charged objects, the electric field in the space enclosed by a uniformly charged spherical shell is zero everywhere in the enclosed space.**

Physically this means that a uniformly charged shell exerts no electric force on a charged particle located inside the shell.



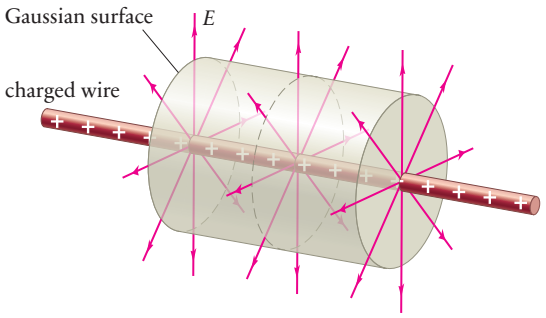
CONCEPTS

Symmetry and Gauss's law

The symmetry of an object is determined by its *symmetry operations*—manipulations that leave its appearance unchanged (see Section 1.2). A sphere, for example, looks the same if we reorient it by rotating it about any axis (Figure 24.13*a*). This type of symmetry is called **spherical symmetry.** An infinitely long, cylindrical rod does not look any different if we rotate it, reverse it, or translate it about its long axis (Figure 24.13*b*). The rod is said to have **cylindrical symmetry.** An infinite flat sheet has **planar symmetry:** It remains unchanged if it is rotated about an axis perpendicular to the sheet or translated along either of the two axes perpendicular to this axis (Figure 24.13*c*). Many other types of symmetry may occur, but these three types play an important role in electrostatics. For charge configurations that exhibit any of these three symmetries, we can calculate the electric field due to the charge distribution directly using Gauss's law.

Because objects are never infinite, they cannot exhibit true cylindrical or planar symmetry. However, for a long straight wire or a large flat sheet we can often obtain good results by assuming they have cylindrical or planar symmetry. When we work problems, the words *long* and *large* imply that you may assume the object has infinite dimensions compared to other length scales of interest.

Figure 24.13 Three symmetries important for applications of Gauss's law.

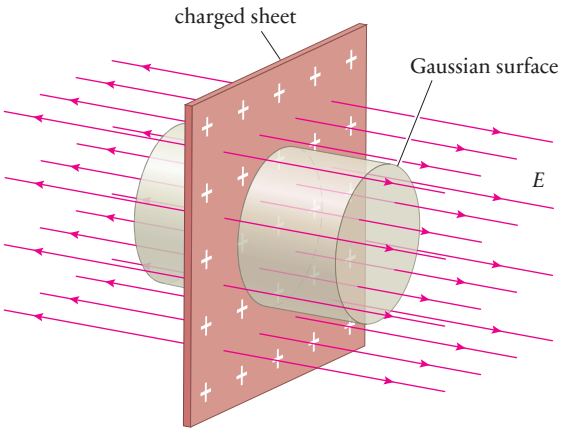


24.11 There are two reasons the field line flux through a closed surface may be zero: because the field is zero everywhere or because the outward flux is balanced by an equal inward flux. Why can't the latter situation be true for the Gaussian surface in Figure 24.12*c*?

Particles, shells, and spheres are the only objects that exhibit spherical symmetry. (Notice that unless specified otherwise, *shell* means *spherical shell*.) Figure 24.14 illustrates a different type of symmetry: the *cylindrical symmetry* of an infinitely long, uniformly charged straight wire.* Because of this symmetry, rotating the wire about its axis or moving it along the axis should not have any effect on the electric field at any position in space. For this to be the case, the field lines must be arranged radially along planes that are perpendicular to the wire (Figure 24.14). We can take advantage of this symmetry by drawing a Gaussian surface in the shape of a cylinder that is concentric with the wire, as shown in Figure 24.14.

*For the wire to exhibit cylindrical symmetry, it has to be infinitely long. If the wire has finite length, you can tell when it is moved along its axis.

Figure 24.14 The electric field of an infinite uniformly charged wire exhibits cylindrical symmetry. We can examine this field by surrounding the wire with a concentric cylindrical Gaussian surface.



24.12 Consider a point on the curved part of the Gaussian surface in Figure 24.14. Does the magnitude of the electric field at that point increase, decrease, or stay the same if you (*a*) change the location of the point on the curved surface or (*b*) increase the radius of the Gaussian surface? (*c*) What is the field line flux through the left and right surfaces of the Gaussian surface?

We can use the cylindrical Gaussian surface to determine how the electric field due to the charged wire

CONCEPTS

Figure 24.15 The electric field of a uniformly charged sheet exhibits planar symmetry. We examine its field by drawing a cylindrical Gaussian surface that straddles the sheet.

decreases with distance from the wire. As you can see from the figure, the field line flux through the curved surface of the cylinder is independent of its radius r. No matter how large we make the radius of the cylinder, the same number of field lines pass through it. The area A of the curved surface is equal to the perimeter times the height h of the cylinder: $A = 2\pi rh$. As we increase the radius r of the cylinder, the surface area increases proportionally to r, and so the field line density must decrease as $1/r$ to maintain a constant number of field lines. Because the field line density is a measure of the electric field strength, this means that the electric field due to the wire decreases as $1/r$, as we established in Example 23.4. A quantitative expression for the electric field due to a charged rod is given in Section 24.8.

Figure 24.15 shows a situation with a different symmetry: a charged sheet. If the sheet is very large and the charge is uniformly distributed along it, then the electric field lines must be perpendicular to the sheet and also uniformly distributed along it. The one-dimensional symmetry exhibited by the electric field due to the charged sheet is an example of *planar symmetry*. To take advantage of this symmetry, we draw a cylindrical Gaussian surface that straddles the sheet, as illustrated in Figure 24.15.

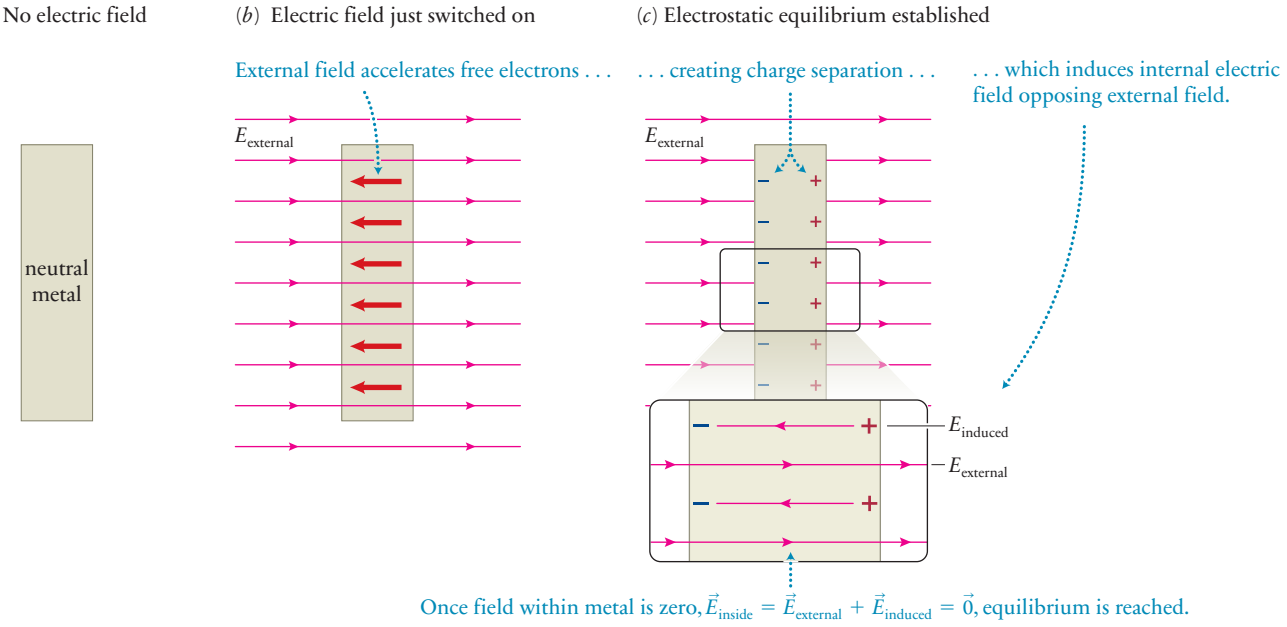
CONCEPTS

24.13 Consider a point on the right surface of the Gaussian surface in Figure 24.15. Does the magnitude of the electric field at that point increase, decrease, or stay the same if you (*a*) change the location of the point on the right surface, or (*b*) increase the height h of the Gaussian surface? (*c*) Is the field line flux through the right surface of the Gaussian surface positive, negative, or zero? (*d*) How does the field line flux through the right surface compare to that through the left surface? (*e*) Is the field line flux through the curved surface of the Gaussian surface positive, negative, or zero?

Because the area of the right surface and the field line flux through that surface don't change as we change the height of the cylinder, we conclude that the electric field line density doesn't change with distance to the plane. Hence the magnitude of the electric field due to the charged sheet is the same everywhere (see also Example 23.6).

24.5 Charged conducting objects

Let as now apply the relationship between field line flux and enclosed charge to charged conducting objects. As we saw in Chapter 22, conducting materials permit the free flow of charge carriers within the bulk of the material. Conducting objects typically contain many charge carriers that are free to move, such as electrons (in a metal) or ions (in a liquid conductor). The material as a whole can still be electrically neutral; a neutral piece of metal, for example, contains as many positively charged protons as negatively charged electrons.



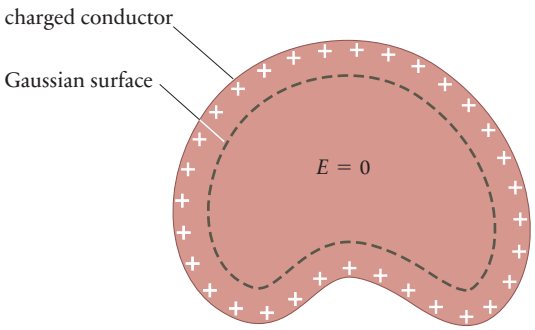
A consequence of this free motion of charged particles within a conducting object is that the particles always arrange themselves in such a way as to make the electric field inside the bulk of the object zero. To see how this comes about, consider a free electron in a slab of metal. If no field is present, no electric force is exerted on the electron. If we apply an external field, however, the free electron is subject to a force in a direction opposite the direction of the electric field (opposite because of the negative charge of the electron).

In a similar way, all the free electrons in a slab of metal initially accelerate in a direction opposite the direction of an applied field (**Figure 24.16**). This leaves behind a positive charge on one side of the slab and creates a negative charge on the opposite side. Because of this rearrangement of charge, an induced electric field builds up in a direction opposite the direction of the external field. As a result, the electric field inside the slab, which is the sum of the external electric field and the induced electric field, decreases. As this field decreases, so does the force exerted on the free electrons in the slab. When enough charge carriers have accumulated on each side of the slab to make the electric field inside the slab zero, the electric force exerted on the free electrons in the metal becomes zero and the material reaches **electrostatic equilibrium**—the condition in which the distribution of charge in a system does not change. The time interval it takes for a metal to reach electrostatic equilibrium is very short (about 10^{-16} s), so the rearrangement of charge carriers is virtually instantaneous. The important point to remember is:

The electric field inside a conducting object that is in electrostatic equilibrium is zero.

Keep in mind that this statement holds *only* in electrostatic equilibrium. When charge carriers are made to flow through a conducting object—as in any electric or electronic device, like your stereo or a refrigerator—the electric field is *not* zero inside the object!

Figure 24.16 Why the electric field inside the bulk of a conducting object is zero when the object is in electrostatic equilibrium.



Suppose now we add charge to a conducting object. It makes sense to assume that the charged particles will arrange themselves over the object in such a way as to spread out as far as possible from one another, given that particles carrying like charges repel. We can use a Gaussian surface to obtain a better understanding of where the charged particles go.

24.14 Consider a spherical Gaussian surface inside a positively charged conducting object that has reached electrostatic equilibrium. (*a*) Is the field line flux through the Gaussian surface positive, negative, or zero? (*b*) What can you conclude from your answer to part *a* about the charge enclosed by the Gaussian surface?

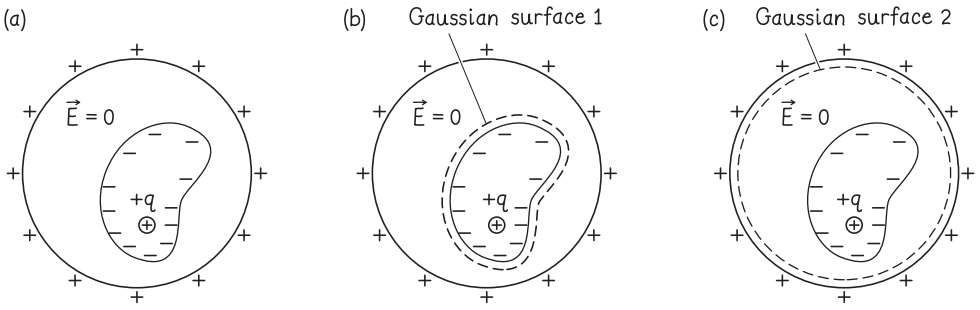
We can extend the result of Checkpoint 24.14 to conducting objects of any shape. Consider, for example, the irregularly shaped, charged conducting object shown in **Figure 24.17**. Draw a Gaussian surface of the same shape as the object, just below its surface. Given that the field is zero everywhere inside the conducting object, the field line flux through the Gaussian surface is zero and the charge enclosed by the Gaussian surface is also zero. Because we can choose the Gaussian surface arbitrarily close to the surface of the object, we conclude:

Any surplus charge placed on an isolated conducting object arranges itself at the surface of the object. No surplus charge remains inside the conducting object once that object has reached electrostatic equilibrium.

Figure 24.17 Because the electric field inside a conducting object in electrostatic equilibrium is zero, we conclude that there cannot be any surplus charge inside the object.

24.15 Suppose the charged conducting object in Figure 24.17 contains an empty cavity. Does any surplus charge reside on the inner surface of the cavity?

CONCEPTS



EXAMPLE 24.4 Charged particle in a cavity

An electrically neutral, conducting sphere contains an irregularly shaped cavity. Inside the cavity is a particle carrying a positive charge $+q$. What are the sign and magnitude of the charge on the sphere's outer surface?

1 GETTING STARTED I am told that a sphere made of material that is an electrical conductor has a cavity in its interior and that a particle in the cavity carries charge $+q$. My task is to determine the sign and magnitude of any charge residing on the sphere's outer surface. I begin by sketching a vertical cross section through the sphere showing the cavity and the

(Continued)

Figure 24.18

charged particle inside it (**Figure 24.18*a***). The problem states that the sphere is electrically neutral, but the question posed implies that some charge resides on its outer surface. Because $\vec{E} = \vec{0}$ inside the conducting material, I know that an equal quantity of the opposite charge must accumulate somewhere else on the sphere.

❷ **DEVISE PLAN** The sphere is conducting, so I know that once electrostatic equilibrium is reached, the electric field inside the bulk of the sphere must be zero: $\vec{E} = \vec{0}$. I can use this information to draw any Gaussian surface inside the sphere and use the following reasoning to determine the charge enclosed by my Gaussian surface: Because $\vec{E} = \vec{0}$ inside the bulk of the sphere and because I draw my Gaussian surface inside the sphere, $\vec{E} = \vec{0}$ everywhere on the Gaussian surface. Therefore the field line flux through the Gaussian surface is zero, which means the charge enclosed by this surface must be zero. Because I can draw my Gaussian surface anywhere inside the bulk of the conductor, I can use this information to determine the distribution of charge on the sphere.

❸ **EXECUTE PLAN** I begin by drawing a Gaussian surface 1 enclosing the cavity (Figure 24.18*b*). Because the field line flux through this surface is zero, the charge enclosed by the surface must be zero. There is charge $+q$ inside the surface (in the charged particle), however, and so in order for the charge enclosed by the surface to be zero, a quantity of charge $-q$ must have migrated from someplace in the region surrounding the cavity and accumulated on the inner cavity surface.

Because the sphere is electrically neutral, the charge $-q$ that migrated to the inner cavity surface must leave a charge $+q$ behind somewhere else on the sphere. If I now draw Gaussian surface 2 just inside the sphere's outer surface (Figure 24.18*c*), I see that, because the field line flux through this Gaussian surface has to be zero, the charge enclosed by this surface is also zero. The positive charge $+q$ that results from the migration of charge $-q$ to the cavity surface must therefore reside outside Gaussian surface 2. Because I can draw surface 2 arbitrarily close to the sphere's outer surface, I conclude that the sphere's outer surface carries a charge $+q$. ✔

❹ **EVALUATE RESULT** The negative charge that migrates from the region outside the cavity to the cavity surface arranges itself in such a way as to cancel the electric field that the charged particle creates in the region outside the cavity. Therefore all the field lines that start on the charged particle must end on the negative charge at the cavity surface. In order for all the field lines to end here, the quantity of negative charge on the cavity surface must be equal to the quantity of charge on the particle. The sphere is electrically neutral, and my choice for where I draw Gaussian surface 2 requires that all the positive charge resulting from the migration of negative charge to the cavity surface must accumulate outside Gaussian surface 2, which means right at the sphere's outer surface. Thus my answer makes sense.

That the electric field inside any conductor is zero in electrostatic equilibrium allows us to draw one additional important conclusion. Because the electric fields must be zero everywhere, including at the surface of a conducting object, there cannot be any component of the electric field parallel to the surface of the object, and therefore we can conclude:

In electrostatic equilibrium, the electric field at the surface of a conducting object is perpendicular to that surface.

If there were a component of the electric field parallel to the surface, that component would cause any free charge carrier to move along the surface, which means the conductor is not in electrostatic equilibrium.

CONCEPTS

24.16 In Example 24.4, is the electric field inside the cavity zero?

Self-quiz

1. In **Figure 24.19**, which of the two charged spheres carries a charge of greater magnitude?
2. Consider Gaussian surfaces 1–3 in Figure 24.19. Determine the field line flux through each surface (considering just the two dimensions shown).
3. In Figure 24.19, is the field line density greater at point A or point B? At which of these locations is the magnitude of the electric field greater? Is the field line density at point C zero or nonzero?
4. The electric field lines in **Figure 24.20** tell you there must be one or more charged particles inside the Gaussian surface defined by the dashed line. Could the electric field shown be due to a single particle inside the Gaussian surface? What must the signs and relative magnitudes of the charged particle(s) be in order to create the electric field lines shown?
5. **Figure 24.21** shows a small ball that carries a charge of $+q$ inside a conducting metal shell that carries a charge of $+2q$. (*a*) What are the sign and magnitude of the charge on the inner surface of the shell? (*b*) What are the sign and magnitude of the charge on the outer surface of the shell?

Figure 24.19

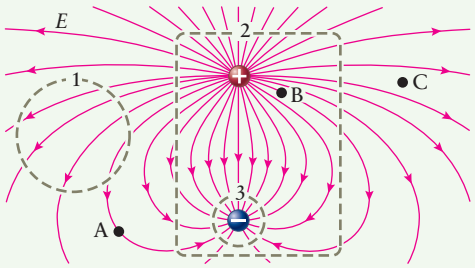


Figure 24.20

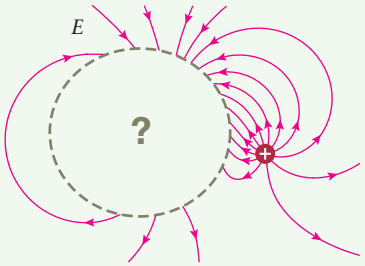

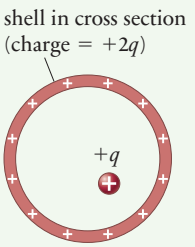

Figure 24.21

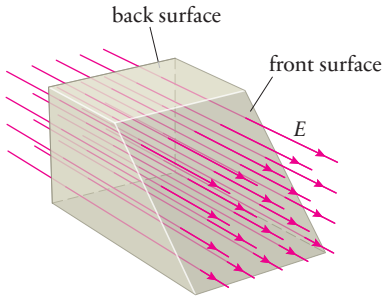
Answers

1. The number of field lines is proportional to the charge on the object. Because more lines emanate from the charged object on the top, that object must carry a greater charge.
2. For surface 1, all lines that enter the surface also exit the surface, so the field line flux is zero. For surface 2, 25 lines exit the surface and 6 lines enter the surface. The field line flux through surface 2 is thus $25 - 6 = 19$. Fifteen field lines cross surface 3, with all lines entering from the outside. The field line flux for surface 3 is -15.
3. Point B has the greater field line density because the lines are closer together at B than they are at A. The magnitude of the electric field is greater at point B because electric field strength is proportional to the field line density. Even though C is not on a field line, the field line density, which is represented by the spacing of the field lines *around* point C, is nonzero.
4. Because electric field lines converge on one point near the top of the area enclosed by the surface and diverge from a point near the bottom, there must be objects that carry both negative and positive charges inside the surface. Because more field lines enter the surface than exit the surface, the negatively charged object(s) must carry a charge of greater magnitude than the positively charged object(s).
5. (*a*) Because the electric field in the conducting shell is zero, the field line flux through a Gaussian surface drawn inside the material of the conducting shell must be zero. According to Gauss's law, the charge enclosed in the surface must also be zero. The charge on the inner surface of the shell must therefore be $-q$, which added to $+q$ gives zero. (*b*) For a neutral shell, a charge of $-q$ on the inside surface of the shell would leave a surplus of $+q$ on the outside surface of the shell. The surplus charge of $+2q$ that was placed on the shell also resides on the outside surface. The charge residing on the outside surface of the shell is thus $+3q$.

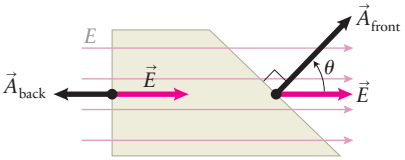
24.6 Electric flux

We introduced two important concepts in the first part of this chapter: the field line density, which is proportional to the strength of the electric field, and the field line flux, which represents the number of field lines going outward through a closed surface minus the number of field lines going inward. In this section we'll turn these concepts into quantities we can calculate.



Consider, for example, a trapezoidal box in a uniform electric field $\vec{E}$ (**Figure 24.22***a*). The field line flux through the closed surface of the trapezoidal box is zero: Twenty field lines go into the back surface and 20 come out through the front surface. Another way of putting this is to say that the field line flux into the back surface is equal in magnitude to the field line flux out of the front surface. Instead of using field lines, however, whose number is chosen arbitrarily, we'll work with a quantity called the **electric flux,** represented by the symbol Φ_E (Φ is the Greek capital phi). The magnitude of the electric flux through a surface with area A in a uniform electric field of magnitude E is defined as

$$\Phi_E \equiv EA\cos\theta \quad \text{(uniform electric field)}, \tag{24.1}$$

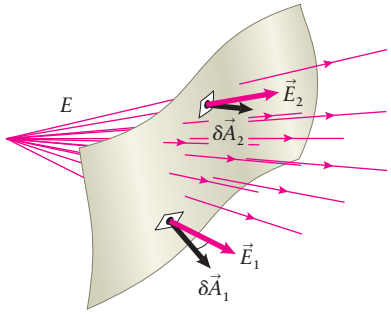


where θ is the angle between the electric field and the normal to the surface.

Figure 24.22 Determining the electric flux through a flat surface.

(*a*) Trapezoidal box in uniform electric field

(*b*) Vector areas of front and back surfaces



24.17 (*a*) Consider the front surface of the trapezoidal box in Figure 24.22*a*, detached from the rest of the trapezoidal box. Does the field line flux through that surface increase, decrease, or stay the same if any of the following quantities is increased: (*i*) the area of the front surface, (*ii*) the magnitude of the electric field (keeping the area constant), (*iii*) the slope of the front surface (that is to say, the angle between the surface and the direction of the electric field is increased)? (*b*) Does the *electric flux* through the front surface increase, decrease, or stay the same if any of these quantities is changed?

As Checkpoint 24.17 shows, electric flux, as we've defined it in Eq. 24.1, behaves like the field line flux. To make the correspondence more precise, we define an *area vector* $\vec{A}$ for a flat surface area as a vector whose magnitude is equal to the surface area A and whose direction is normal to the plane of the area. On closed surfaces we choose $\vec{A}$ to point outward (we'll deal with open surfaces later). Figure 24.22*b* shows the area vectors associated with the front and back surfaces of the (closed) trapezoidal box. With this definition, Eq. 24.1 can be written as a scalar product (Eq. 10.33):

$$\Phi_E \equiv EA\cos\theta = \vec{E}\cdot\vec{A} \quad \text{(uniform electric field)}, \tag{24.2}$$

where θ is the angle between $\vec{E}$ and $\vec{A}$. Electric flux is a scalar, and the SI unit of electric flux is $\text{N}\cdot\text{m}^2/\text{C}$.

Figure 24.23 To obtain the electric flux through an irregularly shaped, nonplanar surface and/or for a nonuniform electric field, we divide the surface into small segments. For very small segments, each segment is essentially flat and the field through each segment is essentially uniform. The flux through the entire surface is then given by the sum of all of the contributions through each segment.

24.18 Let the area of the back surface of the trapezoidal box in Figure 24.22 be $1.0\ \text{m}^2$, the magnitude of the electric field be $1.0\ \text{N/C}$, and $\theta = 30°$ for the front surface. (*a*) What are the magnitudes of the area vectors for the front and back surfaces of the trapezoidal box? (*b*) What are the electric fluxes through the front and back surfaces?

The above definition of electric flux applies only for uniform electric fields and flat surfaces. Let us therefore consider the more general case of an irregular surface in a nonuniform field (**Figure 24.23**). To calculate the electric flux through that surface, we divide the entire surface into small segments of surface area δA_i, with each segment being small enough that we

QUANTITATIVE TOOLS

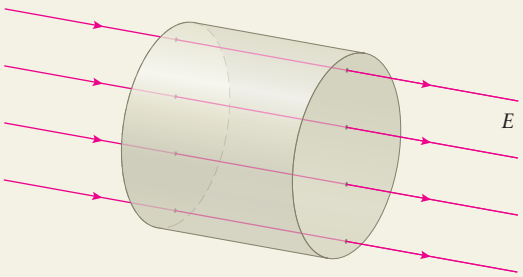
can consider it to be essentially flat, and we can define an area vector $\delta\vec{A}_i$ whose magnitude is equal to the surface area $\delta\vec{A}_i$ of the segment and whose direction is normal to the segment. This allows us to apply Eq. 24.2 to each individual segment. The electric flux through a single segment is then $\Phi_{Ei} = \vec{E}_i \cdot \delta\vec{A}_i$, where $\vec{E}_i$ is the electric field vector at the location of the segment. To calculate the electric flux through the entire surface we must sum the electric flux through all the surface segments:

$$\Phi_E = \Sigma \vec{E}_i \cdot \delta\vec{A}_i. \tag{24.3}$$

If we let the area of each segment approach zero, then the number of segments approaches infinity and the sum is replaced by an integral:

$$\Phi_E = \lim_{\delta A_i \to 0} \Sigma \vec{E}_i \cdot \delta\vec{A}_i = \int \vec{E} \cdot d\vec{A}. \tag{24.4}$$

The integral in Eq. 24.4 is called a *surface integral* (see Appendix B); $d\vec{A}$ is the area vector of an infinitesimally small surface segment. If the surface is closed, this surface integral is written as



$$\Phi_E = \oint \vec{E} \cdot d\vec{A}, \tag{24.5}$$

where the circle through the integral sign indicates that the integration is to be taken over the entire closed surface and $d\vec{A}$ is chosen to point outward. Because evaluating a surface integral is mathematically more complicated than single-variable integration, it is important to exploit any symmetry to simplify the calculation.

EXAMPLE 24.5 Cylindrical Gaussian surface in a uniform electric field

Consider a cylindrical Gaussian surface of radius r and length ℓ in a uniform electric field $\vec{E}$, with the length axis of the cylinder parallel to the electric field (**Figure 24.24**). What is the electric flux Φ_E through this Gaussian surface?

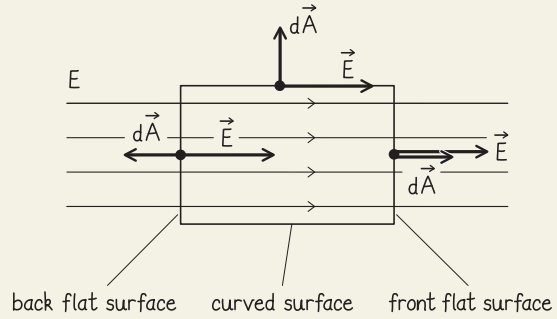


Figure 24.24 Example 24.5.

❶ **GETTING STARTED** From Figure 24.24 I see that a cylindrical Gaussian surface consists of three regions: front and back flat surfaces and a curved surface joining them. The electric field is perpendicular to the front and back flat surfaces and parallel to the curved surface.

❷ **DEVISE PLAN** The electric flux is given by Eq. 24.5, so I can calculate the electric flux through the Gaussian surface by applying Eq. 24.5 to each of the three regions and then summing the three contributions to the electric flux. In order to evaluate the scalar product $\vec{E} \cdot d\vec{A}$ for each region, I sketch a side view of the Gaussian surface showing the vectors $\vec{E}$ and $d\vec{A}$ for each of the three regions (**Figure 24.25**).

Figure 24.25

❸ **EXECUTE PLAN** Applying Eq. 24.5 to the three regions, I can write the flux through the Gaussian surface as the sum of three surface integrals: one over the back surface, one over the curved surface, and one over the front surface:

$$\Phi_E = \oint \vec{E} \cdot d\vec{A} = \underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{back flat surface}} + \underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{curved surface}} + \underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{front flat surface}}. \tag{1}$$

From my sketch, I see that on the back flat surface the angle between $\vec{E}$ and $d\vec{A}$ is 180°, so $\vec{E} \cdot d\vec{A} = E(\cos 180°)\, dA = -E\, dA$. Because the magnitude of the electric field is the same everywhere, I can pull E out of the integral:

$$\underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{back flat surface}} = \int (-E)\, dA = -E \int dA = -E(\pi r^2),$$

where πr^2 is the area of the back flat surface.

(Continued)

QUANTITATIVE TOOLS

The integral over the curved region of the Gaussian surface yields a value of zero because the angle between between $\vec{E}$ and $d\vec{A}$ is 90° everywhere on the curved region, so $\vec{E} \cdot d\vec{A} = E(\cos 90°)\, dA = 0$.

Finally, for the front flat surface I have $\vec{E} \cdot d\vec{A} = E(\cos 0°)\, dA = E\, dA$, so

$$\int_{\substack{\text{front flat}\\ \text{surface}}} \vec{E} \cdot d\vec{A} = \int E\, dA = E \int dA = E(\pi r^2).$$

Adding up the three terms in Eq. 1 yields

$$\Phi_E = -E(\pi r^2) + 0 + E(\pi r^2) = 0. \checkmark$$

4 EVALUATE RESULT Because there is no charge enclosed by the Gaussian surface, I know that the field line flux through the surface must be zero, a fact I confirm by looking at Figure 24.24: The four field lines shown contribute a flux of −4 on the back flat surface, +4 on the front flat surface, and 0 along the curved surface, for a total of $-4 + 4 + 0 = 0$. It therefore makes sense that the electric flux through this Gaussian surface also is zero.

24.19 Consider a spherical Gaussian surface of radius r with a particle that carries a charge $+q$ at its center. (*a*) On the Gaussian surface, what is the magnitude of the electric field due to the particle? (*b*) What is the electric flux through the sphere due to the charged particle? (*c*) Combining your answers to parts *a* and *b*, what is the relationship between the electric flux through the sphere and the enclosed charge q_{enc}? (*d*) Would this relationship change if you doubled the radius r of the sphere?

24.7 Deriving Gauss's Law

Checkpoint 24.19 shows that the electric flux through a spherical Gaussian surface is equal to the charge q enclosed by the sphere times $4\pi k$, where $k = 9.0 \times 10^9\ \text{N} \cdot \text{m}^2/\text{C}^2$ is the proportionality constant that appears in Coulomb's law (see Eqs. 22.1 and 22.5). This relationship is usually written in the form

$$\Phi_E = 4\pi k q = \frac{q}{\epsilon_0}, \tag{24.6}$$

where ϵ_0 is called the **electric constant:**

$$\epsilon_0 \equiv \frac{1}{4\pi k} = 8.85418781 \times 10^{-12}\ \text{C}^2/(\text{N} \cdot \text{m}^2). \tag{24.7}$$

Equation 24.6 is a special case of **Gauss's law,** which states that the electric flux through the closed surface of an arbitrary volume is

$$\Phi_E = \oint \vec{E} \cdot d\vec{A} = \frac{q_{\text{enc}}}{\epsilon_0}, \tag{24.8}$$

where q_{enc} is the **enclosed charge**—the sum of all charge on an object or portion of an object enclosed by the closed surface. The formal proof of Gauss's law is an extension of the calculation you performed in Checkpoint 24.19 and is shown in the box "Electric flux though an arbitrary closed surface."

Gauss's law is a direct consequence of Coulomb's law with its $1/r^2$ dependence and the superposition of electric fields. In that respect, it contains nothing new. However, as the next section shows, Gauss's law greatly simplifies the calculation of electric fields due to charge distributions that exhibit one of the three symmetries we discussed in Section 24.4.

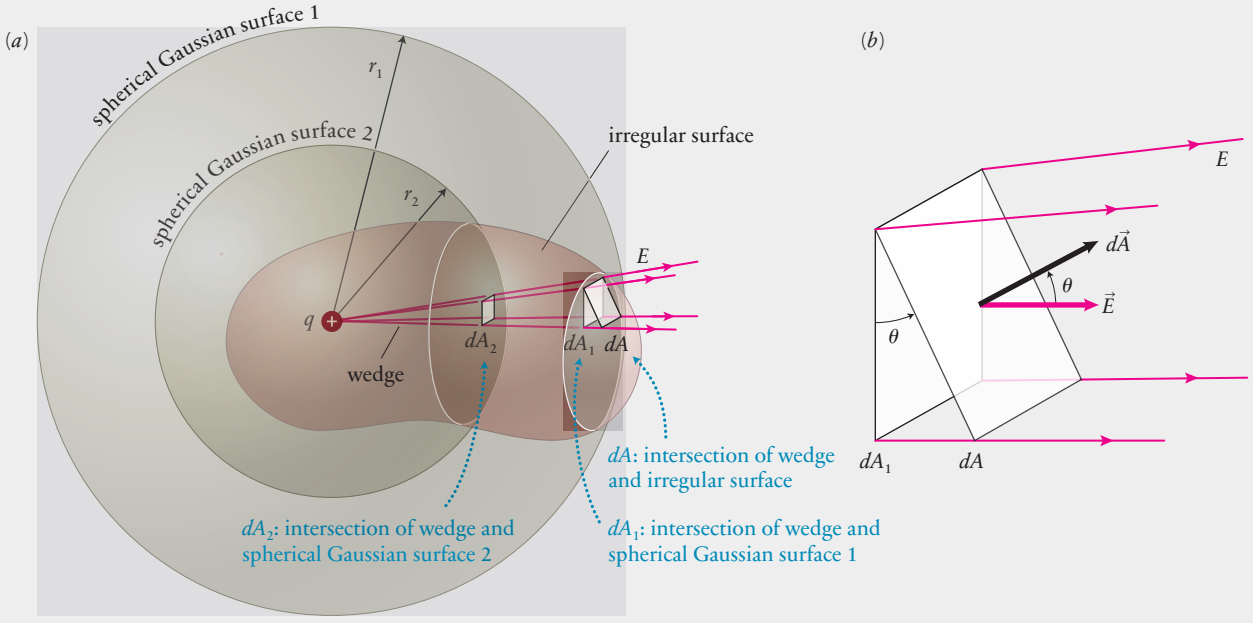
24.20 Suppose Coulomb's law showed a $1/r^{2.00001}$ dependence instead of a $1/r^2$ dependence. (*a*) Calculate the electric flux through a spherical Gaussian surface of radius R centered on a particle carrying a charge $+q$. (*b*) Substitute your result in Eq. 24.8. What do you notice?

QUANTITATIVE TOOLS

Electric flux through an arbitrary closed surface

Consider a particle that carries a positive charge $+q$, surrounded by the irregularly shaped closed surface shown in **Figure 24.26*a***.

1. To determine the electric flux through the irregular surface, we divide the volume enclosed by the surface into small square wedges that taper to a point at the charged particle, one of which is shown. We calculate the electric flux through the surface segment dA cut out by each wedge and then sum the contributions from all the wedges.
2. To determine the electric flux through dA in Figure 24.26*a*, we draw two spherical Gaussian surfaces around q: one with a radius r_1 equal to the distance between dA and q, the other with an arbitrary radius r_2. Our wedge from step 1 now defines two other small surface segments dA_1 and dA_2 on these two spheres.
3. If the segment dA is made very small, then the field lines in the wedge are nearly parallel to one another. Therefore, according to what we found in Section 24.6, the electric flux through dA is equal to that through dA_1 (Figure 24.26*b*). In addition, as you showed in Checkpoint 24.19, this flux is also equal to that through surface segment dA_2. In fact, the electric flux is the same through *any* surface that cuts through the wedge. Put differently, any surface that cuts through the wedge intercepts the same number of field lines.
4. We can repeat this procedure for each wedge. Each time, we see that the electric flux through a segment dA on the irregular surface is equal to that through a corresponding segment dA_2. As we add the contributions of all the wedges, we conclude that the electric flux through the closed irregular surface is equal to that through a sphere of arbitrary radius r centered on q.
5. If there is more than one charged particle inside the irregularly shaped surface, we can use the above arguments for each particle individually and then use the superposition of electric fields (Section 23.3):



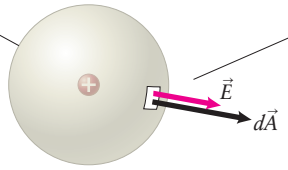
$$\vec{E} = \Sigma \vec{E}_i,$$

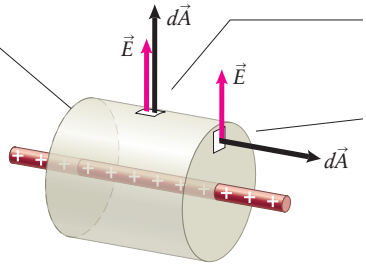
where $\vec{E}_i$ is the electric field due to particle i alone. The electric flux due to all charged particles is then the sum of the electric fluxes due to the individual electric fields:

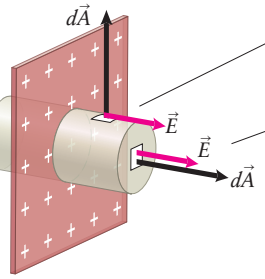
$$\Phi_E = \Sigma \Phi_{Ei} = \Sigma \frac{q_i}{\epsilon_0} = \frac{q_{\text{enc}}}{\epsilon_0}.$$

24.21 Suppose q is *outside* the irregularly shaped surface in Figure 24.26. Show that the electric flux due to q through the closed surface is zero. (Hint: Draw a small wedge from q through the surface and determine the electric flux through the two intersections between the wedge and the surface.)

Figure 24.26 Formal proof of Gauss's law.







24.8 Applying Gauss's Law

Gauss's law relates the electric flux through a closed surface to the charge enclosed by it. In Section 24.5 we encountered one important application of Gauss's law: If we can choose a Gaussian surface such that the electric field is zero everywhere on that surface (inside a conducting material, for example), then we know that the charge enclosed by that surface must be zero. In this section we show how Gauss's law can be used to avoid having to carry out any integrations to calculate the electric field. In principle one can calculate the electric flux through any surface, but the calculation is not trivial in general. For the surfaces and charged objects shown in Section 24.4 and summarized in **Figure 24.27**, however, the electric flux is easy to calculate because the field lines are either parallel to the surface (in which case the electric flux is zero) or perpendicular to it and the magnitude of the electric field is constant (in which case the electric flux is simply the product of the magnitude of the electric field E and the surface area A).

To see the benefit of Gauss's law, consider a charged spherical shell of radius R that carries a uniformly distributed positive charge q. The electric field due to this charged shell can be calculated using the procedure outlined in Section 23.7: Divide the shell into infinitesimally small segments that carry a charge dq, apply Coulomb's law to each small segment, and integrate over the entire shell (Eq. 23.15):

$$\vec{E}_{\text{sP}} = k \int \frac{dq_{\text{s}}}{r_{\text{sP}}^2} \hat{r}_{\text{sP}}. \tag{24.9}$$

Figure 24.27 Applying Gauss's law to determine the electric fields of symmetrical charge distributions.

Symmetry of charge distribution	Electric field geometry	Gaussian surface	To find electric flux
Spherical (charged sphere)	$\vec{E}$ radiates uniformly outward in three dimensions.	Concentric sphere 	At all points, $\vec{E}$ is perpendicular to surface and has same magnitude.
Cylindrical (infinite charged rod)	$\vec{E}$ radiates uniformly outward perpendicular to axis.	Coaxial cylinder 	*Cylindrical surface:* At all points, $\vec{E}$ is perpendicular to surface and has same magnitude. *End faces:* $\vec{E}$ is parallel to face, so flux is zero.
Planar (infinite charged sheet)	$\vec{E}$ is uniform and perpendicular to plane.	Cylinder or box perpendicular to plane 	*Surface perpendicular to plane:* $\vec{E}$ is parallel to face, so flux is zero. *Faces parallel to plane:* At all points, $\vec{E}$ is perpendicular to surface and has same magnitude.

QUANTITATIVE TOOLS

As you may imagine, this so-called *direct integration* is no simple matter (see Section 13.8 for a similar integral), even though the result, which we derived qualitatively in Section 24.4, is surprisingly simple. Taking advantage of the symmetry of the problem, however, we can use Gauss's law to calculate the answer in just two steps.

We begin by drawing a concentric spherical Gaussian surface of radius $r > R$ around the shell (**Figure 24.28*a***). According to Gauss's law, the flux through the Gaussian surface is equal to the enclosed charge divided by ϵ_0:

$$\Phi_E = \frac{q_{\text{enc}}}{\epsilon_0} = \frac{q}{\epsilon_0}. \tag{24.10}$$

In addition, we know that because of the spherical symmetry the electric field has the same magnitude E at each position on the Gaussian surface and the field is perpendicular to the surface. Because the electric field is perpendicular, we have $\vec{E} \cdot d\vec{A} = E\,dA$, and because E has the same value everywhere on the Gaussian surface, we can pull the electric field out of the integral in Eq. 24.5:

$$\Phi_E = \oint \vec{E} \cdot d\vec{A} = \oint E\,dA = E \oint dA = EA, \tag{24.11}$$

where A is the area of the spherical Gaussian surface:

$$A = 4\pi r^2. \tag{24.12}$$

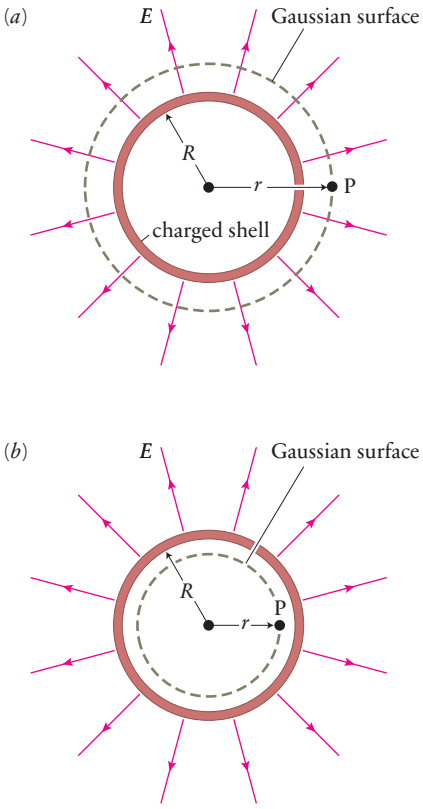
Substituting Eq. 24.12 into Eq. 24.11, we obtain

$$\Phi_E = 4\pi r^2 E. \tag{24.13}$$

Combining Eqs. 24.10 and 24.13, we obtain

$$4\pi r^2 E = \frac{q}{\epsilon_0} \tag{24.14}$$

or



$$E = \frac{1}{4\pi\epsilon_0}\frac{q}{r^2} = k\frac{q}{r^2}. \tag{24.15}$$

This is exactly the magnitude of the electric field due to a particle carrying a charge q located at the center of the shell, as we concluded in Example 23.7 for a solid sphere.

We can also use Gauss's law to determine the electric field inside the shell by drawing a concentric spherical Gaussian surface with radius $r < R$ (Figure 24.28*b*). For this surface the enclosed charge is zero, $q_{\text{enc}} = 0$, so the right side of Eq. 24.14 becomes zero. Consequently, the electric field inside the uniformly charged spherical shell must be zero.

Note that our calculation did not involve working out any integrals, even though Eq. 24.5 does contain an integral—the symmetry of the problem allows us to bypass the integration. The Procedure box on page 864 shows how to calculate the electric field using Gauss's law for charge distributions that exhibit one of the symmetries listed in Figure 24.27. In the next three exercises we apply this procedure to calculate the electric field of a number of different charge distributions.

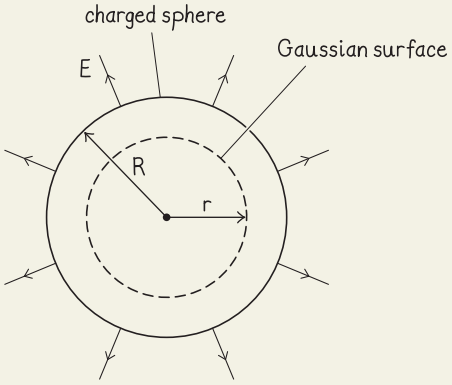
Figure 24.28 Applying Gauss's law to a charged spherical shell.

PROCEDURE: Calculating the electric field using Gauss's law

Gauss's law allows you to calculate the electric field for charge distributions that exhibit spherical, cylindrical, or planar symmetry without having to carry out any integrations.

1. Identify the symmetry of the charge distribution. This symmetry determines the general pattern of the electric field and the type of Gaussian surface you should use (see Figure 24.27).
2. Sketch the charge distribution and the electric field by drawing a number of field lines, remembering that the field lines start on positively charged objects and end on negatively charged ones. A two-dimensional drawing should suffice.
3. Draw a Gaussian surface such that the electric field is either parallel or perpendicular (and constant) to each face of the surface. If the charge distribution divides space into distinct regions, draw a Gaussian surface in each region where you wish to calculate the electric field.
4. For each Gaussian surface determine the charge q_{enc} enclosed by the surface.
5. For each Gaussian surface calculate the electric flux Φ_E through the surface. Express the electric flux in terms of the unknown electric field E.
6. Use Gauss's law (Eq. 24.8) to relate q_{enc} and Φ_E and solve for E.

You can use the same general approach to determine the charge carried by a charge distribution given the electric field of a charge distribution exhibiting one of the three symmetries in Figure 24.27. Follow the same procedure, but in steps 4–6, express q_{enc} in terms of the unknown charge q and solve for q.



EXERCISE 24.6 Electric field inside uniformly charged sphere

Consider a charged sphere of radius R carrying a positive charge q that is uniformly distributed over the volume of the sphere. What is the magnitude of the electric field a radial distance $r < R$ from the center of the sphere?

SOLUTION The sphere has spherical symmetry, so I know that the field must point radially outward in all directions. I therefore draw a concentric spherical Gaussian surface with a radius $r < R$ (**Figure 24.29**). Because the sphere carries a uniformly distributed charge q, the amount of charge enclosed by the Gaussian surface is determined by the ratio of the volumes of the Gaussian surface and the charged sphere:

$$q_{\text{enc}} = \frac{\frac{4}{3}\pi r^3}{\frac{4}{3}\pi R^3} q = \frac{r^3}{R^3} q. \tag{1}$$

Figure 24.29

The electric flux is given by the product of the magnitude of the electric field $E(r)$ and the surface area A of the Gaussian surface (Eq. 24.13):

$$\Phi_E = 4\pi r^2 E. \tag{2}$$

Substituting Eqs. 1 and 2 into Eq. 24.8, I obtain

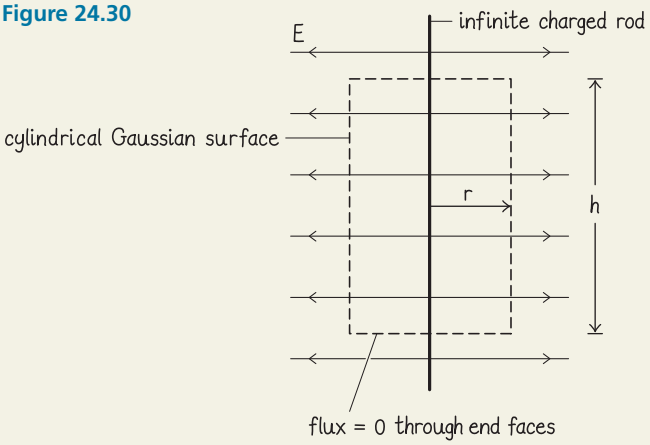
$$4\pi r^2 E = \frac{r^3}{R^3}\frac{q}{\epsilon_0}$$

or

$$E = \frac{1}{4\pi\epsilon_0}\frac{q}{R^3} r = k\frac{q}{R^3} r, \checkmark$$

the same result I obtained in Checkpoint 23.15.

24.22 What is the electric field outside a solid sphere carrying a charge $+q$ uniformly distributed throughout its volume?



EXERCISE 24.7 Electric field of an infinitely long charged thin rod

What is the electric field magnitude a radial distance r from the central length axis of an infinitely long thin rod carrying a positive charge per unit length λ?

SOLUTION An infinitely long rod has cylindrical symmetry. I assume the rod's diameter is vanishingly small. From the symmetry, I know that the electric field points radially outward (see Section 24.4). I therefore make a sketch showing the rod and a few representative field lines. I then draw a cylindrical Gaussian surface of radius r and height h around the rod (**Figure 24.30**). The cylinder encloses a length h of the rod, so the enclosed charge is

$$q_{\text{enc}} = \lambda h. \tag{1}$$

Figure 24.30

The electric flux through the top and bottom faces of the Gaussian surface is zero because the electric field is parallel to those faces. I also know that symmetry requires the electric field to have the same magnitude E at each position on the cylindrical part of the surface. I can therefore pull the electric field out of the integral. The electric flux through that part of the surface is

$$\Phi_E = \int_{\text{cyl surface}} \vec{E} \cdot d\vec{A} = \int E\, dA = E \int dA. \tag{2}$$

The area of the cylindrical surface is equal to the circumference of the cylinder, $2\pi r$, times its height h, so Eq. 2 becomes

$$\Phi_E = E(2\pi r h). \tag{3}$$

Substituting Eqs. 1 and 3 into Eq. 24.8, I obtain

$$E(2\pi r h) = \frac{\lambda h}{\epsilon_0}$$

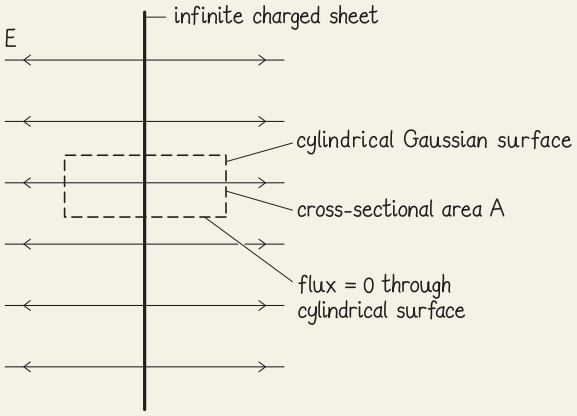
or

$$E = \frac{\lambda}{2\pi\epsilon_0 r} = \frac{2k\lambda}{r}. \checkmark$$

This is the same result I obtained by direct integration in Example 23.4 for a finite charged rod in the limit that I am close to the rod (which makes the rod appear infinitely long). The direct integration, however, took almost two pages of work!

24.23 The direct integration procedure also yields an expression for a rod of *finite* length (see Example 23.4). Can you use Gauss's law to derive this expression as well? Why or why not?

EXERCISE 24.8 Electric field of an infinite charged sheet



What is the electric field a distance d from a thin, infinite nonconducting sheet with a uniform positive surface charge density σ?

SOLUTION An infinite sheet has planar symmetry. From the symmetry I know that the electric field points away from the sheet and that the magnitude of the electric field is the same everywhere (see Section 24.4). I make a sketch of the sheet and the electric field and then draw a Gaussian surface in the form of a cylinder that straddles the sheet (**Figure 24.31**). If the cross section of the cylinder has area A, then the cylinder encloses a piece of the sheet of area A and the enclosed charge is

$$q_{\text{enc}} = \sigma A. \tag{1}$$

The electric flux through the cylindrical part of the Gaussian surface is zero because the field lines are parallel to that surface. The field is perpendicular to the two ends and

Figure 24.31

(Continued)

points outward, however, so the electric flux through those ends is the product of the area of each end, A, and the magnitude of the electric field:

$$\Phi_E = 2EA. \qquad (2)$$

Substituting Eqs. 1 and 2 into Eq. 24.8, I get

$$2EA = \frac{\sigma A}{\epsilon_0}$$

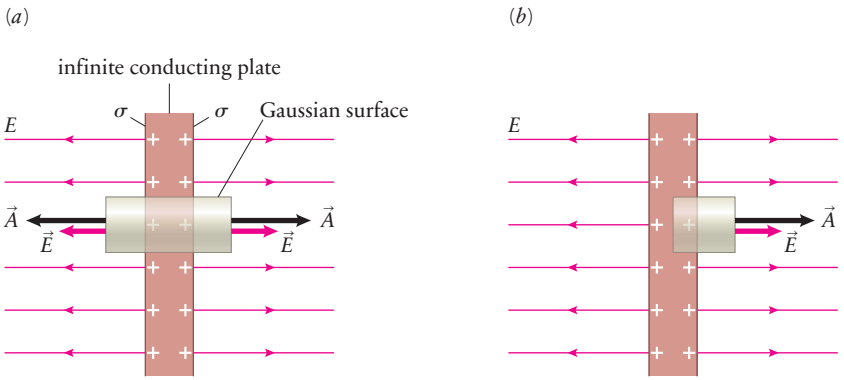
or

$$E = \frac{\sigma}{2\epsilon_0}. \checkmark$$

Because $1/(2\epsilon_0) = 2\pi k$, I can also write this as $E = 2\pi k\sigma$, which is the same result I obtained by direct integration in Example 23.6 for a uniformly charged disk in the limit that I am very close to the disk (which makes the disk appear like an infinite sheet).

The situation is a little different for a *conducting* plate. Consider, for example, the infinite charged conducting plate shown in **Figure 24.32a**. As we saw in Section 24.5, any charge resides on the outside surfaces of the conducting object, so we have to consider the charge on *both* surfaces. If the surface charge density on the plate is σ and we use the same cylindrical Gaussian surface as we did for the nonconducting sheet, then the enclosed charge is not σA but $2\sigma A$ (σA for each of the two surfaces). Then Gauss's law yields

$$\Phi_E = \frac{q_{\text{enc}}}{\epsilon_0} = \frac{2\sigma A}{\epsilon_0}. \qquad (24.16)$$



Substituting Eq. 24.16 into Eq. 2 of Exercise 24.8 yields

$$E = \frac{\sigma}{\epsilon_0} \quad \text{(infinite conducting plate)}. \qquad (24.17)$$

Alternatively, you can choose a cylindrical Gaussian surface that has one end embedded in the plate (Figure 24.32*b*). In that case only one of the two surfaces is enclosed and so the enclosed charge is σA. However, now the electric flux through the left end is zero because $E = 0$ inside the bulk of the plate, so the electric flux through the Gaussian surface is not $2EA$ but EA. Substituting these values into Gauss's law yields again Eq. 24.17.

24.24 (*a*) A very large metal plate of surface area A carries a positive charge q. What is the surface charge density of the plate? What is the magnitude of the field created by the plate? (*b*) A very large, thin nonconducting sheet of surface area A carries a fixed, uniformly distributed positive charge q. What is the surface charge density of the sheet? What is the magnitude of the field created by the sheet?

Figure 24.32 Applying Gauss's law to an infinite charged conducting plate.

QUANTITATIVE TOOLS

Chapter Summary

Electric field lines and electric flux (Sections 24.1–24.3, 24.6)

Concepts **Electric field lines** let us visualize the electric field around any charge distribution. The lines are drawn so that at any point the electric field $\vec{E}$ is tangent to the lines.

The number of electric field lines that emanate from a positively charged object or terminate on a negatively charged object is proportional to the charge carried by the object.

The **field line density** at a given position in an electric field is the number of field lines per unit area that cross a surface perpendicular to the field lines at that position. At every position in a field line diagram, the magnitude of the electric field is proportional to the field line density at that position.

The electric flux through a closed surface depends only on the amount of charge enclosed by the surface. The flux through a closed surface due to charge carriers outside the surface is always zero.

Quantitative Tools The *area vector* $\vec{A}$ associated with a flat surface area has a magnitude A equal to the surface area and is directed normal to the plane of the area.

The **electric flux** Φ_E ($\mathrm{N \cdot m^2/C}$) through a surface due to an electric field $\vec{E}$ is

$$\Phi_E = \begin{cases} \int \vec{E} \cdot d\vec{A} & (24.4) \\ \oint \vec{E} \cdot d\vec{A} \quad \text{(closed surface)}, & (24.5) \end{cases}$$

where $d\vec{A}$ is an infinitesimal surface area segment and $\vec{E}$ is the electric field at that location. If the surface is closed, the direction of $d\vec{A}$ is chosen to point outward.

Gauss's law (Sections 24.4, 24.7)

Concepts A **Gaussian surface** is any closed surface used to apply Gauss's law. When using Gauss's law to determine an electric field, we choose a Gaussian surface such that the electric field is the same (and possibly zero) everywhere along as many regions of the surface as possible.

The electric field outside a uniformly charged spherical shell is the same as the electric field due to a particle that carries an equal charge and is located at the shell center. The shell's contribution to the electric field is zero everywhere inside the shell.

Quantitative Tools **Gauss's law:** The electric flux through a Gaussian surface is

$$\Phi_E = \oint \vec{E} \cdot d\vec{A} = \frac{q_{\text{enc}}}{\epsilon_0}, \tag{24.8}$$

where q_{enc} (the **enclosed charge**) is the sum of all the charge inside the surface, and

$$\epsilon_0 \equiv \frac{1}{4\pi k} = 8.85 \times 10^{-12}\ \mathrm{C^2/(N \cdot m^2)} \tag{24.7}$$

is the **permittivity constant** ($k = 9.0 \times 10^9\ \mathrm{N \cdot m^2/C^2}$, Eq. 22.5).

Calculating electric fields (Sections 24.5, 24.8)

Concepts A Gaussian surface used to determine an electric field should have the same symmetry (spherical, cylindrical, planar) as the symmetry of the charge distribution producing the field. See Figure 24.27 and the Procedure box on page 864.

Quantitative Tools The magnitude of the electric field a distance r from the center of a sphere that has radius $R \geq r$ and contains charge of magnitude q distributed uniformly throughout the sphere volume is

$$E = \frac{1}{4\pi\epsilon_0}\frac{q}{R^3}r = k\frac{q}{R^3}r.$$

The magnitude of the electric field a distance r from an infinite rod having a uniform linear charge density λ is

$$E = \frac{\lambda}{2\pi\epsilon_0 r} = \frac{2k\lambda}{r}.$$

A system in which the distribution of charge does not change is in **electrostatic equilibrium.** The electric field inside a conducting object that is in electrostatic equilibrium is zero. Any surplus charge placed on the object arranges itself at the surface of the object, and the electric field at the surface is perpendicular to the surface. A metal reaches electrostatic equilibrium so quickly that this rearrangement is virtually instantaneous.

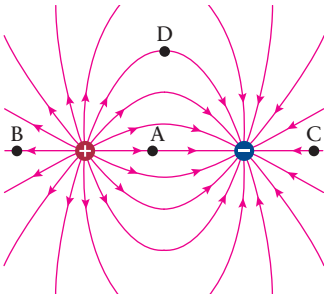
The magnitude of the electric field produced by a nonconducting sheet having a uniform surface charge density σ is

$$E = \frac{\sigma}{2\epsilon_0}.$$

The magnitude of the electric field produced by an infinite conducting plate having a uniform surface charge density σ is

$$E = \frac{\sigma}{\epsilon_0}. \tag{24.17}$$

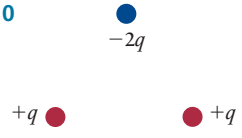
Questions and Problems



For instructor-assigned homework, go to Mastering Physics

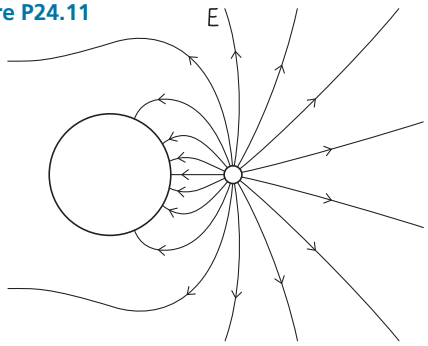
Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

24.1 Electric field lines



1. Suppose a charged particle is located at the origin. What is the direction of the electric field at the point (0.6, 1.2) if the particle is (*a*) positively charged and (*b*) negatively charged? •
2. During an airplane flight let it gets positively charges due to the friction with air and the dust particles. In that situation the flux of electric field into the aircraft is zero, positive or negative? Justify your answer. •
3. Two positive charges having magnitude +q each are separated by a distance 6 mm apart. Compute the electric field at a point located 3 mm: (*a*) on the line joining of the two charges and (*b*) not on the line joining of the two charges. •
4. You and a friend are asked to draw the two-dimensional electric field line pattern for two charged objects located near each other. The charge on the first object is $+2q$ (with q positive), and the charge on the second object is $-q$. You show 32 field lines emanating from the first charge and 16 field lines terminating on the second charge. Your friend shows 24 field lines emanating from the first object and 12 terminating on the second object. Which diagram is correct? •
5. A positively charged test particle is released from rest in a uniform electric field. The only force experienced by the particle is the electric force in that field. (*a*) Describe the trajectory the particle follows. (*b*) How does the trajectory change, if at all, if the particle is given an initial velocity in the direction of the electric field? (*c*) How does the trajectory change if the particle has an initial velocity that makes an angle $\theta \neq 0$ with the electric field? (*d*) Repeat parts *a*–*c* for a negatively charged test particle. ••
6. A certain field line diagram illustrates the electric field due to three particles that carry charges 6.0 μC, -2.0 μC, and -4.0 μC. If twelve field lines emanate from the positively charged particle, how many field lines terminate on each of the negatively charged particles? ••
7. Figure P24.7 shows the electric field produced by an electric dipole. How would a positively charged test particle begin to move when released from rest (*a*) at point A, (*b*) at point B, (*c*) at point C, and (*d*) at point D? Assume that no other objects exert forces on the test particle. (*e*) How does your answer to part *a* change if the test particle has an initial velocity that makes some angle $\theta \neq 0$ with the electric field at A? ••

Figure P24.7

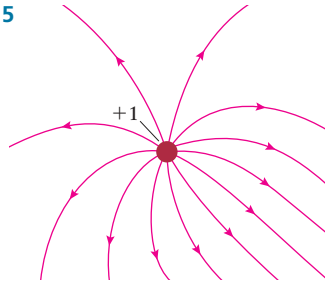


8. Two particles of charge $+q$ are located at opposite ends of one diagonal of a square, and two particles of charge $-q$ are located at opposite ends of the square's other diagonal. Sketch the pattern of electric field lines created, showing eight lines per particle in the plane that contains the square. ••
9. Assume that a test particle is released from rest in an electric field and experiences no forces other than the electric force exerted by that electric field. Does an electric field line passing through the particle's initial position represent the particle's trajectory over time? If not, illustrate with an example. ••
10. Draw several field lines surrounding the three charged particles shown in Figure P24.10. ••

Figure P24.10

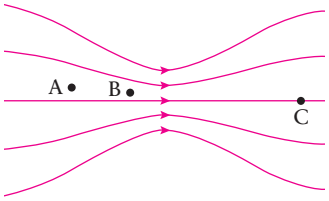
11. Two classmates sitting next to you have made an electric field diagram. You are looking at it (not during a test) to see if they did it correctly, but part of the diagram is covered by a quarter, as shown in Figure P24.11. If your classmates made the diagram correctly, what can you say about the region covered by the quarter? State all the information you can determine about any charged particles in that region. ••

Figure P24.11



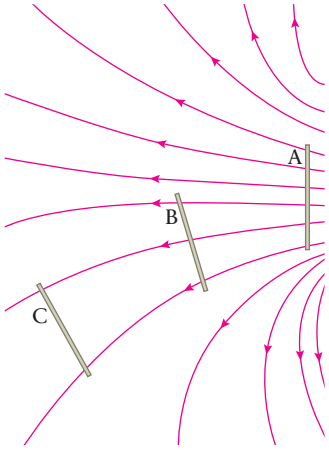
12. Outline an algorithm for a computer program that traces out the electric field lines surrounding a charged object. Assume that functions have already been provided to draw the charged object itself and to draw line segments between pairs of points that your program chooses. •••
13. There are many parallels between gravitational phenomena and electrical phenomena: One can think of a test object with mass in a gravitational field as analogous to a test object with positive charge in an electric field. (*a*) Draw the gravitational field line pattern for the Earth-Moon system, showing arrows on the lines to indicate direction. (*b*) Now consider a system made up of two charged objects. Which type of charge (positive or negative) must each object carry in order to have an electric field line pattern match the gravitational field line pattern that you drew in part *a*? (*c*) Do you see any differences between electrical and gravitational phenomena? •••

24.2 Field line density



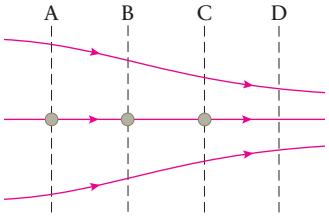
14. A small charged ball is suspended at the center of a spherical balloon that is nestled snugly inside a cubical cardboard box. On one side, the balloon touches the wall of the box. (*a*) At this point of contact, is the electric field magnitude on the balloon surface equal to the electric field magnitude on the box surface? Assume neither object is polarized. (*b*) At this point of contact, is the number of field lines per unit of balloon surface area equal to the number of field lines per unit of box surface area? •
15. Where in Figure P24.15 other than around the point charge is the electric field greatest in magnitude? •

Figure P24.15



16. Consider 500 uniform electric field lines that pass through a hollow tube of length 10 m and cross-sectional area 1m^2. If the tube is cut at the middle in such way the new cross-section makes an angle of 60° with the electric field lines, then compare the area of the two cross-sections. •
17. Consider the pattern of five field lines shown in Figure P24.17. Rank positions A, B, and C according to the magnitude of their electric fields, from greatest to smallest. •

Figure P24.17

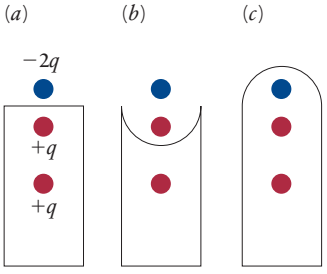


18. Make a geometric argument, based on how the field lines spread out into space, that the magnitude of the electric field surrounding a long, straight, charged wire is proportional to $1/r$, where r is the radial distance from the long axis of the wire. ••
19. An aluminum tube of length 8 m has been uniformly charged with 10 μC of charge. Considering symmetry, estimate the electric field at the geometric center of the tube lying on the axial position. ••
20. Figure P24.20 shows electric field lines due to a distribution of charge (not shown). The labeled regions of space are all equal in size. In which of the labeled regions, A, B, and C, is (*a*) the electric field greatest and (*b*) the electric field smallest? (*c*) How much greater is the largest labeled electric field than the smallest nonzero labeled electric field? ••

Figure P24.20

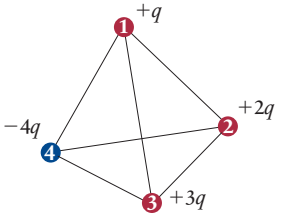
21. Identical charged pellets are released from rest from equidistant starting lines A, B, and C in Figure P24.21, in a region of nonuniform electric field. (*a*) Rank the pellets according to the time interval it takes the pellet on line A to cross line B, the pellet on B to cross C, and the pellet on C to cross D, smallest interval first. (*b*) How does your answer to part *a* change if each pellet is given an identical initial velocity directed upward along lines A, B, and C? ••

Figure P24.21



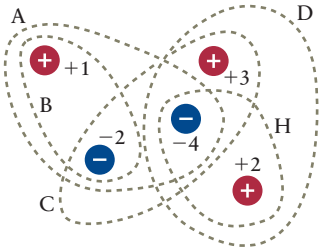
22. You decide to make an electric field line diagram in two dimensions, with 16 lines per coulomb of charge. (*a*) How many lines should you draw surrounding a particle that carries +1.5 C of charge? Should the lines enter or leave that particle? (*b*) Answer the same questions for a particle that carries −0.375 C of charge. (*c*) Could you represent a particle that carries +0.8 C in this diagram? ••
23. Two flat surfaces are near two different charged objects, and the surfaces are identical in size. Surface A has N field lines passing perpendicularly through it. Surface B has only $N/2$ field lines passing through it, and they pass through at an angle 72° from normal. Is the field line density greater near surface A or surface B, and by how much? •••

24.3 Closed surfaces



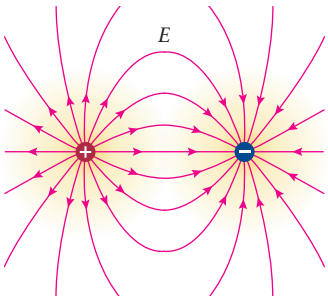
24. A negative charge is located inside the swim ring. Is there any location on the surface of the swim ring where the electric field line flux is positive? •
25. Closed surface A is a sphere of radius R, closed surface B is a sphere of radius $2R$, and closed surface C is a cube with side length R. At the geometric center of each closed surface is a small ball that is completely enclosed by the surface and carries electrical charge $+q$. Assuming there are no other charged objects inside any of the closed surfaces, rank the surfaces according to the electric field line flux through them, largest first. •
26. Three charged pellets are arranged along a line. Three hypothetical closed surfaces are drawn around this set of three pellets. The three surfaces have identical cylindrical walls but different top caps (Figure P24.26). Rank the closed surfaces from smallest to greatest in terms of the electric field line flux through them. •

Figure P24.26



27. In Figure P24.27, assume that a Gaussian surface drawn to surround only sphere 1 would have an electric field line flux of +4. Sketch Gaussian surfaces that contain sphere 1 plus one or more additional spheres and have field line fluxes of (*a*) +24, (*b*) −4, and (*c*) +8. ••

Figure P24.27

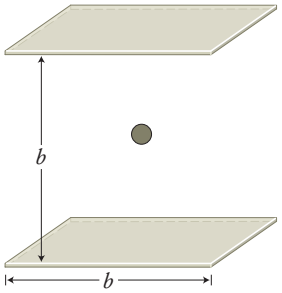


28. In the electric field line diagram for the charge arrangement shown in Figure P24.28, 12 field lines emanate from the object of charge +1 C. What is the field line flux through closed surfaces (*a*) A, (*b*) B, (*c*) C, (*d*) D, and (*e*) H? ••

Figure P24.28

29. In a certain field line diagram, a single electron is drawn that has four field lines terminating on it. If a closed surface in another part of this diagram is shown to have 16 field lines coming out of it, what can be said about the number of charge carriers inside the surface and the type of charge they carry? ••
30. For the dipole in Figure P24.30, can you draw a two-dimensional closed surface through which the field line flux is (*a*) zero, (*b*) +16, (*c*) −16, and (*d*) +3? ••

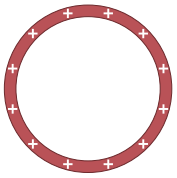
Figure P24.30



31. Make an argument based on Gauss's law that a charged object cannot be held in stable translational equilibrium by electric fields alone. For a start, assume there is no other charged object in the region of interest even though the external electric field can be due to charged objects outside this region. •••
32. The chapter explains that the charge inside a closed surface is proportional to the flux through that surface. To illustrate why the surface must be closed, draw an example of a charge distribution and a surface for which the flux through the surface would be considerably altered if the surface had any holes (unclosed regions of the surface through which flux is not counted). •••

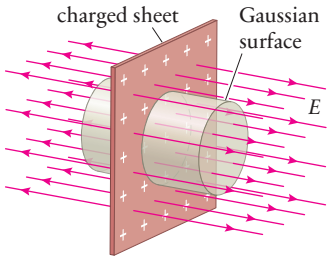
24.4 Symmetry and Gaussian surfaces

33. (*a*) Can you draw a Gaussian surface that offers a simple way to compute the electric field surrounding a charged dipole? (*b*) If not, does this mean that the relationship between field line flux and enclosed charge and the relationship between field line density and magnitude of the electric field do not apply to charged dipoles? •
34. A charge of $+2q$ is enclosed inside a hollow copper sphere having a wall thickness of 5 mm. Compute the electric flux through the copper sphere. •



35. For a charged particle placed at the center of a spherical Gaussian surface, the field line flux through the surface is $+\Phi$. Suppose that the spherical Gaussian surface is replaced by a cubical Gaussian surface composed of six square plates. Square plates are positioned above and below the charged particle to form two sides of the cubical Gaussian surface that is centered on the charged particle, as shown in Figure P24.35. What is the field line flux through each plate? •

Figure P24.35

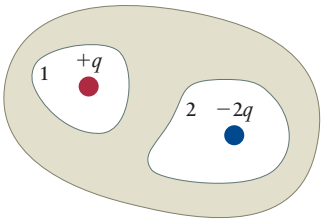


36. Figure P24.36 shows a cross section through an infinitely long, uniformly charged hollow cylinder. How does the magnitude of the electric field vary with the radial distance r from the cylinder's long central axis (a) inside the hole in the cylinder and (b) outside the cylinder? ••

Figure P24.36 Charged hollow cylinder

37. Figure P24.37 shows a cylindrical Gaussian surface straddling a charged sheet. Are there any other shapes that would be convenient for the Gaussian surface in this situation? ••

Figure P24.37



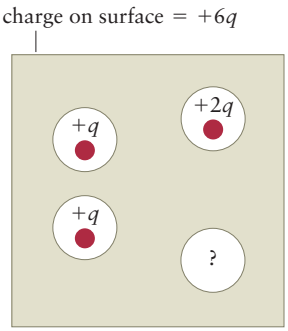
38. Suppose you want to determine the amount of charge on a spherical shell. You start out by surrounding the shell with a cylindrical Gaussian surface. Is it possible to use the flux everywhere on the surface of the cylinder to determine the charge on the spherical shell? Why isn't this recommended in the chapter? ••
39. The magnitude of the electric field a distance R away from a particle carrying charge q is E_0. Now consider this same quantity of charge q distributed uniformly throughout the volume of a nonconducting solid sphere of radius R. What is the electric field magnitude, in terms of E_0, (a) a distance $2R$ from the center of the sphere, (b) at the sphere surface, and (c) a distance $R/4$ from the sphere center? ••
40. You are given a uniformly charged spherical shell that has a radius R and carries a positive charge q. In order to measure the electric field magnitude inside, you drill a small hole that removes 0.01% of the shell's material and insert a probe into the shell. What are the direction and approximate magnitude of the electric field at the shell center? (Hint: The answer is small but not zero.) •••
41. You and your friend are working in a lab and wish to measure the surface charge density on a slab of metal. The slab is very long and very wide, but flat. You begin adding up the field line flux through a cylindrical Gaussian surface that passes through the slab as in Figure P24.37. Your friend begins adding up the field line flux through a cubical Gaussian surface that passes through the slab. Her cube is a little shorter than your cylinder, and it is wider than your cylinder. Will the two of you still obtain the same result for the surface charge density? If so, why? If not, what needs to be changed about your friend's cube? •••
42. You have a hollow spherical shell of radius R that carries a positive charge. The shell is very thin. You make many Gaussian surfaces concentric with the shell to determine the electric field line density at various distances from the center. Qualitatively plot the electric field line density as a function of the distance from the center of the shell. Show regions inside the shell as well as outside. •••

24.5 Charged conducting objects

43. The two-cavity metal object in Figure P24.43 is electrically neutral, but each cavity contains a charged particle as shown. What are (a) the charge on the surface of each cavity and (b) the charge on the outer surface of the object? •

Figure P24.43

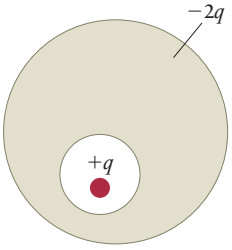
44. Some charged particles are suspended inside a hollow metal object by supports made of a material that is an electrical insulator. The metal object has charge $+q$ distributed over its outer surface and charge $-2q$ distributed over its inner surface. (a) How much charge is suspended in the cavity? (b) What is the charge on the object? (Hint for part b: What is the electric field a very large distance r from the center of the object?) ••
45. Can a car protect the driver and the passengers from an external electric field? (b) Also, justify the need of keeping sophisticated electronic devices enclosed inside a metallic box. ••
46. A *coronal discharge* occurs when the electric field magnitude just above the surface of a conductor exceeds approximately 3×10^6 N/C, a magnitude strong enough to ionize atoms in the air by ripping electrons from them. Coronal discharge is most likely to occur near a sharp tip of a conductor. (This is why solder joints in



electronics must not have sharp protrusions and why it's easier to draw a spark from your fingertip than from your knee after scuffing your feet on a carpet.) (*a*) Make an argument based on the geometry of the field lines emerging from a conducting surface that charge is more likely to concentrate on a convex region of the surface than on a concave region. (*b*) Sketch a paring knife that has a surplus charge on it, and shade the regions where charge is most likely to concentrate on the surface. ••

47. Two concentric spherical metal shells are insulated from each other and from the surroundings. The inner shell carries a charge $+2q$, and the outer shell carries a charge $-q$. In electrostatic equilibrium, what is the charge on (*a*) the outer surface of the inner shell, (*b*) the inner surface of the outer shell, and (*c*) the outer surface of the outer shell? (*d*) The shells are then connected to each other by a metal wire. Do parts *a–c* for the situation obtained after electrostatic equilibrium is reached. ••

48. A small ball carrying a charge $-2q$ is placed at the center of a spherical metal shell that carries a charge $+q$. What are the sign and magnitude of the charge (*a*) on the inner surface of the shell and (*b*) on the outer surface of the shell? (*c*) Do your answers change if the ball is not at the center of the shell? If so, how? ••



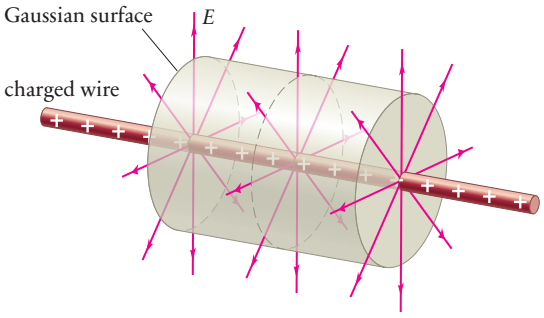
49. Figure P24.49 shows a neutral conducting block with four hollow chambers inside. A charge of $+6q$ has collected on the outer surface of the block. Inside three of the chambers are particles that carry charges $+q$, $-2q$, and $+3q$. Determine the charge inside the fourth chamber in terms of q. ••

Figure P24.49

50. A pellet carrying charge $+q$ is centered inside a spherical cavity that has been cut off-center in a solid metal sphere that carries charge $-2q$ (Figure P24.50). (*a*) How much charge resides on the inner surface of the cavity? Is this charge distributed uniformly or nonuniformly? (*b*) How much charge resides on the outer surface of the metal sphere? Is this charge distributed uniformly or nonuniformly? •••

Figure P24.50

51. A particle carries a charge of $2q$ and is located at the origin. The particle is surrounded by a conducting shell of inner radius R and thickness t. The shell carries a charge of $-3q$. Determine (*a*) the charge on the inner surface of the shell and (*b*) the charge on the outer surface of the shell. (*c*) Make a qualitative plot of the electric field line density as a function of distance from the origin. Be sure to show the field line density in the hollow region, inside the material of the shell, and outside. •••



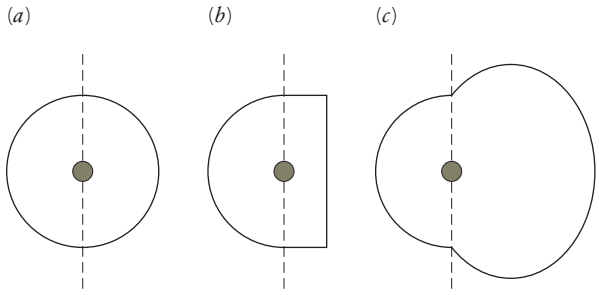
24.6 Electric flux

52. A charge of 35 nC is placed at the center of the rugby ball. Calculate the net flux through the balls surface. Comment on the location on the ball's surface where the electric field is minimum. •

53. A charge of 50 nC is located at the center of a hollow sphere of radius 10 cm. For what radius of the sphere will the electric field line density over the surface be: (*a*) doubled and (*b*) halved? •

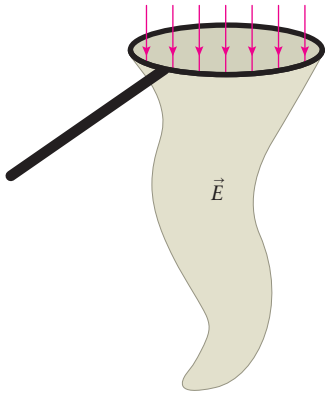
54. Figure P24.54 shows a cylindrical Gaussian surface enclosing a segment of a long charged wire. Consider using a spherical Gaussian surface to enclose the same segment of the wire. (*a*) Which surface, cylindrical or spherical, has the greater electric flux through it? (*b*) Which surface is more appropriate for calculating the electric flux? Justify your answer. •

Figure P24.54



55. A particle carries a charge of 10 μC. Calculate the electric flux through single face if the charge is placed at the geometric center of (*a*) an octahedron and (*b*) a dodecahedron. •

56. Use a symmetry argument to determine the electric flux through a Gaussian surface that encloses both charged particles that form an electric dipole. Does the value calculated for the flux depend on the shape of the surface? ••



57. Figure P24.57 shows a charged particle surrounded by three different closed surfaces, (*a*), (*b*), and (*c*). In each case, the charge on the particle and the geometry of the left side (left of the dashed line) of the surface are identical. The closed surfaces have different geometries to the right of the dashed line. In which case is the flux through the right side of the surface the greatest? In which case is it the smallest? ••

Figure P24.57

58. A butterfly net hangs from a circular loop of diameter 400 mm. You hold the loop horizontally in a region where the electric field is 150 N/C downward, as shown in Figure P24.58. (*a*) What is the electric flux through the net? (*b*) Does the flux through the net increase or decrease if you rotate the loop so that it lies in a vertical plane? ●●

Figure P24.58

59. A particle that carries an unknown amount of charge is placed at the center of a hollow metal sphere of inner radius R_i and outer radius R_o. The magnitude of the electric field outside the sphere at any radial distance r from the center is $3kq/r^2$ (with $q > 0$) and is directed toward the center. The charge on the inner surface of the sphere is $-2q$. What are (*a*) the charge on the particle and (*b*) the charge on the sphere? ●●

60. A small conducting ball that carries a charge of 20.0 nC is located at the center of an electrically neutral hollow conducting spherical shell of inner radius 8 cm and outer radius 10 cm. What is the surface charge density on (*a*) the sphere's inner surface and (*b*) its outer surface? (*c*) Determine the electric flux through three concentric spherical Gaussian surfaces having radii 5 cm, 9 cm, and 11 cm, respectively. ●●

61. A uniformly charged sphere 5 cm in radius carries a charge of 8.0 nC. A thick hollow conducting spherical shell of inner radius 10 cm and outer radius 12 cm having a charge 4.0 nC is concentric with the sphere. (*a*) Calculate the surface charge density on the inner and outer radius of the shell. (*b*) Draw three concentric spherical Gaussian surfaces having radius 8 cm, 11 cm, and 14 cm. What is the electric flux through each of these surfaces? (*c*) Compute the electric flux through a spherical Gaussian surface concentric with the sphere, and having a radius of 2 cm. ●●●

24.7 Deriving Gauss's law

62. Three particles each carrying charge $+q$ are located at the corners of an equilateral triangle of side length a, and the triangle is centered on the origin of a Cartesian coordinate system. What is the electric flux through a spherical Gaussian surface centered at the origin if the radius of the Gaussian surface is (*a*) $a/4$ and (*b*) $2a$? ●

63. A particular closed surface has four sides. The electric flux is $+800\ \text{Nm}^2/\text{C}$ through side 1, $+300\ \text{Nm}^2/\text{C}$ through side 2, and $-1200\ \text{Nm}^2/\text{C}$ through side 3. (*a*) If no surplus charge is enclosed by the surface, what is the flux through side 4? (*b*) If the flux through side 4 is $-400\ \text{Nm}^2/\text{C}$, how much surplus charge is enclosed by the surface? ●

64. Consider a dipole located at the center of a cylindrical Gaussian surface such that the axis of the dipole aligns with the axis of the cylinder. (*a*) Find the total flux through the Gaussian surface. (*b*) Comment on the total flux through the Gaussian surface if the if the dipole is translated in such a way that the negative charge is moved out of the cylindrical surface. ●

65. Consider a rod of length ℓ that carries a uniform charge distribution. Is Gauss's law practical for calculating the electric field at a radial distance r from the midpoint of the rod's length (*a*) when $r \ll \ell$, (*b*) when $r = \ell$, and (*c*) when $r \gg \ell$? For each case in which your answer is yes, describe the shape of the most useful Gaussian surface. ●●

66. Any collection of N charged particles can be divided into N collections each containing one of the particles. Use the superposition property of electric fields to show that the electric flux through any Gaussian surface due to a collection of N charged particles is the sum of the fluxes through the same Gaussian surface produced by the N individual particles. ●●

67. A horizontal rectangular sheet of length ℓ and width w is positioned with its center a vertical distance $w/2$ below an infinitely long positively charged rod that has a uniform linear charge density λ. (*a*) If the sides of length ℓ are parallel to the rod's axis, what is the magnitude of the electric flux through the sheet? (*b*) If the vertical distance between the sheet center and the rod is reduced to $w/4$, does the flux magnitude increase, decrease, or stay the same? ●●

68. A cubical shell with edges of length a is positioned so that two adjacent sides of one face are coincident with the $+x$ and $+y$ axes of a rectangular coordinate system and the corner formed by these two sides is at the origin. (*a*) Sketch the electric field vectors in the region of the shell if an electric field of magnitude $E = bx^2$ directed along the $+x$ axis exists in this region. (*b*) How much charge is contained in the volume of the shell? ●●

69. A cubical Gaussian surface 30 mm on each side is centered on a particle that carries a charge of $+3.0\ \mu\text{C}$. (*a*) If you draw a field line diagram with four field lines per microcoulomb, how many lines pass through the Gaussian surface? In which direction are these lines? (*b*) Ignoring corners and edges, how many field lines pass through each face of the Gaussian surface? (*c*) What is the electric flux through the Gaussian surface? (*d*) What is the electric flux through one face? (*e*) Which of your answers change if the particle is moved 10 mm away from the center of the Gaussian surface? (You don't need to obtain new values for the answers that change, if any.) ●●

70. There is a Gauss's law for gravity analogous to Gauss's law for electricity. (*a*) If the electric flux through a closed surface is proportional to the enclosed charge, what is the gravitational flux proportional to? (*b*) Write an equation for Gauss's law for gravity. ●●

71. A dipole that carries charges $\pm q$ is aligned along the y axis of an xyz rectangular coordinate system, with the midpoint of the dipole at the origin. (*a*) Use Gauss's law to calculate the electric flux through the xz plane, which bisects the dipole and is perpendicular to the dipole moment. (Hint: Calculate the electric flux for each charge separately and apply the principle of superposition.) (*b*) Calculate the flux through the xz plane by integrating the electric field in Eq. 23.8 over the plane. (You'll need to generalize Eq. 23.8 to any point on the xz plane by making the substitution $x^2 \rightarrow r^2 = (x^2 + z^2)$.) (*c*) Which of the two techniques lets you obtain the flux through the xz plane more easily? ●●●

24.8 Applying Gauss's law

72. A positively charged hollow conducting sphere of radius 20 cm has a charge of 10 nC. If the same charge is distributed over the volume of a sphere having the radius 20 cm, compare the magnitude of the electric field at a distance of 1 m for both the hollow and solid spheres. Comment on the result. ●

73. A uniformly charged solid sphere of radius 10 cm has a charge of 5 nC. Determine (*a*) the volume charge density on the sphere, and the electric field, (*b*) 2 cm, and (*c*) 11 cm from the center of the sphere. ●

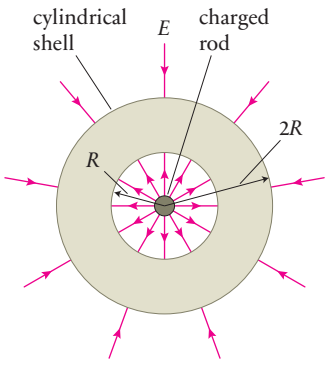
74. A positively charged thin cylindrical shell of length 50 cm and radius 1 mm has no end caps and a uniform surface charge density of 3×10^{-6} C/m^2. (*a*) What is the charge on the shell? Determine the electric field magnitude far from either end of the shell at (*b*) $r = 0.9$ mm and (*c*) $r = 1.1$ mm, where r is the radial distance from the long central axis of the shell. ●

75. An infinitely long positively charged cylindrical shell of radius a has a uniform linear charge density λ_a. An infinitely long cylindrical shell of radius $b > a$ is concentric with the first and has a uniform linear charge density λ_b. (*a*) Determine $\vec{E}$ in all regions. (*b*) If $\lambda_a = +5.0$ nC/m, which type of charge must the shell of radius b carry and what value must λ_b have in order for the electric field to be zero for radial distances $r > b$? (*c*) Sketch the electric field lines for this situation. ●●

76. Two parallel vertical sheets of infinite extent carry surplus charge and are 50 mm apart. Determine the magnitude and direction of the electric field in all regions of space (*a*) when each sheet has a uniform surface charge density $\sigma = +3.0$ nC/m^2 and (*b*) when $\sigma = +3.0$ nC/m^2 for the left sheet and $\sigma = -3.0$ nC/m^2 for the right sheet. (*c*) Draw a diagram showing the sheets and the electric field lines for the situations described in parts *a* and *b*. ●●

77. A long, thin, positively charged wire runs along the long central axis of a hollow conducting cylinder of length 10 m, inner radius 50 mm, and outer radius 70 mm. The wire has a uniform linear charge density of $+1.5$ μC/m, and the cylinder has zero net charge. (*a*) Ignoring the regions near the two ends, calculate the surface charge density on the cylinder's inner and outer surfaces. Again ignoring the ends, determine the electric field magnitude at (*b*) $r = 49$ mm, (*c*) $r = 51$ mm, and (*d*) $r = 100$ mm, where r is the radial distance from the wire. ●●

78. A positively charged nonconducting hollow sphere of outer radius R and inner radius $R/2$ has a uniform volume charge density ρ. Determine the magnitude and direction of the electric field as a function of r, the radial distance from the sphere center. ●●



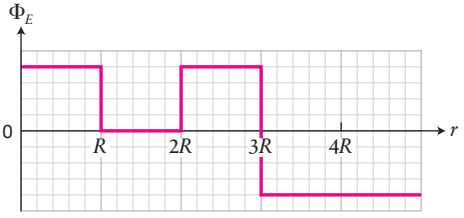
79. A positively charged nonconducting sphere of radius a has a uniform volume charge density ρ_0. It is snugly surrounded by a positively charged thick, nonconducting spherical shell of inner radius a and outer radius b. This thick shell has a volume charge density $\rho_0 r/a$ for $a < r \leq b$. Determine the electric field in all regions as a function of r, the radial distance from the center of the sphere. ●●

80. An infinitely long nonconducting solid cylinder of radius R has a nonuniform but cylindrically symmetrical charge distribution. The volume charge density is given by $\rho(r) = c/r$, where c is a positive constant having units C/m^2 and r is the radial distance from the long central axis of the cylinder. (*a*) What is the charge in a section of the cylinder of length ℓ? Write an expression for the electric field magnitude for (*b*) $r < R$ and (*c*) $r > R$. ●●

81. An infinitely long positively charged wire with a uniform linear charge density $+\lambda$ is parallel to the y axis of a Cartesian coordinate system and passes through the x axis at $x = -d$. At the origin, the electric field due to this charged wire has magnitude E_0 and is directed to the right along the positive x axis. A second infinite charged wire, parallel to the first and with a uniform linear charge density, passes through the x axis at $x = +3d$. The vector sum of the electric field at the origin due to the two lines of charge has magnitude $2E_0$. What is the linear charge density of the second charged wire? Obtain all the possible answers. ●●

82. Figure P24.82 shows a cross section through a system that consists of an infinitely long charged rod centered in a thick cylindrical shell of inner radius R and outer radius $2R$. The shell is made of a conducting material; the rod is made of a nonconducting material and has a uniform linear charge density. The electric field associated with the system is indicated by the field lines in the diagram. For each finite length ℓ of the system, there is a charge of $-q$ on the shell inner surface. For that same finite length ℓ, determine the charge on (*a*) the rod and (*b*) the shell outer surface. (*c*) In length ℓ, what is the charge on the shell? (*d*) What is the ratio of the surface charge density on the shell's inner surface to the surface charge density on the outer surface? ●●

Figure P24.82



83. A positively charged solid non-conducting cylinder of length $\ell = 1$ m and radius $R = 2$ cm has a uniform volume charge density of 9×10^{-6} C/m^3. (*a*) What is the charge inside the cylinder? Avoiding the regions near the ends, determine the electric field magnitude at (*b*) $r = 1$ cm and (*c*) $r = 3$ cm, where r is the radial distance from the long central axis of the cylinder. ●●

84. Three nonconducting infinite sheets are parallel to each other. Each sheet has a uniform surface charge density. Sheet 1 is negatively charged with surface charge density $-\sigma$, and is defined to be the plane $x = 0$. Sheet 2 has an unknown surface charge density and is at a distance of 2.0 m to the right of sheet 1. Sheet 3, negatively charged with surface charge density -3σ, is located further to the right of Sheet 2 at a distance of 2.0 m from sheet 2. The electric field is zero at a point between Sheet 1 and Sheet 2, at a distance of 0.5 m from Sheet 1. (*a*) What is the surface charge density on sheet 2? What is the electric field at (*b*) $x = -1.0$ m, (*c*) $x = 3.0$ m, and (*d*) $x = 7.0$ m? ●●

85. A particle that carries positive charge $+q$ is located at the center of one or more concentric, thick or thin spherical shells. The shells are either made of a conducting material but are electrically neutral or made of a nonconducting material and have uniform surface charge densities. Figure P24.85 is the graph of the electric flux passing through spherical Gaussian surfaces centered on the particle, as a function of radial distance r from the particle. (*a*) What is the minimum number of spherical shells required to produce the graph? (*b*) Describe each shell completely, specifying its charge, its inner and outer radii, and whether it is made of a conducting or nonconducting material. ●●

Figure P24.85

86. Can the graph in Figure P24.85 be produced by a system that consists of only charged particles? If not, explain why not. If so, describe the system that contains the minimum number of charged particles. ●●

87. At what minimal radius along the perpendicular bisector of a wire of length 0.25 m carrying 30 nC of charge does the assumption of cylindrical symmetry in applying Gauss's law give an answer whose error exceeds 5%? ●●

88. An infinitely long positively charged wire carries a uniform linear charge density λ. A charged particle, carrying a charge q, is placed at a distance $2d$ from the wire. (*a*) What is the relation between q and λ so that the magnitude of the electric field at the midpoint between the particle and the wire is pointing toward the charge and has magnitude $2E$, where E is the magnitude of the electric field produced by the wire? (*b*) At what positions is the vector sum of the electric fields generated by the wire and by the particle equal to zero? (*c*) What is the magnitude of the electric field produced by the wire at the locations identified in part (*b*)? (Express your results in terms of E.) ●●

89. The origin of an x axis is placed at the center of a nonconducting solid sphere of radius R that carries a charge q_{sphere} distributed uniformly throughout its volume. A particle that carries an unknown charge q_{part} is located on the x axis at $x = +2R$. The magnitude of the electric field due to the sphere-particle combination is zero at $x = +R/4$ on the x axis. (*a*) What is q_{part} in terms of q_{sphere}? (*b*) At what other locations on the x axis is the electric field zero? ●●●

90. A particle that carries charge $+4q$ is located at the origin of an x axis, and a uniformly charged nonconducting solid sphere of radius R and carrying charge $+q$ is centered at $x = +6R$ on the x axis. (*a*) At what locations on the x axis is the electric field zero? (*b*) If the nonconducting sphere is replaced by a conducting sphere of the same radius and carrying the same charge, would the answers to part *a* change? ●●●

91. The nonuniform volume charge density inside a positively charged solid nonconducting sphere of radius R is $\rho(r) = \rho_0 r/R$, where r is the radial distance from the sphere center. (*a*) Calculate the electric field as a function of r for $r < R$ and $r > R$. Repeat for volume charge densities of (*b*) $\rho(r) = \rho_0(1 - \frac{1}{2}R/r)$ and (*c*) $\rho(r) = \rho_0(1 - R/r)$. ●●●

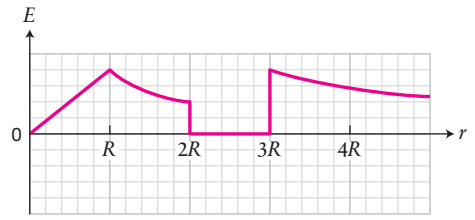
92. A positively charged nonconducting solid sphere of radius R has a nonuniform volume charge density given by ρ_0 for $r \le R/2$ and given by $2\rho_0(1 - r/R)$ for $R/2 \le r \le R$, where r is the radial distance from the sphere center. (*a*) Determine the charge q on the sphere in terms of ρ_0 and R. (*b*) Determine $\vec{E}$ in terms of ρ_0, r, and R. (*c*) Show that the electric field is continuous at the boundaries. ●●●

Additional Problems

93. In electrostatics, the electric field lines are always associated with source charges. If there is no electric field at a particular location in space, can we say that there are no charges surrounding that location? ●

94. Two charges $+q$, each having same mass m, were placed at rest at a distance of 10 cm and 20 cm above an infinite sheet that has been negatively charged with surface density σ. Compare the acceleration of the two charges. ●

95. A particle carrying charge q and having mass m is placed at rest at a distance d above an infinite sheet that has been charged to surface charge density σ. The sheet carries the same type of charge as the particle. What is the velocity of the particle when it is a distance $2d$ above the sheet? ●



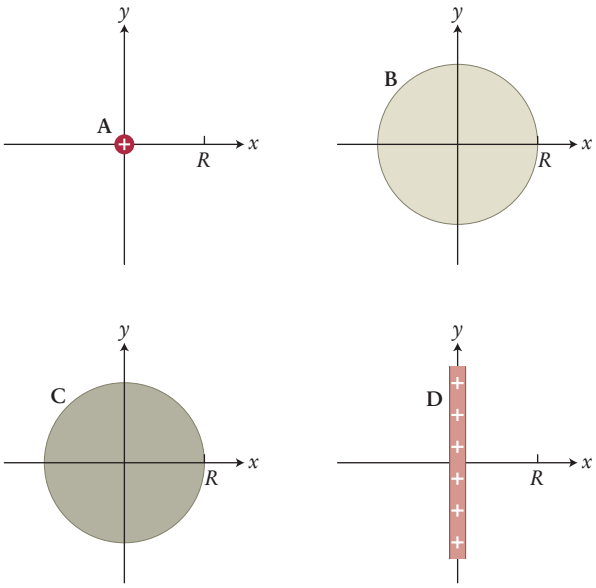
96. Infinite positively charged sheet 1 has uniform surface charge density $\sigma_1 = +4.0$ nC/m^2 and is located in the yz plane of a Cartesian coordinate system. Infinite negatively charged sheet 2 is parallel to sheet 1 and has uniform surface charge density $\sigma_2 = -8.0$ nC/m^2. Sheet 2 is 4 m to the right of sheet 1 along the $+x$ axis. (*a*) Determine the magnitude and direction of the electric field in all regions of space. (*b*) Draw a diagram showing the

locations of the two sheets, labeling the regions and drawing the field lines for each region. ●●

97. A conducting, thick spherical shell of inner radius 100 mm and outer radius 120 mm has no net charge. A particle carrying a 3.0-nC charge is placed at its center. (*a*) Draw the electric field line diagram for the situation, marking the location of all charge on your diagram. (*b*) Calculate the surface charge density at the inner and outer shell surfaces. (*c*) Determine the electric field as a function of *r*, the radial distance from the center of the shell. (*d*) Draw an electric field line diagram for the situation when the particle is displaced by 30 mm from the shell's center. ●●

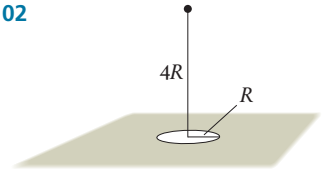
98. A system is composed of two infinitely long concentric cylinders, an outer cylinder O and an inner cylinder I. Each is either conducting or nonconducting, and both have a uniform surface or volume charge density. Cylinder O is a shell, and cylinder I is either solid or a shell. The graph in Figure P24.98 shows the magnitude of the electric field as a function of the radial distance *r* from the long central axis of the concentric cylinders. At all values of *r*, the electric field either is zero or has a nonzero magnitude and is directed away from the long central axis. (*a*) Deduce whether the cylinders are conducting or nonconducting, and give the relevant radii *R* (inner and outer radii for O; either one radius or two for I depending on whether it is solid or a shell) in terms of the general radius *R* shown in the graph. (*b*) What is the ratio of the charge on cylinder I to the charge on cylinder O? ●●

Figure P24.98



99. Near Earth's surface, the electric field has a magnitude of 150 N/C and points downward. Treating Earth's surface as a conducting sphere, calculate the surface charge density necessary to produce this electric field. ●●

100. An electron is fired toward a nonconducting infinite sheet carrying a uniformly distributed charge from 5.00 m away. The electron has an initial speed of 3×10^6 m/s along a line perpendicular to the sheet. The electron reverses its motion when it is 2.00 m away from the sheet. (*a*) What is the surface charge density on the sheet? (*b*) Given the same initial velocity, from what distance should the electron be fired if it is to just reach the sheet? ●●



101. Figure P24.101 shows four charge distributions in an *xyz* coordinate system. A is a charged particle at the origin, B is a charged conducting solid sphere of radius *R* centered at the origin, C is a uniformly charged nonconducting solid sphere of radius *R* centered at the origin, and D is a nonconducting infinite sheet of uniformly distributed charge in the *yz* plane, shown in cross section. In each case the electric field at $x = R$ is the same. Rank the magnitudes of the electric fields for the four cases, largest first, at (a) $x = 2R$ and (*b*) $x = R/2$. ●●

Figure P24.101

102. A positively charged nonconducting infinite sheet that has a uniform surface charge density σ lies in an *xy* plane. As shown in Figure P24.102, a circular region of radius *R* has been cut out of the sheet. (*a*) What is the electric field magnitude at the center of the circle? (*b*) Use superposition to calculate the electric field, both magnitude and direction, at a distance $z = 4R$ above the center of the circle. ●●

Figure P24.102

103. A nonconducting positively charged slab 1 of thickness 2*a* has a nonuniform but symmetrical volume charge density $\rho_0 x/a$. The sheet is centered, at $x = 0$, on the *yz* plane of a Cartesian coordinate system. (*a*) Determine the magnitude and direction of the electric field in all regions of space as a function of *x*, the distance from the *yz* plane. (*b*) A nonconducting charged slab 2, of thickness 2*t*, is placed parallel to sheet 1 such that sheet 2 intersects the *x* axis at $x = d$. Sheet 2 is positively charged and has a uniform volume charge density ρ_0. Determine the electric field in all regions of space as a function of *x*. ●●●

104. A quantity of positive charge is distributed throughout the volume of a long nonconducting rod, which lies on the *z* axis and is centered at $z = 0$. The rod's radius *R* is much smaller than its length ℓ. For positions $r \ll \ell$ and $|z| \ll \ell$, calculate the electric fields inside and outside

the rod as a function of the radial distance r from the rod's long central axis if the volume charge density is (*a*) ρ_0 and (*b*) $\rho_0(1 - 2r/R)$. ●●●

105. You are a crewmember on a space station orbiting Earth. To investigate some physics you remember from college, you drill a small hole all the way through a large solid nonconducting sphere of radius R that has a negative charge q_s evenly distributed throughout its volume, making sure the hole goes through the sphere's center. You then go outside the station with the sphere and release a small pellet carrying positive charge $+q_p$ at one entrance of the hole. You are gratified to observe that the pellet oscillates with the frequency you calculated beforehand based on Gauss's law and your knowledge of simple harmonic motion. What is that frequency? ●●● CR

106. You need to create a uniform electric field in a small region of space, and all you have to work with is one large styrofoam ball that carries a uniform volume charge distribution ρ. You cut the ball into two sections and scoop a hemispherical hole out of each section so that putting the sections back together results in a spherical cavity *off-center* inside the ball. You know that the cavity can be described as a region composed of equal amounts of uniformly distributed positive and negative charge carriers, giving it a charge of zero. You suspect the principle of superposition might be useful. What is the electric field magnitude in the cavity? ●●● CR

107. Electrical power lines are often not insulated, and the magnitude of the electric field of the surrounding air is about 3×10^6 N/C. At greater electric field magnitudes, the air dissociates into charged particles, causing a breakdown and a big spark. You've been given a long sample of wire to test in the lab under electrostatic conditions, and you measure its diameter to be 16.6 mm. You have lots of equipment to produce a uniform linear charge density on the wire sample, and you figure you'd better build in a safety factor of 3 to account for humid days and so forth. What maximum charge density is safe? ●●● CR

108. An infinitely large positively charged nonconducting sheet 1 has uniform surface charge density $\sigma_1 = +130.0\ \text{nC/m}^2$ and is located in the xz plane of a Cartesian coordinate system. An infinitely large positively charged nonconducting sheet 2 has uniform surface charge density $\sigma_2 = +90.0\ \text{nC/m}^2$ and intersects the xz plane at the z axis, making an angle of 30° with sheet 1. (*a*) Draw a diagram showing the end view of the sheets in the xy plane. (*b*) Determine the expression for the electric field in the region between the sheets for positive values of x and y. Calculate the value of the electric field at (3 m, 1 m, 0). ●●●

QUANTITATIVE TOOLS

25.4 Calculating work and energy in electrostatics
25.5 Potential difference
25.6 Electrostatic potentials of continuous charge distributions
25.7 Obtaining the electric field from the potential

As we saw in our study of mechanics, it is often easier to solve problems by using the concepts of energy and work than by using forces. In this chapter we study how to apply energy considerations to electric interactions. Because there are two types of charge—positive and negative—the energy changes associated with changes in charge configurations are a bit more complicated than those associated with changes in gravitational configurations. We first analyze the potential energy associated with a stationary charge distribution and then introduce a new quantity, *potential difference*, that is related to potential energy and that plays an important role in electronics because, unlike potential energy, it can be measured readily.

25.1 Electric potential energy

Figure 25.1 shows the energy changes that occur in closed systems of two charged objects. In Figure 25.1*a*, a positively charged particle is released from rest in the constant electric field of a massive stationary object carrying a negative charge. The attractive electric interaction between the particle and the object accelerates the particle toward the object (assuming that the only interaction is electric), and so the kinetic energy of the system increases. This increase in kinetic energy must be due to a decrease in **electric potential energy,** the potential energy associated with the relative positions of charged objects. As we can see, the electric potential energy of two oppositely charged objects decreases with decreasing separation between the two.

Figure 25.1*b* shows what happens in a system of two objects carrying like charges. In this case the particle is accelerated away from the object, and so the kinetic energy increases and the electric potential energy decreases with *increasing* separation between the two.

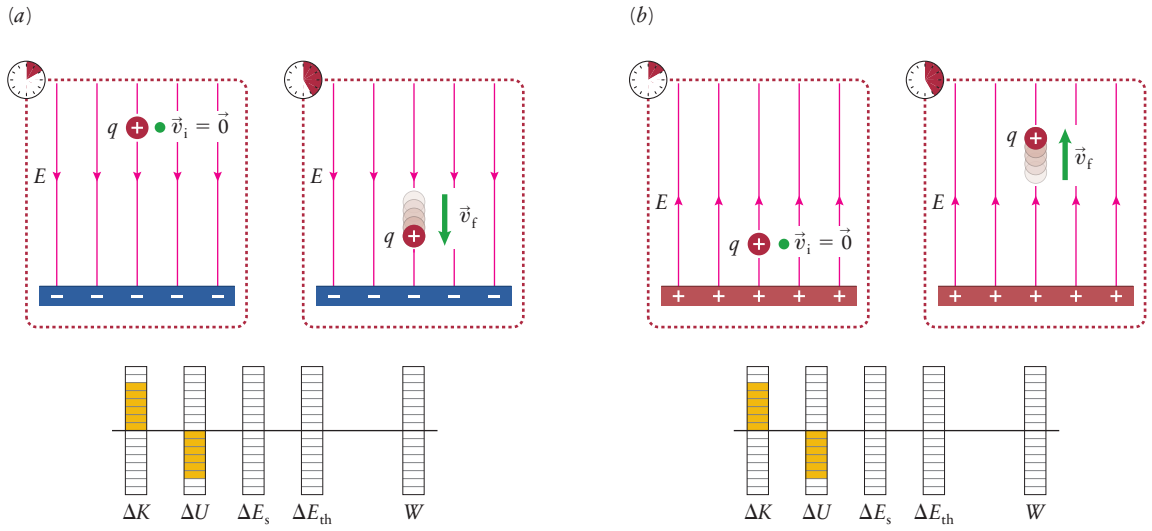
The situation depicted in Figure 25.1*a* is the electric equivalent of free fall. While all objects in free fall near Earth's surface experience the same acceleration, objects in electric fields experience *different* accelerations. Consider, for example, two particles with different masses in free fall near Earth's surface (**Figure 25.2*a*** on the next page). Even though the particle with the greater mass is subject to a greater gravitational force, its acceleration is the same as that of the particle with the smaller mass. The reason is that the particle's inertia (its resistance to acceleration) is equal to its mass (see Chapter 13). Now consider the situation illustrated in Figure 25.2*b*. Two particles carrying the same charge $+q$, but of different mass, are released near the surface of a massive negatively charged object. The electric forces exerted by the negatively charged object on the two particles are equal in magnitude, but because the masses of the two particles are different, the particles' accelerations are different as well.

25.1 Suppose both particles in Figure 25.2*b* are released from rest. Let $m_2 > m_1$ and consider only electric interactions. (*a*) How do their kinetic energies compare after they have both undergone the same displacement? (*b*) How do their momenta compare? (*c*) How do their kinetic energies and momenta compare at some fixed instant after they have been released? (*d*) How would you need to adjust the charges on the particles in order for the two particles to have the same acceleration upon release?

Changes in electric potential energy can also be associated with changes in the orientation of charged objects. Consider, for example, the situation illustrated

CONCEPTS

Figure 25.1 Energy diagrams for closed systems in which a positively charged particle is released from rest near a massive stationary object that carries a (*a*) negative or (*b*) positive charge.



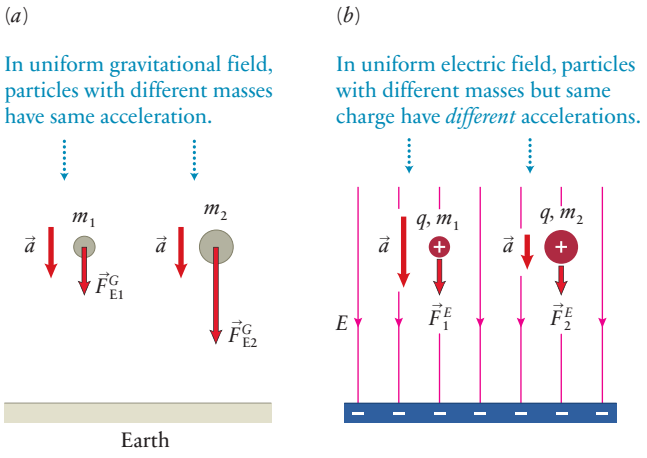


Figure 25.2 The free motion of charged particles in an electric field is different from the free fall of objects in a gravitational field.

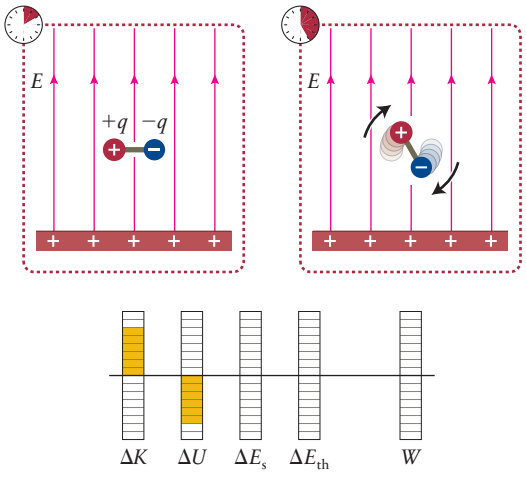
in **Figure 25.3**. An electric dipole is held near the surface of a massive positively charged object. If the electric field of the massive object is uniform, then the dipole begins rotating as shown (see Sections 23.4 and 23.8). As it begins rotating, the dipole gains rotational kinetic energy. This means that the electric potential energy of the system must be changing as the orientation of the dipole changes. This change occurs because the positive side of the dipole gets farther away from the positively charged object, while the negative side gets closer to it; as we've seen, both of these motions correspond to a decrease of electric potential energy.

25.2 As the dipole in Figure 25.3 continues to rotate, it reaches the point where its axis is aligned with the electric field of the massive object. (*a*) What happens to the electric potential energy as the dipole moves beyond that point? (*b*) Describe the motion of the dipole beyond that point. (*c*) How would the motion of the dipole change if it were released with a different orientation from the one shown in Figure 25.3?

Figure 25.3 Energy diagram for a system in which a dipole is released from rest near a positively charged stationary object.



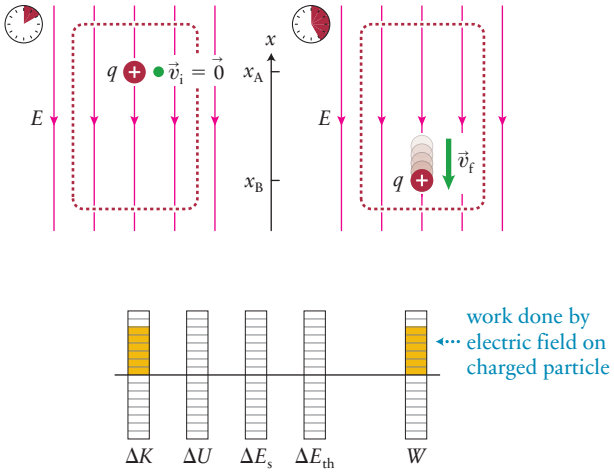


Figure 25.4 Energy diagram for a positively charged particle in the uniform electric field of a stationary, negatively charged object that is not part of the system.

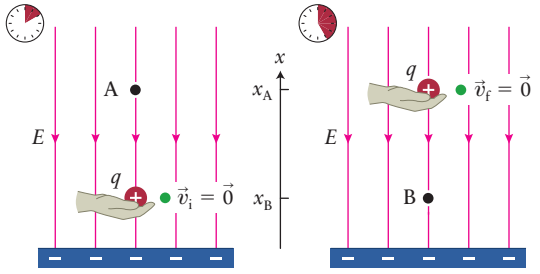


25.2 Electrostatic work

In general, we shall be considering the motion of a charged object through the constant electric field created by other stationary charged objects (such a field is sometimes called an *electrostatic field*). Therefore, our system—the charged object whose motion we are considering—is not closed. The energy of the system is not constant, and we must take into account the work done by the electric field on the system. For example, considering just the particle in Figure 25.1*a* as our system, we obtain the energy diagram shown in **Figure 25.4**. The particle can have only kinetic energy, so its increase in kinetic energy is now due to work done by the electric field on it.

25.3 (*a*) Suppose the particle in Figure 25.4 moves along the x axis from point A at $x = x_A$ to point B at $x = x_B$. How much work is done by the electric field $\vec{E}$ on it? (*b*) Suppose now that an external agent moves the particle back from B to A, starting and ending at rest as shown in **Figure 25.5**. How much work does the electric field do on the particle as it is moved? (*c*) How much work does the agent do on the particle while it is moved? (*d*) What is the combined work done by the agent and by the electric field on the particle as it is moved? (*e*) Draw an energy diagram to illustrate the energy changes of the particle as the agent moves it from B to A.

Figure 25.5 Checkpoint 25.3.

CONCEPTS

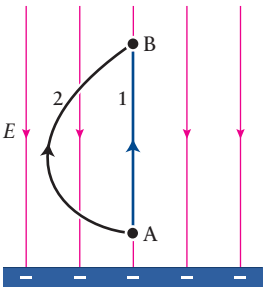
Checkpoint 25.3 illustrates the importance of distinguishing between the work done by the electric field on a charged particle and the work done by the agent moving it. We shall refer to the work done by an electrostatic field as **electrostatic work.** If the particle begins and ends at rest, the electrostatic work is equal in magnitude and opposite in sign to the work done by the agent doing the moving. Then the total work done on the particle—the sum of the electrostatic and mechanical work—is zero. Indeed, the kinetic energy of the particle does not change, and because the particle possesses no other form of energy, its energy remains unchanged: $\Delta E = W = 0$.

Note that the electric force between charged particles, just like the gravitational force, is a central force: Its line of action always lies along the line connecting the two interacting particles (see Section 13.2). A direct consequence of this fact is:

The electrostatic work done on a charged particle as it moves from one point to another is independent of the path taken by the particle and depends on only the positions of the endpoints of the path.

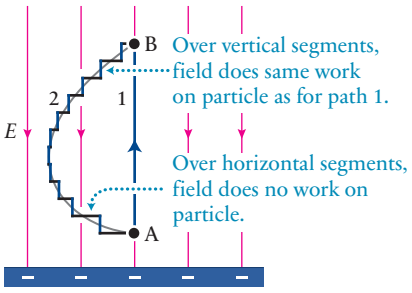
The proof of this statement parallels the one for gravitational forces in Section 13.6. Imagine, for example, lifting a particle from A to B along curved path 2 in **Figure 25.6*a*** instead of along straight path 1. As shown in Figure 25.6*b*, the path can be approximated by small straight horizontal and vertical segments. Along the horizontal segments, the electric force is perpendicular to the force displacement, so the electrostatic work on the particle along these segments is zero. Along the vertical segments, the electrostatic work on the particle is nonzero, but note that each vertical segment corresponds to an equivalent vertical segment on path 1. Thus, the displacements along all the vertical segments of path 2 add up to precisely the displacement along path 1. In other words, the electrostatic work on the particle along path 2 (or any other path from A to B) is equal to that along path 1.

Figure 25.6*c* shows how this argument can be generalized to a nonuniform electric field. Imagine a particle being moved from point A to point C along the gray trajectory in the electric field caused by an object carrying a charge at the origin. We can approximate the trajectory by a succession of small circular arcs centered about the origin and small straight radial segments. The electrostatic work done on the particle along the circular arcs is zero because the force exerted on the particle is perpendicular to the force displacement. The radial segments, on the other hand, contribute to the electrostatic work done on the particle. The sum of all the radial segments, however, is equal to the radial displacement from A to B. Because no electrostatic work is done on the particle along the circular path from B to C, we thus see that the electrostatic work done on the particle along the gray trajectory from A to C is equal to the electrostatic work done along the path from A to B. The electrostatic work done on the particle along *any* path from A to C is thus the same as the electrostatic work done from A to B.



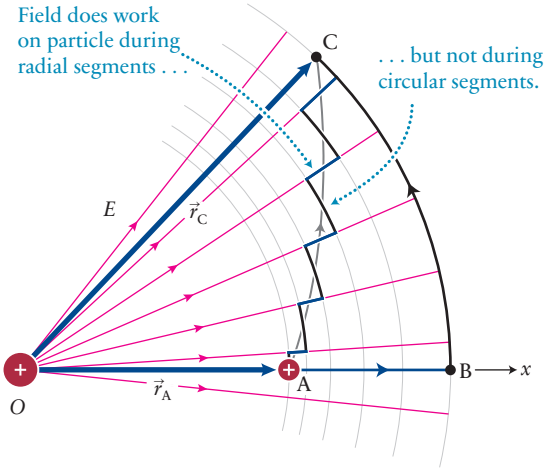
25.4 Suppose the electrostatic work done on a charged particle as it moves along the gray path from A to C in Figure 25.6*c* is W. What is the electrostatic work done on the particle (*a*) along the path from C to B to A and (*b*) along the closed path from A to C to B and back to A?

Checkpoint 25.4 shows that the electrostatic work done on a charged particle that moves around a closed path—*any* closed path—in an electrostatic field is zero.



CONCEPTS

Figure 25.6 The electrostatic work done on a charged particle as the particle moves from point A to point B is independent of the path taken; it depends only on the positions of the endpoints of the path.



(*a*) Two paths by which particle can move from A to B

(*b*) Path 2 approximated by vertical & horizontal segments

(*c*) Same argument applied to nonuniform electric field

We obtained a similar result for the work done by the gravitational force (Eq. 13.17). The physical reason for this result is that the electric force between two charged particles, like the gravitational force between two objects that have mass, is nondissipative: When charged particles are moved around in electrostatic fields, no energy is irreversibly converted to other forms of energy. This is so because the electric interaction is nondissipative.

25.5 (*a*) If the electrostatic work done on a charged particle as it moves around a closed path is zero, does this also mean that the electrostatic work done on the particle is zero as it moves along a piece of the closed path? (*b*) In Checkpoint 25.3*a* we found that the electrostatic work done on the particle is the product of the x components of the electric force and the force displacement. Is the same true for the electrostatic work done on a particle that is moved along path AB in Figure 25.6*c*? (*c*) What happens to this electrostatic work if (*i*) the charge on the particle and (*ii*) the mass of the particle is doubled?

The third part of Checkpoint 25.5 demonstrates a very important point: The electrostatic work done on a charged particle is proportional to the charge carried by that particle. This means that once we have calculated the electrostatic work done on a particle carrying a charge q along some path in an electrostatic field, we don't need to carry out the whole calculation again if we are interested in the electrostatic work done on another particle carrying a charge $2q$. We know that the electrostatic work done on the second particle is twice the electrostatic work done on the first. Thus, if we know the electrostatic work done on a particle carrying a unit positive charge along some path, then we know the electrostatic work done on a particle carrying *any* charge between the same two points! We therefore introduce a new quantity, called **electrostatic potential difference** (or simply **potential difference**), defined as:

The potential difference between point A and point B in an electrostatic field is equal to the negative of the electrostatic work per unit charge done on a charged particle as it moves from A to B.

The potential difference is a scalar, and because the electrostatic work done on a charged particle as it moves from one position to another can be positive or negative, the potential difference can also be positive or negative; the potential difference between any two points B and A is the negative of that between points A and B. It is important to keep in mind that potential difference *is not a form of energy*—it is electrostatic work done per unit charge and therefore has SI units of J/C.

You may be wondering why the potential difference is defined in terms of the *negative* of the electrostatic work done on a particle and not in terms of the energy required to move the particle, which has the opposite sign. The reason is that the energy required to move the particle depends on the change in the particle's kinetic energy. If the particle starts at rest and ends at a nonzero speed, the particle's kinetic energy increases and so the energy required is greater than when it starts and ends at rest. The electrostatic work done on a particle, on the other hand, is independent of any change in the particle's kinetic energy.

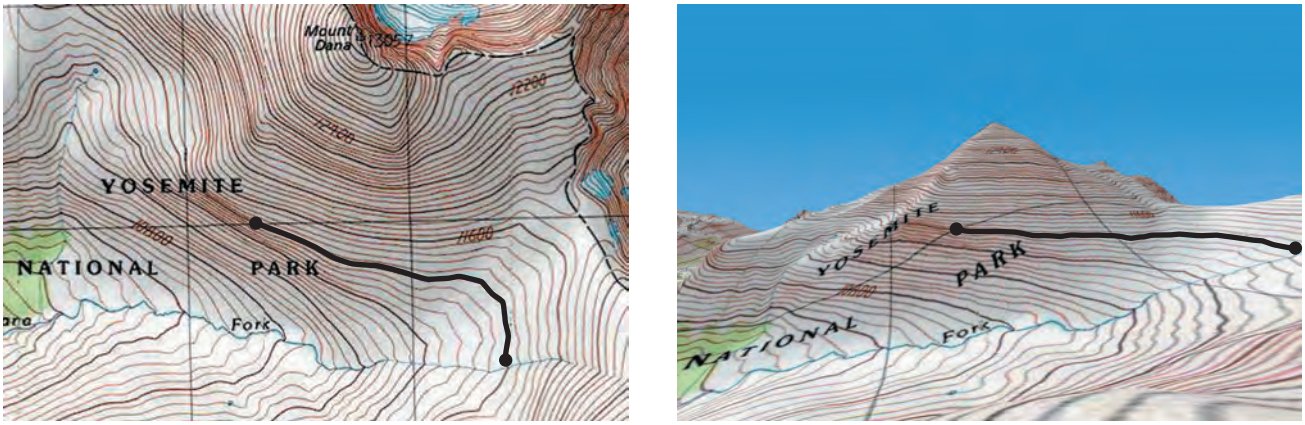
25.6 (*a*) Is the potential difference along any path from A to C in Figure 25.6*c* positive, negative, or zero? (*b*) Along any path from C to B? (*c*) Along the straight path from B to A? (*d*) In Figure 25.4, is the potential difference between the particle's initial and final positions positive, negative, or zero? (*e*) Express this potential difference in terms of the change in the particle's kinetic energy ΔK and its charge q.

In principle, only the potential *difference* between the endpoints of a path is meaningful. We can, however, assign a value to the **potential** at each of these endpoints by choosing a reference point. Specifically, if there is a positive potential difference between points A and B, then A is at a lower potential than B; by assigning a value to the potential at one of the two points, the value of the potential at the other point is fixed. Potential and potential difference, which are immensely useful in solving problems in electrostatics, are discussed in more detail in Section 25.5.

25.3 Equipotentials

As we have seen, the electrostatic work done on a charged particle along the horizontal segments in Figure 25.6*b* and the circular arcs in Figure 25.6*c* is zero. Consequently, the potential difference between any two points on such an arc or horizontal segment is zero. In other words, the potential has the same value at all points along these arcs or segments. Such paths are said to be **equipotential lines:**

An equipotential line is a line along which the value of the electrostatic potential does not change. The electrostatic work done on a charged particle as it moves along an equipotential line is zero.



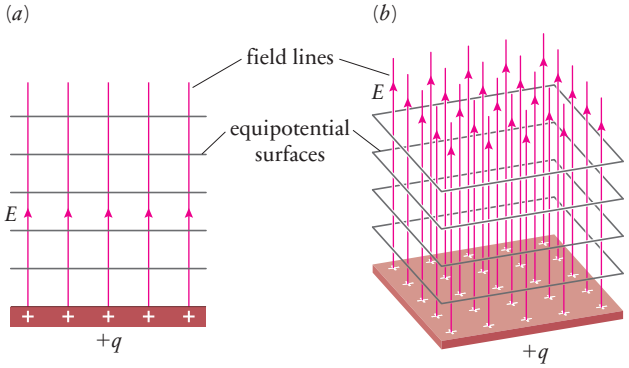
The equipotential lines in Figure 25.6 are much like contour lines on a topographical map. For example, the contour lines in **Figure 25.7** connect points of equal elevation. If you follow a contour line, your elevation remains the same, and so the gravitational potential energy associated with the separation between Earth and your body remains constant. Consequently, no gravitational work is done by Earth on you while you follow contour lines—these lines represent "gravitational equipotential lines."

Returning to the electrostatic case, note that Figure 25.6 is a cross section—a two-dimensional slice of a three-dimensional situation. Thus, the equipotential

CONCEPTS

Figure 25.7 Contour lines on a map are analogous to equipotential lines. If you hike along a contour line, shown in (*a*) two dimensions and (*b*) three dimensions, you neither gain nor lose gravitational potential energy.

(*a*) (*b*)

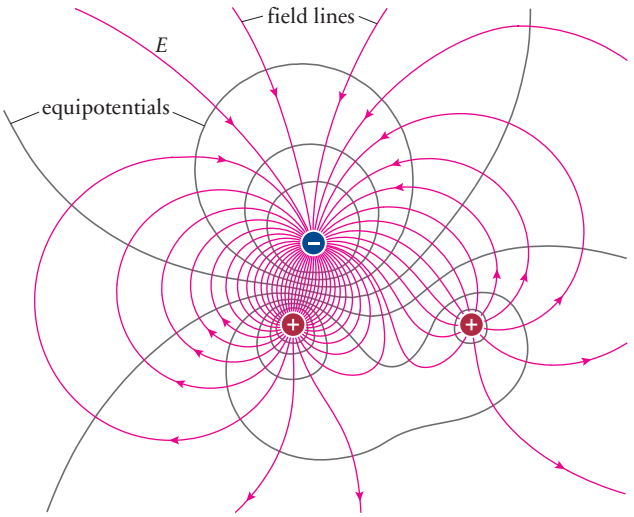


line segments shown are really parts of **equipotential surfaces.** In Figure 25.6*a*, for example, the electrostatic work done on a charged particle is zero along *any* displacement parallel to the surface of the negatively charged object, into or out of the plane of the drawing. Consequently, as shown in **Figure 25.8**, any surface parallel to the surface of the charged sheet causing the electric field is an equipotential surface. Often we'll use the term *equipotential* to denote an equipotential line or surface.

Just as with vector fields and field line diagrams, it is impossible to draw equipotential surfaces at all locations. In general, equipotentials are drawn with some fixed potential difference between them, just as contour lines represent a fixed difference in altitude. Keep in mind, however, that at any point between the equipotential surfaces shown in a figure we can, in principle, draw another equipotential surface.

25.7 Consider a single charged particle. Are there any equipotential lines or equipotential surfaces surrounding this particle?

Figure 25.8 Equipotential surfaces in a uniform electric field in (*a*) two dimensions; and (*b*) three dimensions.



The equipotential surfaces in Figure 25.8 and those in Checkpoint 25.7 are perpendicular to the electric field lines. This is true for *any* stationary charge distribution:

The equipotential surfaces of a stationary charge distribution are everywhere perpendicular to the corresponding electric field lines.

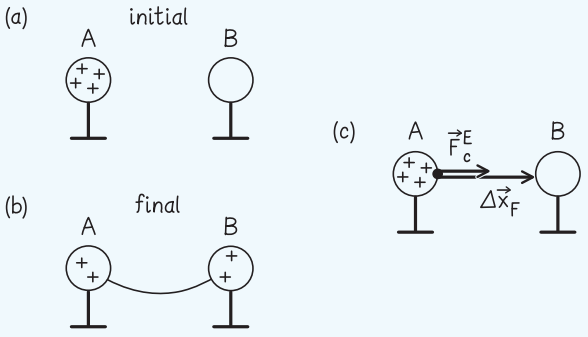
The proof of this statement is straightforward: If the electric field line were not perpendicular to the equipotential surface, then the electric field would have a nonzero component along the surface. This means there would be a nonzero component of electric force along the surface. By definition, however, the electrostatic work done on a charged particle is zero along an equipotential surface, and so there cannot be such a component.

Figure 25.9 shows a two-dimensional view of the equipotential surfaces of a more complicated stationary charge distribution. Note how, at every point in the

Figure 25.9 Field lines and equipotentials for three stationary charged particles.

CONCEPTS

diagram, the equipotentials are, indeed, perpendicular to the field lines.



Recall from Section 24.5 that in electrostatic equilibrium, the electric field inside the bulk of a conducting object is zero, regardless of the shape of the object or any charge carried by it. This means that no electrostatic work is done on a charged particle inside a charged or uncharged conducting object. Thus, the entire volume of the conducting object is an *equipotential volume*. In electrostatic equilibrium, all points within a conducting object are at the same electrostatic potential.

EXAMPLE 25.1 Potential differences

Two metallic spheres A and B are placed on nonconducting stands. Sphere A carries a positive charge, and sphere B is electrically neutral. The two spheres are connected to each other via a wire, and the charge carriers reach a new electrostatic equilibrium. (*a*) Is the electric potential energy of the charge configuration after the spheres are connected greater than, smaller than, or equal to that of the original configuration? (*b*) Before the spheres are connected, is the potential difference between A and B positive, negative, or zero? Is it positive, negative, or zero after the spheres are connected?

1 GETTING STARTED I need to evaluate the electric potential energy—the energy associated with the configuration of charge carriers—and the potential difference—the negative of the electrostatic work per unit charge done on a charge carrier. I begin with two sketches: one showing the charge distribution before the spheres are connected, and one showing the distribution after they are connected (**Figures 25.10*a*** and *b*). Once the spheres are connected, they form one conducting object, and the positive charge initially on A spreads out over both spheres.

Figure 25.10

2 DEVISE PLAN To evaluate the potential difference between A and B, I need to determine the negative of the electrostatic work done on a charged particle as it is moved from A to B and then divide the result by the charge on the particle.

3 EXECUTE PLAN (*a*) After the two spheres are connected, the charge carriers spread out over both spheres, so they are farther apart than they were before the connection was made. Because I know that energy is required to push positively charged particles together, I conclude that the electric potential energy associated with the charge configuration in Figure 25.10*b* is smaller than that associated with the configuration in Figure 25.10*a*. ✔

(*b*) When a positive charge carrier is moved from A to B, the electrostatic work done on the carrier is *positive* because the electric force exerted on the carrier (directed away from sphere A) and the force displacement (from A to B) point in the same direction (Figure 25.10*c*). Consequently, the potential difference between A and B must be negative. ✔

Once the spheres are connected, they form one conducting object. Because the electric field is zero inside the entire object, no energy is required to move charge carriers around inside A and B, or from A to B, or vice versa. Thus, the potential difference between A and B after they are connected is zero. ✔

4 EVALUATE RESULT I know that a closed system always tends to arrange itself so as to lower the system's potential energy (see Section 7.8). It therefore makes sense that the electric potential energy of the system is smaller after the spheres are connected. That the potential difference between A and B is negative before they are connected is a direct consequence of the definition of potential difference. After A and B are connected, they form one large equipotential volume and so it makes sense that the potential difference is zero.

Example 25.1 allows us to make another very useful observation:

An electrostatic field is directed from points of higher potential to points of lower potential.

Because the electric field gives the direction of the force exerted on a positively charged particle, a direct consequence of this fact is:

In an electrostatic field, positively charged particles tend to accelerate toward regions of lower potential, whereas negatively charged particles tend to accelerate toward regions of higher potential.

CONCEPTS

25.8 When you hold a positively charged rod above a metallic sphere without touching it, a surplus of negative charge carriers accumulates at the top of the sphere, leaving a surplus of positive charge carriers at the bottom. Is the potential difference between the top and the bottom of the sphere positive, negative, or zero?

Self-quiz

1. Consider the situation illustrated in **Figure 25.11**. A positively charged particle is lifted against the uniform electric field of a negatively charged plate. Ignoring any gravitational interactions, draw energy diagrams for the following choices of systems: (*a*) particle and plate, $v_f = 0$; (*b*) particle only, $v_f = 0$; (*c*) particle, plate, and person lifting, $v_f = 0$; (*d*) particle and plate, $v_f \neq 0$.
2. A positively charged particle is moved from point A to point B in the electric field of the massive, stationary, positively charged object in **Figure 25.12**. (*a*) Is the electrostatic work done on the particle positive, negative, or zero? (*b*) How is the electrostatic work done on the particle along the straight path from A to B different from the electrostatic work done on the particle along a path from A to B via C?
3. **Figure 25.13** shows both the electric field lines and the equipotentials associated with the given charge distribution. (*a*) Is the potential at point A higher than, lower than, or the same as the potential at point B? (*b*) Is the potential at point C higher than, lower than, or the same as that at point B? (*c*) Is the potential at point C higher than, lower than, or the same as that at point A?

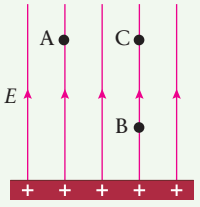

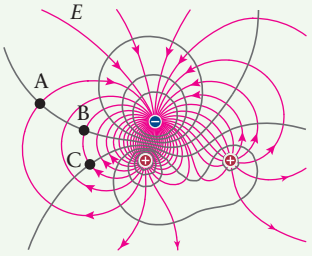

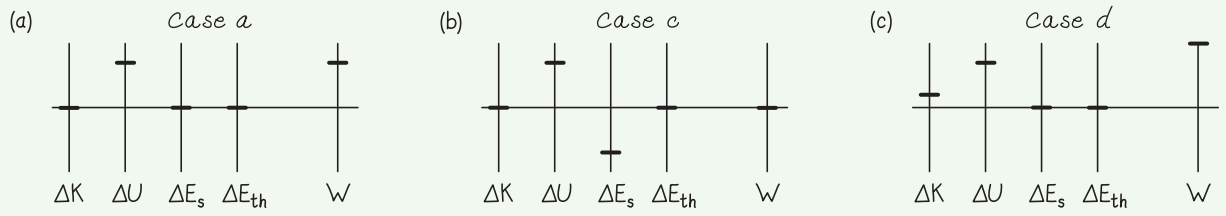

Figure 25.13

Answers

1. Only the person involves the conversion of source energy, so $\Delta E_s = 0$ in cases *a*, *b*, and *d*. When $v_f = 0$, $\Delta K = 0$; in *d*, $v_f \neq 0$ and so $\Delta K > 0$. For case *a*, the electric potential energy of the system increases as a result of positive work done by the agent (hand) on the particle, see **Figure 25.14a**. For case *b*, the (kinetic) energy of the particle alone does not change because the positive work done by the agent on the particle and the negative electrostatic work done on it are equal in magnitude, so all bars are zero. For case *c*, a decrease in the source energy (provided by the agent) is responsible for the increase in electric potential energy of the system (Figure 25.14*b*). For case *d*, the positive work done by the agent increases both the kinetic energy of the particle and the electric potential energy of the system (Figure 25.14*c*).

Figure 25.14

2. (*a*) The electrostatic work done on the particle while it moves from point A to point B is negative because the angle between the force exerted on the particle and the force displacement is between 90° and 180° (see Eqs. 10.35 and 10.33). (*b*) The electrostatic work done along the two paths is the same because the electrostatic work done on a particle between two points is independent of the path taken.
3. (*a*) The same, because these points lie along an equipotential surface. (*b*) Higher. The potential increases in a direction opposite to the direction of the electric field, so point C is at a higher potential than point B. (*c*) Higher. Points A and B are at the same potential, and point C is at a higher potential than point B.

25.4 Calculating work and energy in electrostatics

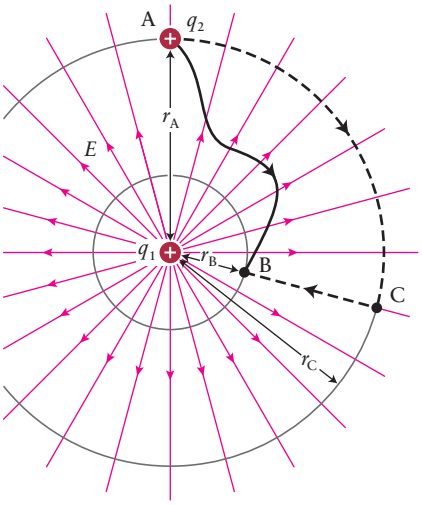

Figure 25.15 The electrostatic work done by particle 1 on particle 2 as the latter is moved from A to B is the same for the meandering solid path and for the dashed path ACB.

To quantify the electrostatic work done on a charged particle, consider charged particles 1 and 2 in **Figure 25.15**. Particle 2 is moved from point A to point B through the nonuniform electric field of particle 1, which is held stationary. The electrostatic work done by particle 1 on particle 2 as it is moved along the solid path from A to B is given by (Eq. 10.44)

$$W_{12}(\mathrm{A}\to\mathrm{B}) = \int_{\mathrm{A}}^{\mathrm{B}} \vec{F}_{12}^{E}\cdot d\vec{\ell}, \tag{25.1}$$

where $\vec{F}_{12}^{E}$ is the electric force exerted by particle 1 on particle 2 and $d\vec{\ell}$ is an infinitesimal vector segment of the path. This line integral (see Appendix B) is generally not easy to calculate because the magnitude of the electric force and the angle between the force and the path segment $d\vec{\ell}$ vary along the path. However, as we saw in Section 25.2, the electrostatic work done on particle 2 along the solid path from A to B in Figure 25.15 is the same as that done along the dashed path from A to C to B. The circular path from A to C is along an equipotential (see Checkpoint 25.7), so the electrostatic work done on the particle along that path is zero. The electric force is given by Coulomb's law (Eq. 22.7). If we take particle 1 to be at the origin, we can write $r_{12} = r$ for the distance between the two particles and $\hat{r}_{12} = \hat{r}$ for the unit vector pointing from particle 1 to particle 2. Along the radial path from C to B, an infinitesimal vector segment of the path can be written as $d\vec{\ell} = dr\,\hat{r}$, and so with $k = 1/(4\pi\epsilon_0)$ (Eq. 24.7), the integrand in Eq. 25.1 becomes

$$\vec{F}_{12}^{E}\cdot d\vec{\ell} = \frac{1}{4\pi\epsilon_0}\frac{q_1q_2}{r^2}\,\hat{r}\cdot(dr\,\hat{r}) = \frac{1}{4\pi\epsilon_0}\frac{q_1q_2}{r^2}\,dr. \tag{25.2}$$

The line integral in Eq. 25.1 thus becomes

$$W_{12}(\mathrm{A}\to\mathrm{B}) = W_{12}(\mathrm{C}\to\mathrm{B}) = \frac{q_1q_2}{4\pi\epsilon_0}\int_{r_C}^{r_B}\frac{1}{r^2}\,dr$$

$$= -\frac{q_1q_2}{4\pi\epsilon_0}\left[\frac{1}{r}\right]_{r_C}^{r_B} = \frac{q_1q_2}{4\pi\epsilon_0}\left[\frac{1}{r_C}-\frac{1}{r_B}\right]. \tag{25.3}$$

The distance from particle 1 to point A is the same as the distance from particle 1 to point C, so we have $r_A = r_C$ and

$$W_{12}(\mathrm{A}\to\mathrm{B}) = \frac{q_1q_2}{4\pi\epsilon_0}\left[\frac{1}{r_A}-\frac{1}{r_B}\right]. \tag{25.4}$$

Generalizing this result to arbitrary initial and final points, we get

$$W_{12} = \frac{q_1q_2}{4\pi\epsilon_0}\left[\frac{1}{r_{12,\mathrm{i}}}-\frac{1}{r_{12,\mathrm{f}}}\right], \tag{25.5}$$

where $r_{12,\mathrm{i}}$ and $r_{12,\mathrm{f}}$ are the initial and final values of the distance separating particles 1 and 2. Note that this expression is independent of the path taken: The electrostatic work done on particle 2 depends on only the distance between the two particles at the endpoints. Equation 25.5 also does not require particle 1 to be at the origin.

QUANTITATIVE TOOLS

25.9 (*a*) Using Eq. 25.5, determine whether the electrostatic work done on particle 2 along path CB in Figure 25.15 is positive, negative, or zero. (*b*) Does moving the particle carrying charge q_2 along path CB involve positive, negative, or zero mechanical work done on the particle? Assume the particle begins and ends at rest; verify the consistency of your answer with part *a*. (*c*) By how much does the electric potential energy of the two charged particles change as particle 2 is moved from C to B? Is this change positive, negative, or zero?

As Checkpoint 25.9 demonstrates, the change in electric potential energy of the system that comprises the two particles in Figure 25.15 is the negative of the electrostatic work done by particle 1 on the system that comprises particle 2 only. (This relationship between electrostatic work and change in electric potential energy can also be seen in Figures 25.1 and 25.4.) Taking the negative of Eq. 25.5, we thus obtain

$$\Delta U^E = \frac{q_1 q_2}{4\pi\epsilon_0}\left[\frac{1}{r_{12,\mathrm{f}}} - \frac{1}{r_{12,\mathrm{i}}}\right]. \tag{25.6}$$

Equation 25.6 gives only the *change* in electric potential energy, not *the* potential energy for a given configuration of charge. To obtain such an expression, we must first choose a zero of potential energy. It is customary to choose this zero to correspond to the configuration for which the force between the interacting particles is zero—that is to say, for infinite separation: $U^E = 0$ when $r_{12} = \infty$. Substituting this choice of reference point for the initial point in Eq. 25.6, we obtain

$$\Delta U^E \equiv U^E_{\mathrm{f}} - U^E_{\mathrm{i}} = U^E_{\mathrm{f}} - 0 = \frac{q_1 q_2}{4\pi\epsilon_0}\left[\frac{1}{r_{12,\mathrm{f}}} - 0\right]. \tag{25.7}$$

Thus, the **electric potential energy** for two particles carrying charges q_1 and q_2 and separated by distance r_{12} is

$$U^E = \frac{q_1 q_2}{4\pi\epsilon_0}\frac{1}{r_{12}} \quad (U^E \text{ zero at infinite separation}). \tag{25.8}$$

As this expression shows, the electric potential energy associated with two positively charged particles is positive: If they are brought together starting from infinite separation, the electric potential energy of the two particles increases. This is as it should be, because the two particles repel each other and so energy must be added to the system to bring it together ($W > 0$). The same idea applies to two negatively charged particles because the product $q_1 q_2$ is still positive. For a system of oppositely charged particles, on the other hand, $q_1 q_2 < 0$ and so $U^E < 0$. Indeed, the interaction is attractive and the potential energy decreases as the two are brought together.

25.10 Suppose we keep particle 2 stationary and move particle 1 in so that their final separation is the same as that in Figure 25.15. Is the electrostatic work done on particle 1 as it is moved in also given by the right-hand side of Eq. 25.4?

EXAMPLE 25.2 Putting two charged particles together

Two small pith balls, initially separated by a large distance, are each given a positive charge of 5.0 nC. By how much does the electric potential energy of the two-ball system change if the balls are brought together to a separation distance of 2.0 mm?

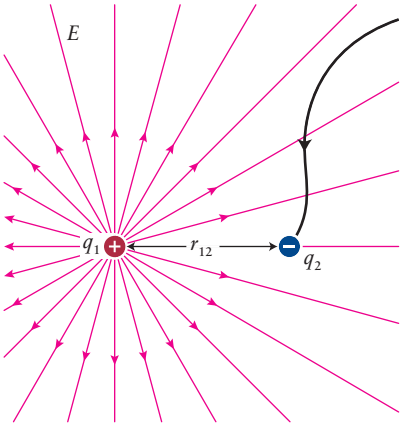
❶ **GETTING STARTED** I am asked to calculate a change in the electric potential energy of a system. I take *large* to mean a separation distance great enough that the balls don't interact. So the initial state is one in which the two pith balls have infinite separation. In the final state they are 2.0 mm apart.

(Continued)

QUANTITATIVE TOOLS

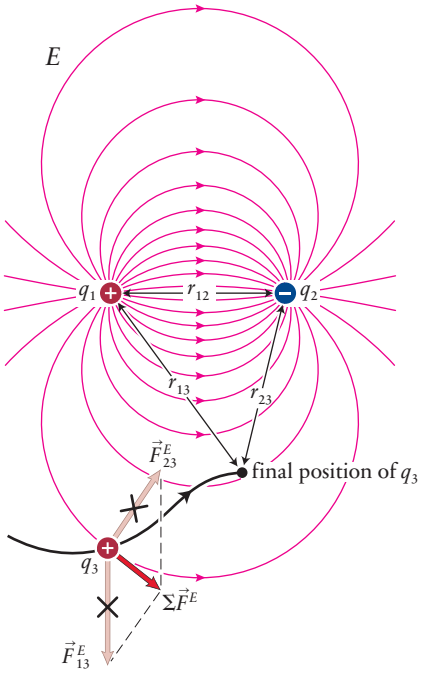
❷ DEVISE PLAN To calculate the change in electric potential energy I can use Eq. 25.6.

❸ EXECUTE PLAN Substituting $q_1 = q_2 = 5.0 \times 10^{-9}$ C, $r_{12,i} \approx \infty$, $r_{12,f} = 2.0 \times 10^{-3}$ m, and $k = 1/(4\pi\epsilon_0) = 9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2$ into Eq. 25.6, I get



$$\Delta U^E = (9.0\times10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)(5.0\times10^{-9}\ \text{C})^2\left[\frac{1}{2.0\times10^{-3}\ \text{m}} - 0\right]$$

$$= 1.1 \times 10^{-4}\ \text{J}.$$



❹ EVALUATE RESULT My answer is positive, which makes sense because the balls repel each other and so work must be done on the system as they are brought together. This work increases the potential energy of the system. The magnitude of the potential energy change is small, but so is the magnitude of the force between the balls: Substituting q_1, q_2, and $r_{12,f}$ into Coulomb's law (Eq. 22.1), I obtain a force magnitude of 0.056 N. This is the maximum force between the two balls, so it makes sense that the energy associated with this interaction is small.

Figure 25.16 To obtain the electrostatic potential energy of a system of three charged particles, we assemble the system one particle at a time.

(*a*) We bring in second charged particle

(*b*) We bring in third charged particle

We can readily generalize the expressions for electrostatic work and electric potential energy for situations involving more than two charged particles. To determine the electric potential energy of a system of three charged particles in a certain configuration, for example, we calculate the electrostatic work done while assembling the system in its final configuration, starting from a situation where all three particles are far apart. Placing the first particle, carrying charge q_1, in its final position involves no electrostatic work because the other two particles are far away and therefore not interacting with particle 1. Next we bring in particle 2, carrying charge q_2, as illustrated in **Figure 25.16a**. The electrostatic work done while moving particle 2 can be found by substituting infinity for $r_{12,i}$ and r_{12} for $r_{12,f}$ in Eq. 25.5:

$$W_{12} = -\frac{q_1 q_2}{4\pi\epsilon_0}\frac{1}{r_{12}}. \tag{25.9}$$

Finally we bring in particle 3, carrying charge q_3, as shown in Figure 25.16*b*. The electrostatic work done while moving particle 3 is given by Eq. 25.1:

$$W_3 = \int_i^f (\Sigma\vec{F}^E_3)\cdot d\vec{\ell}, \tag{25.10}$$

where $\Sigma\vec{F}^E_3$ is the vector sum of the forces exerted on particle 3. Particle 3 is subject to two forces, one exerted by particle 1 and one by particle 2, so

$$\int_i^f (\Sigma\vec{F}^E_3)\cdot d\vec{\ell} = \int_i^f (\vec{F}^E_{13} + \vec{F}^E_{23})\cdot d\vec{\ell}$$

$$= \int_i^f \vec{F}^E_{13}\cdot d\vec{\ell} + \int_i^f \vec{F}^E_{23}\cdot d\vec{\ell} = W_{13} + W_{23}. \tag{25.11}$$

In other words, the electrostatic work done as 3 is moved to its final position is the sum of the electrostatic work done when only 1 is present plus that done when only 2 is present. Now we can apply Eq. 25.5 to each term in Eq. 25.11:

$$W_{13} + W_{23} = -\frac{q_1 q_3}{4\pi\epsilon_0}\frac{1}{r_{13}} - \frac{q_2 q_3}{4\pi\epsilon_0}\frac{1}{r_{23}}. \tag{25.12}$$

The total electrostatic work done on the three-particle system while assembling the charge configuration is the sum of Eqs. 25.9 and 25.12:

$$W = -\frac{q_1 q_2}{4\pi\epsilon_0}\frac{1}{r_{12}} - \frac{q_1 q_3}{4\pi\epsilon_0}\frac{1}{r_{13}} - \frac{q_2 q_3}{4\pi\epsilon_0}\frac{1}{r_{23}}. \tag{25.13}$$

QUANTITATIVE TOOLS

Alternatively, with our choice of zero at infinity, the electric potential energy of the system is

$$U^E = \frac{q_1 q_2}{4\pi\epsilon_0}\frac{1}{r_{12}} + \frac{q_1 q_3}{4\pi\epsilon_0}\frac{1}{r_{13}} + \frac{q_2 q_3}{4\pi\epsilon_0}\frac{1}{r_{23}} \quad (U^E \text{ zero at infinite separation}). \quad (25.14)$$

In words, to determine the electric potential energy of a system of charged particles, we need to add the electric potential energies for each pair of particles.

25.11 Suppose the charged particles in Figure 25.16 are assembled in a different order—say, 3 first, then 1, and finally 2. Do you obtain the same result as in Eq. 25.13 and Eq. 25.14?

25.5 Potential difference

The negative of the electrostatic work per unit charge done on a particle that carries a positive charge q from one point to another is defined as the **potential difference** between those points:

$$V_{AB} \equiv V_B - V_A \equiv \frac{-W_q(A \to B)}{q}. \quad (25.15)$$

Potential difference is a scalar, and the SI units of potential difference are joules per coulomb (J/C). In honor of Alessandro Volta (1745–1827), who developed the first battery, this derived unit is given the name **volt** (V):

$$1\ \text{V} \equiv 1\ \text{J/C}. \quad (25.16)$$

For example, if the electric field in **Figure 25.17** does −12 J of electrostatic work on a particle carrying charge $q_2 = +2.0$ C as it is moved from point A to point B (in other words, it requires +12 J of work by an external agent without the particle gaining any kinetic energy), then the potential difference V_{AB} between A and B is $-(-12\ \text{J})/(2.0\ \text{C}) = +6.0$ V. That is, the potential at B is 6.0 V higher than that at A.

Once we know the potential difference V_{AB} between A and B, we can obtain the electrostatic work done on *any* object carrying a charge q as it is moved along any path from A to B:

$$W_q(A \to B) = -qV_{AB}. \quad (25.17)$$

Keep in mind that the subscripts AB mean "from A to B." Because B is the final position, we write $V_{AB} \equiv V_B - V_A$. So when we refer to the "potential difference between A and B," we always mean the potential at B minus the potential at A.

Potential is important in practical applications because the potential difference between two points can be measured readily with a device called a *voltmeter* (we'll encounter these devices when we discuss electrical circuits in Chapters 31 and 32). In the next chapter we shall discuss the operation of another familiar device, the *battery*, which allows one to maintain a constant potential difference between two points. A 9-V battery, for example, maintains a +9-V-potential difference between its negative and positive terminals. (The positive terminal is at the higher potential, and thus the potential difference is *positive* when going from − to +.) For

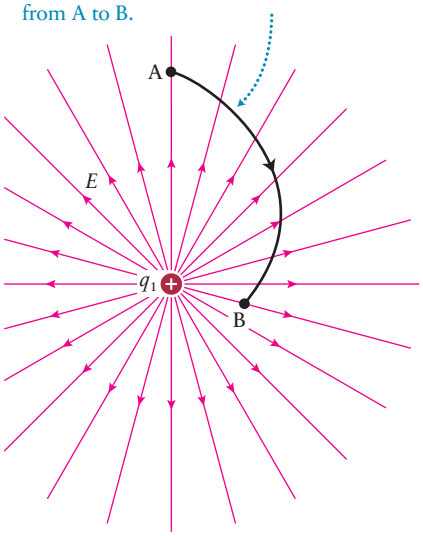


Figure 25.17 Once we know the electrostatic work done by a particle carrying a charge q_1 on a particle carrying a charge q_2 as the latter is moved from A to B in Figure 25.15, we can determine the potential difference between A and B in the electric field of particle 1.

example, when a particle carrying charge +1 C is moved from the negative terminal of a 9-V battery to the positive terminal, the particle undergoes a potential difference $V_{-+} = V_+ - V_- = +9$ V. Equation 25.17 tells us that the electrostatic work done on the particle is equal to

$$W_q(- \rightarrow +) = -qV_{-+} = -(+1\text{ C})(+9\text{ V}) = -9\text{ J}. \quad (25.18)$$

That this quantity is negative indicates that the agent moving the particle must do a positive amount of work on the particle. Likewise, when a particle carrying a charge of −2 C is moved from the − terminal to the + terminal of a 9-V battery, the electrostatic work done on the particle is $-(-2\text{ C})(+9\text{ V}) = +18$ J.

For simplicity, we shall denote the magnitude of the potential difference between the terminals of a battery by V_{batt}. Therefore

$$V_{\text{batt}} = V_+ - V_-. \quad (25.19)$$

Just as with potential energy, only potential *differences* are physically relevant. If we choose a reference point, however, we can determine the value for the potential at any other point. In the preceding section we chose infinity as the reference point for the electric potential energy for charged particles because they do not interact at infinite distance: $U^E(\infty) = 0$. The same choice can be made for the potential, but when we deal with electrical circuits it is customary to assign zero potential to Earth (ground) because Earth is a good and very massive conducting object through which the motion of charge carriers requires negligible energy.

EXERCISE 25.3 Potential and potential difference

The negative terminal of a 9-V battery is connected to ground via a wire. (*a*) What is the potential of the negative terminal? (*b*) What is the potential of the positive terminal? (*c*) What is the potential of the negative terminal if the positive terminal is connected to ground?

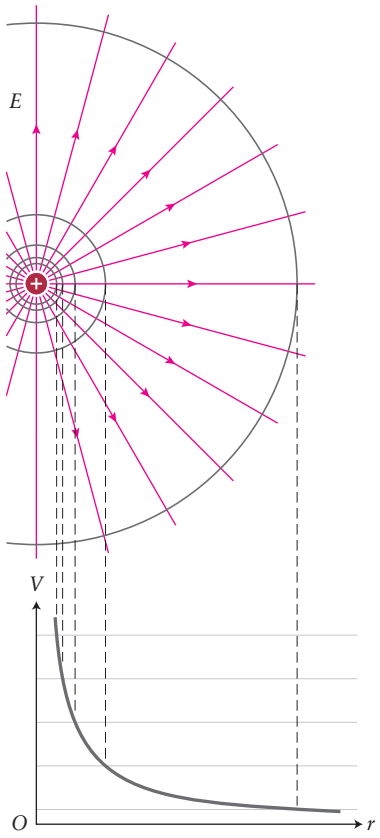
SOLUTION (*a*) I know from Section 25.3 that any conducting objects that are in electrical contact with each other form an equipotential. Once they are in contact, therefore, the ground (which is conducting), the wire, and the negative terminal are all at the same potential. If the potential of the ground is zero (an arbitrary but customary choice), then the potential of the negative terminal is also zero. ✔

(*b*) The potential difference between the negative and positive terminals is +9 V, meaning that the potential of the positive terminal is 9 V higher than that of the negative terminal: $V_{\text{batt}} = V_+ - V_- = +9$ V. If V_- is zero, then the potential of the positive terminal is $V_+ = +9\text{ V} + V_- = (+9\text{ V}) + (0\text{ V}) = +9$ V. ✔

(*c*) With the positive terminal connected to ground, that terminal's potential becomes zero. Because the battery maintains a potential difference of +9 V between the negative and positive terminals, I now have $V_{\text{batt}} = V_+ - V_- = 0 - V_- = +9$ V and so the negative terminal is at a potential of –9 V. ✔

QUANTITATIVE TOOLS

To obtain an explicit expression for the potential difference between two points A and B in the electric field of particle 1 carrying charge q_1, we start with the expression for the electrostatic work done by particle 1 on a particle 2 carrying charge q_2 as it is moved from A to B (Eq. 25.4). All we need to do is add a minus sign and divide by q_2:



$$V_{\text{AB}} \equiv \frac{-W_{12}(\text{A} \rightarrow \text{B})}{q_2} = \frac{q_1}{4\pi\epsilon_0}\left[\frac{1}{r_\text{B}} - \frac{1}{r_\text{A}}\right]. \quad (25.20)$$

For charged particles, the choice of ground as a zero for the potential is not very meaningful. However, if we set the zero for potential at infinity and let r_A be at infinity, we obtain for the potential at a distance $r = r_B$ from a single charged particle

$$V(r) = \frac{1}{4\pi\epsilon_0}\frac{q_1}{r} \quad \text{(potential zero at infinity)}. \tag{25.21}$$

Equation 25.21 confirms that the potential is constant on any spherical surface centered on the charged particle (that is, any surface for which r is constant), as we concluded in Checkpoint 25.7. **Figure 25.18** shows the potential for a charged particle in graphical form. The bottom of the figure shows the $1/r$ dependence of the potential; the top shows a two-dimensional view of the equipotentials around the charged particle. The $1/r$ dependence of the potential is reflected by the increasing spacing of the equipotentials (with a fixed potential difference between them) as r increases.

Figure 25.18 Equipotentials, field lines, and graph of potential for a charged particle.

25.12 (*a*) Using Eq. 25.20, determine whether the potential difference between A and B in Figure 25.17 is positive, negative, or zero. (*b*) From the directions of the electric force and the force displacement, is the electrostatic work done on a positively charged particle as it is moved along a straight path from A to B positive, negative, or zero? Verify that your answer is consistent with the answer in part *a*.

EXAMPLE 25.4 Atomic potential difference

A (simplistic) model of the hydrogen atom treats the electron as a particle carrying a charge $-e$ orbiting a proton (a particle carrying a charge $+e$) in a circle of radius $r_H = 0.53 \times 10^{-10}$ m. (*a*) How much energy is required to completely separate the electron from the proton? For simplicity, ignore the electron's kinetic energy. (*b*) Across what potential difference does the electron travel as it is separated from the proton?

❶ **GETTING STARTED** To completely separate the electron from the proton, I must increase the distance between them from r_H to infinity (at which point their interaction is reduced to zero). By increasing the separation, I increase the potential energy of the electron-proton system. The energy I must add to the system in order to separate the particles is equal to the increase in potential energy of the system.

❷ **DEVISE PLAN** I can calculate the potential energy increase from Eq. 25.6, setting $r_i = r_H$ and $r_f = \infty$. I can obtain the potential difference between the initial and final positions of the electron by taking the negative of the electrostatic work done by the electric field of the proton on the electron during the separation and dividing this value by the charge on the electron.

❸ **EXECUTE PLAN** (*a*) The change in the electric potential energy of the two-particle system is

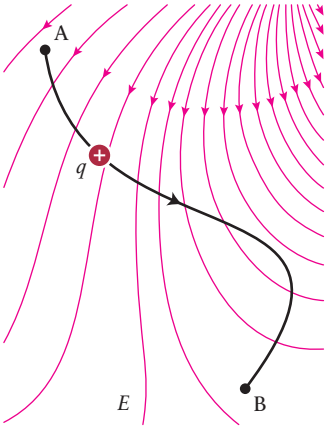
$$\Delta U^E = \frac{q_1 q_2}{4\pi\epsilon_0}\left[\frac{1}{r_f} - \frac{1}{r_i}\right] = \frac{-e^2}{4\pi\epsilon_0}\left[0 - \frac{1}{r_H}\right]$$

$$= (9.0\times10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(1.6\times10^{-19}\ \text{C})^2}{0.53\times10^{-10}\ \text{m}} = 4.3\times10^{-18}\ \text{J}.$$

Because there are no changes in any other forms of energy in the system, the energy required to separate the electron and the proton in a hydrogen atom is 4.3×10^{-18} J. ✔

(*b*) The answer I obtained in part *a* is the mechanical work an external agent must do on the electron to separate it from the proton. I know that the energy of the electron does not change because the electron gains no kinetic energy. Considering just the electron as my system, I thus have $\Delta E = 0$ and so the work done on the electron is zero. This work has two parts: mechanical work done by the external agent and electrostatic work done by the electric field of the proton. Because the sum of these two parts is zero, I know that the electrostatic work done by the electric field of the proton on the electron must be the negative of the mechanical work done by the external agent, so $W_{pe}(r_H \to \infty) = -4.3 \times 10^{-18}$ J. The potential difference is thus (Eq. 25.15)

$$V_{H\infty} = \frac{-W_{pe}(r_H \to \infty)}{q} = \frac{-(-4.3\times10^{-18}\ \text{J})}{-1.6\times10^{-19}\ \text{C}} = -27\ \text{V}. \checkmark$$



❹ **EVALUATE RESULT** The positive sign on ΔU^E in part *a* means that the potential energy of the proton-electron system increases when the two are moved apart. Therefore mechanical work must be done to pull them apart, as I expect because the electron and proton attract each other. The value I obtain is extremely small, but I know that 1 m^3 of matter contains about 10^{29} atoms (see Exercise 1.6), so

(Continued)

the electric potential energy in a cubic meter of matter is on the order of $(10^{28})(4.3 \times 10^{-18}\ \text{J}) \approx 10^{11}\ \text{J}$. In the box "Coherent versus incoherent energy" on page 221 I learned that the amount of chemical energy in a pencil is on the order of 10^5 J. Given that chemical energy is derived from electric potential energy stored in chemical bonds and that the volume of a pencil is about $10^{-5}\ \text{m}^3$, my answer for part *a* is not unreasonable.

For part *b*, I could have used Eq. 25.20 directly. Substituting the values given into that equation, I obtain the same answer, which gives me confidence in the answer I obtained.

Figure 25.19 To determine the potential difference between two points in an electric field, we must evaluate the electrostatic work done on a charged particle as the particle is moved along a path between those points.

To obtain a more general result for the potential difference between one point and another in an arbitrary electric field $\vec{E}$, consider the situation illustrated in **Figure 25.19**. A particle carrying a charge q is moved from point A to point B in an electric field due to some charge distribution (not visible in the illustration). The electrostatic work done on the particle is

$$W_q(\text{A} \to \text{B}) = \int_{\text{A}}^{\text{B}} \vec{F}_q^E \cdot d\vec{\ell}. \tag{25.22}$$

The vector sum of the forces exerted on the particle is equal to the product of the electric field and the charge q (Eq. 23.6):

$$\vec{F}_q^E = q\vec{E}, \tag{25.23}$$

so

$$W_q(\text{A} \to \text{B}) = q\int_{\text{A}}^{\text{B}} \vec{E} \cdot d\vec{\ell}. \tag{25.24}$$

The potential difference between point A and point B is therefore

$$V_{\text{AB}} \equiv \frac{-W_q(\text{A} \to \text{B})}{q} = -\int_{\text{A}}^{\text{B}} \vec{E} \cdot d\vec{\ell}. \tag{25.25}$$

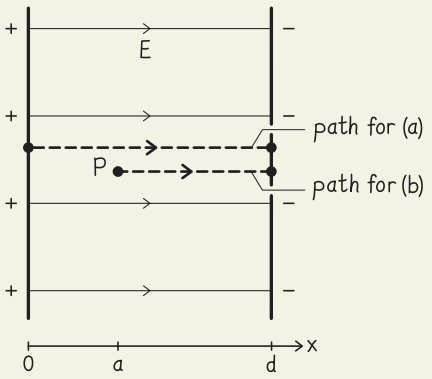
In evaluating this line integral, we must keep in mind that the integral does not depend on the path taken but only on the endpoints. It therefore pays to choose a path that facilitates evaluating the integral. The Procedure box below and the next example will help you gain practice calculating potential differences between two points.

PROCEDURE: Calculating the potential difference between two points in an electric field

The potential difference between two points in an electric field is given by Eq. 25.25. The following steps will help you evaluate the integral:

1. Begin by making a sketch of the electric field, indicating the points corresponding to the two points between which you wish to determine the potential difference.
2. To facilitate evaluating the scalar product $\vec{E} \cdot d\vec{\ell}$, choose a path between the two points so that $\vec{E}$ is either parallel or perpendicular to the path. If necessary, break the path into segments. If $\vec{E}$ has a constant value along the path (or a segment of the path), you can pull it out of the integral; the remaining integral is then equal to the length of the corresponding path (or the segment of the path).
3. Remember that to determine V_{AB} ("the potential difference between points A and B"), your path begins at A and ends at B. The vector $d\vec{\ell}$ therefore is tangent to the path, in the direction that leads from A to B (see also Appendix B).

At this point you can substitute the expression for the electric field and carry out the integral. Once you are done, you may want to verify the algebraic sign of the result you obtained: *negative* when a positively charged particle moves along the path in the direction of the electric field, and *positive* when it moves in the opposite direction.



QUANTITATIVE TOOLS

EXAMPLE 25.5 Electrostatic potential in a uniform field

Consider a uniform electric field of magnitude E between two parallel charged plates separated by a distance d. (*a*) What is the potential difference between the positive plate and the negative plate? (*b*) What is the value of the potential at a point P that lies between the plates and is a distance $a < d$ from the positive plate, if the potential of the negative plate is zero?

❶ **GETTING STARTED** I begin by making a sketch of the two parallel plates and the electric field (**Figure 25.20**). For part *a* I must calculate the potential difference between the positive and negative plates, so I choose a path that begins at the positive plate and ends at the negative plate. For part *b* I am asked to determine, relative to the potential at the negative plate, the potential at a point P located between the plates a distance a from the positive plate, so I choose a path that runs from P to the negative plate. I indicate the endpoints for both paths in my drawing and choose my x axis to be parallel with the electric field with the positive plate at $x = 0$.

Figure 25.20

❷ **DEVISE PLAN** To obtain the potential difference between the endpoints of each path, I apply Eq. 25.25. With my choice of $+x$ axis the $d\vec{\ell}$ vector in Eq. 25.25 becomes $d\vec{\ell} = dx\,\hat{\imath}$. Because $\vec{E} = E\,\hat{\imath}$ I thus have $\vec{E}\cdot d\vec{\ell} = E\,dx$, and because the field is uniform, E is constant. For part *b*, once I have the potential difference between the endpoints of the path from P to the negative plate, I can determine the potential at P because I am told that the potential at the negative plate is zero.

❸ **EXECUTE PLAN** (*a*) Applying Eq. 25.25 to the path from $x_i = 0$ (positive plate) to $x_f = d$ (negative plate), I get

$$V_{0d} = -\int_0^d E\,dx = -E\int_0^d dx = -Ed, \checkmark \qquad (1)$$

where I have pulled E out of the integral because it is constant.

(*b*) If I start the line integral in Eq. 1 at point P, I obtain

$$V(d) - V(a) = -E\int_a^d dx = -E(d-a)$$

or, because $V(d) = 0$,

$$V(a) = E(d-a). \checkmark$$

❹ **EVALUATE RESULT** The negative sign in Eq. 1 means that the potential at the end of the path (that is, at the negative plate) is *lower* than the potential at the beginning (the positive plate). This negative potential difference is in agreement with the sign of the electrostatic work done on a positively charged particle: Positive electrostatic work is done on the particle as it is moved from the positive plate to the negative plate, and so, according to Eq. 25.15, the potential difference should indeed be negative.

My result for part *b* indicates that the potential is positive at $x = a$ $(a < d)$, decreases linearly with the distance a to the positive plate, and goes to zero at $a = d$. That makes sense, because I know that the potential of the positive plate must be higher than that of the negative plate and if $a = d$, I get $V(d) = 0$, as expected.

With an appropriate choice of reference point for the potential, Eq. 25.25 allows us to assign values to the potential at every point surrounding a charge distribution. This "potential field" is related to the electric field: Each can be determined from the other. A drawing that shows a set of equipotentials for a charge distribution is equivalent to a drawing that shows a set of field lines for that charge distribution. In Section 25.7 we shall show how the electric field can be derived from the potential field. The potential field, however, has advantages over the electric field. First, it is a scalar field whereas the electric field is a vector field, and so calculations involving the potential are generally simpler. Second, while no devices exist to measure electric field strength directly, we can measure the potential difference between two points with a voltmeter.

25.13 Verify that Eq. 25.25 is consistent with Eq. 25.20 by substituting the expression for the electric field of a charged particle.

QUANTITATIVE TOOLS

By following the same procedure as in Checkpoint 25.13, we can now obtain the potential for a group of charged particles. Recall that the electric field due to a group of charged particles is equal to the sum of the electric fields of the individual charged particles (Eq. 23.5),

$$\vec{E} = \sum_n \vec{E}_n. \tag{25.26}$$

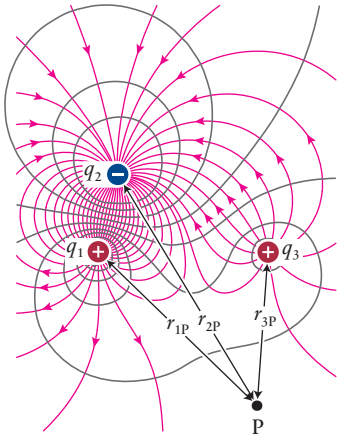
This gives us

$$V_{AB} = \int_A^B \vec{E} \cdot d\vec{\ell} = -\int_A^B \left(\sum_n \vec{E}_n \right) \cdot d\vec{\ell}. \tag{25.27}$$

Because the integral of a sum is equal to a sum of integrals, we have

$$-\int_A^B \left(\sum_n \vec{E}_n \right) \cdot d\vec{\ell} = -\sum_n \int_A^B \vec{E}_n \cdot d\vec{\ell}. \tag{25.28}$$

The line integral after the summation sign is the negative of the potential difference due to the field $\vec{E}_n$, so we see that the total potential difference is the sum of the potential differences caused by the individual particles:



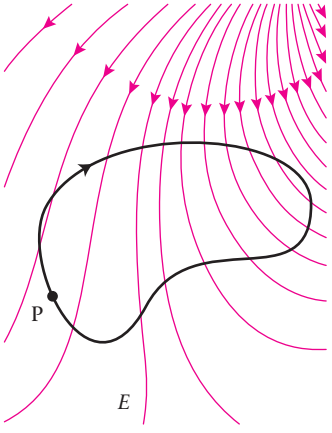
$$V_{AB} = \sum_n V_{AB,n}, \tag{25.29}$$

where $V_{AB,n}$ is the potential difference caused by particle n. Substituting the potential of a single particle, Eq. 25.21, and again letting the potential at infinity be zero, we get

$$V_P = \frac{1}{4\pi\epsilon_0} \sum_n \frac{q_n}{r_{nP}} \quad \text{(potential zero at infinity)}, \tag{25.30}$$

where q_n is the charge carried by particle n and r_{nP} is the distance of particle n from the point P at which we are evaluating the potential (**Figure 25.21**).

Figure 25.21 The potential at point P due to a group of charged particles is the algebraic sum of the potentials at P due to the individual particles.



The line integral on the right in Eq. 25.25 has an important significance. As we argued in Section 25.2, the electrostatic work done on a charged particle moving around a closed path (as in **Figure 25.22**) is zero. Therefore, Eq. 25.24 must yield zero for a closed path:

$$W_q(\text{closed path}) = q \oint \vec{E} \cdot d\vec{\ell} = 0, \tag{25.31}$$

where the circle through the integral sign indicates that the integration is to be taken around a closed path. Because Eq. 25.31 holds for any value of q, we have

$$\oint \vec{E} \cdot d\vec{\ell} = 0 \quad \text{(electrostatic field)}. \tag{25.32}$$

Figure 25.22 The electrostatic work done on a charged particle as the particle is moved around a closed path starting and ending at some point P is zero.

In other words, for any electrostatic field, the line integral of the electric field around a closed path is zero. This is equivalent to saying that you cannot extract energy from an electrostatic field by moving a charged particle around a closed path. In terms of potential, this means that if we start at some point P on the closed path and the potential has a value V_P at that point, then the potential can take on other values as we go around the closed path, but as we return to P, the value of the potential must once again be V_P. As we shall see later in Chapter 30, it *is* possible to get energy out of electric fields, however. Here we have shown only that it is *not* possible to extract energy by moving a charged particle around a

closed path in *electrostatic* fields—that is, those due to stationary charge distributions.

25.14 Describe how the potential varies as you go around the closed path in Figure 25.22 in the direction shown, starting from a potential V_P at P.

25.6 Electrostatic potentials of continuous charge distributions

For extended objects with continuous charge distributions, we cannot use Eq. 25.30 directly to calculate the potential. Instead we must divide the object into infinitesimally small segments, each carrying charge dq_s (which we can treat as a charged particle), and then integrate over the entire object.

Consider, for example, the object shown in **Figure 25.23**. Let the zero of potential again be at infinity. Treating each segment as a charged particle, we calculate its contribution to the potential at P (Eq. 25.21):

$$dV_s = \frac{1}{4\pi\epsilon_0}\frac{dq_s}{r_{sP}}, \tag{25.33}$$

where r_{sP} is the distance between P and dq_s. The potential due to the entire object is then given by the sum over all the segments that make up the object. For infinitesimally small segments, this yields the integral

$$V_P = \int dV_s = \frac{1}{4\pi\epsilon_0}\int\frac{dq_s}{r_{sP}} \quad \text{(potential zero at infinity)}, \tag{25.34}$$

where the integral is taken over the entire object. Note the parallel between this integral and the integral in Eq. 23.15 for calculating the electric field of a continuous charge distribution. Indeed, the procedure for calculating the potential of a continuous charge distribution is very similar to that for calculating the electric field of a continuous charge distribution (see Section 23.7). However, the potential in Eq. 25.34 is much easier to evaluate because it is a scalar and does not involve any unit vectors. The Procedure box below provides some helpful steps in evaluating Eq. 25.34, and the next two examples show how to put the procedure into practice.

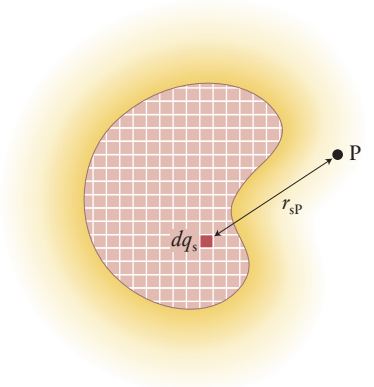


Figure 25.23 The potential due to an extended object is the algebraic sum of the potentials of all the infinitesimally small segments that make up the object.

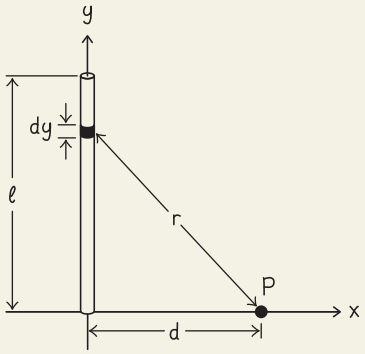
PROCEDURE: Calculating the electrostatic potentials of continuous charge distributions

To calculate the electrostatic potential of a continuous charge distribution (relative to zero potential at infinity), you need to evaluate the integral in Eq. 25.34. The following steps will help you work out the integral:

1. Begin by making a sketch of the charge distribution. Mentally divide the distribution into infinitesimally small segments, each carrying a charge dq_s. Indicate one such segment in your drawing.
2. Choose a coordinate system that allows you to express the position of dq_s in the charge distribution in terms of a minimum number of coordinates (x, y, z, r, or θ). These coordinates are the integration variables. For example, use a radial coordinate system for a charge distribution with radial symmetry. Never place the representative segment dq_s at the origin.
3. Indicate the point at which you wish to determine the potential. Express the factor $1/r_{sP}$, where r_{sP} is the distance between dq_s and the point of interest, in terms of the integration variable(s).
4. Determine whether the charge distribution is one dimensional (a straight or curved wire), two dimensional (a flat or curved surface), or three dimensional (any bulk object). Express dq_s in terms of the corresponding charge density of the object and the integration variable(s).

At this point you can substitute your expressions for dq_s and $1/r_{sP}$ into Eq. 25.34 and work out the integral.



QUANTITATIVE TOOLS

EXAMPLE 25.6 Electrostatic potential of a uniformly charged thin rod

A thin rod of length ℓ carries a uniformly distributed charge q. What is the potential V_P at point P a distance d from the rod along a line that runs perpendicular to the long axis of the rod and passes through one end of the rod?

1 GETTING STARTED I begin by making a sketch. I let the y axis be along the rod, with the origin at the bottom of the rod. Point P then lies on the x axis (**Figure 25.24**). I take the potential at infinity to be zero. What I must calculate is the electrostatic potential V_P at P.

Figure 25.24

2 DEVISE PLAN Because the rod is thin and uniformly charged, I can treat it as a one-dimensional object that has a linear charge density $\lambda = q/\ell$. To determine the electrostatic potential at point P, I divide the rod lengthwise into a large number of infinitesimally small segments, each of length dy. Each segment contributes to the potential at P an amount given by Eq. 25.33. To calculate the potential at P due to the entire rod, I can then use Eq. 25.34 to integrate my result over the entire length of the rod.

3 EXECUTE PLAN Each length segment dy carries a charge $dq_s = \lambda dy = (q/\ell)\,dy$. To calculate the potential at P due to the whole rod, I substitute the distance between each segment dy and P, $r_{sP} = \sqrt{y^2 + d^2}$, and my expression for dq_s into Eq. 25.34 and integrate from the bottom of the rod at $y = 0$ to the top at $y = \ell$:

$$V_P = \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\int_0^{\ell}\frac{dy}{\sqrt{y^2 + d^2}}.$$

Looking up the solution of the integral, I obtain

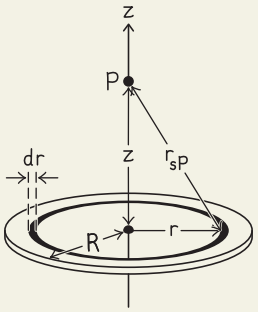
$$V_P = \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\left[\ln(y + \sqrt{y^2 + d^2})\right]_0^{\ell}$$

$$= \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\left[\ln(\ell + \sqrt{\ell^2 + d^2}) - \ln d\right]$$

$$= \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\ln\left(\frac{\ell + \sqrt{\ell^2 + d^2}}{d}\right). \checkmark$$

4 EVALUATE RESULT: If I let ℓ go to zero, my answer should become the same as that for a particle (Eq. 25.21). When $\ell \ll d$, I can ignore the term ℓ^2 in my answer and so the argument of the logarithm becomes $(\ell + d)/d = 1 + \ell/d$. Because $\ln(1 + \epsilon) \approx \epsilon$ when $\epsilon \ll 1$ (see Appendix B), my answer becomes

$$V_P \approx \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\ln\left(\frac{\ell + d}{d}\right) \approx \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\frac{\ell}{d} = \frac{1}{4\pi\epsilon_0}\frac{q}{d},$$



which is indeed equal to the electrostatic potential at a distance $r = d$ from a particle.

EXAMPLE 25.7 Electrostatic potential of a uniformly charged disk

A thin disk of radius R carries a uniformly distributed charge. The surface charge density on the disk is σ. What is the electrostatic potential due to the disk at point P that lies a distance z from the plane of the disk along an axis that runs through the disk center and is perpendicular to the plane of the disk?

1 GETTING STARTED I begin by making a sketch of the disk (**Figure 25.25**). I let the disk be in the xy plane, with the origin at the center of the disk and point P on the z axis.

Figure 25.25

2 DEVISE PLAN Because of the circular symmetry of the disk, I divide it into a large number of thin circular ring segments, each of radius r and thickness dr. All parts of a given ring are the same distance r_{sP} from point P, so each part makes the same contribution to the potential at P. I can therefore calculate the contribution of an entire ring segment to the potential at P using Eq. 25.33, substituting the charge dq_s on the segment and the distance from a point on the segment to P. The charge dq_s on the ring segment is given by the product of its area (circumference times thickness) and the surface charge density: $dq_s = (2\pi r)\,dr\,\sigma$. To calculate the potential at point P due to the entire disk, I can use Eq. 25.34 to integrate my result over the radius of the disk, using r as my integration variable.

3 EXECUTE PLAN: The distance from a point on any ring segment to P is $r_{sP} = \sqrt{z^2 + r^2}$, and so each segment's contribution to the potential is given by

$$dV_P = \frac{1}{4\pi\epsilon_0}\frac{(2\pi r)\sigma\,dr}{\sqrt{z^2 + r^2}}.$$

To calculate the potential at P due to the whole disk, I integrate this expression from $r = 0$ to $r = R$:

$$V_P = \int dV_P = \frac{1}{4\pi\epsilon_0}\int_0^R \frac{2\pi r\sigma}{\sqrt{z^2+r^2}}\,dr.$$

Looking up the solution of the integral, I get

$$V_P = \frac{2\pi\sigma}{4\pi\epsilon_0}\int_0^R \frac{r\,dr}{\sqrt{z^2+r^2}} = \frac{\sigma}{2\epsilon_0}\left(\sqrt{z^2+R^2}-|z|\right). \checkmark$$

4 EVALUATE RESULT When z is very large relative to R, the disk should resemble a particle and my result should reduce to that for a particle (Eq. 25.21). For large $z > 0$ I can use the binomial expansion (see Appendix B) to write the factor in parentheses as

$$\sqrt{z^2(1+R^2/z^2)} - z \approx z\left(1+\tfrac{1}{2}\frac{R^2}{z^2}\right) - z = \tfrac{1}{2}\frac{R^2}{z}.$$

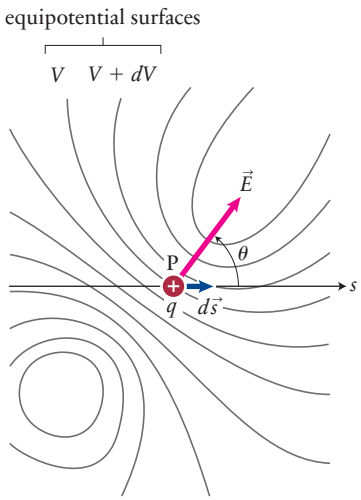
Because $\sigma\pi R^2$ is equal to the charge q on the disk, my expression for V becomes

$$V_P \approx \frac{\sigma}{2\epsilon_0}\left(\tfrac{1}{2}\frac{R^2}{z}\right) = \frac{\sigma\pi R^2}{4\pi\epsilon_0 z} = \frac{1}{4\pi\epsilon_0}\frac{q}{z},$$

which is equal to the result for the potential along a z axis due to a particle located at the origin.

You may have noticed that the two examples above are parallel to corresponding examples in Section 23.7 in which we calculated the electric fields due to a thin charged rod or disk. If you compare the calculations, however, the advantage of working with the potential becomes obvious: Because the potential is a scalar you don't need to take vector sums. Haven't we thrown away some information, though? After all, the answer we get is also just a scalar, not a vector like the electric field. Figure 25.9 gives us some idea of the answer to this question: Because field lines and equipotentials are always perpendicular to each other, you can draw equipotentials if you know the field line pattern or, conversely, draw field lines if you know the equipotentials. It turns out that even though the potential is a scalar and the electric field is a vector, it is possible to determine one from the other.

25.15 Verify that the potentials obtained in Examples 25.6 and 25.7 have the correct sign.



25.7 Obtaining the electric field from the potential

For the potential to be a useful quantity, we must be able to determine the electric field (and therefore the forces exerted by this field) from the potential. For example, let the equipotentials in **Figure 25.26** represent the potential of some charge distribution. How can we use the known potential of the charge distribution to determine the value of the electric field at any point P?

We know that the electric field is perpendicular to the equipotentials, and so the electric field at P must be along the direction indicated in the figure. To determine the magnitude of the electric field, imagine moving a particle carrying a charge q over an infinitesimally small displacement $d\vec{s}$ along some arbitrary axis s. Let the particle be displaced from P, where the potential is V, to a point P′ where the potential is $V + dV$. According to Eq. 25.17, the electrostatic work done on the particle is

$$W_q(\mathrm{P}\to\mathrm{P}') = -qV_{\mathrm{PP}'} = -q(V_{\mathrm{P}'} - V_{\mathrm{P}}) = -q\,dV \qquad (25.35)$$

Figure 25.26 To determine the component of electric field along an axis, we calculate the electrostatic work done on a charged particle as the particle is moved over a short segment along that axis.

because the potential difference between P and P′ is $(V + dV) - V = dV$. On the other hand, we also know that the electrostatic work done on the particle is equal to the scalar product of the electric force exerted on the particle and the force displacement $d\vec{r}_F = d\vec{s}$:

$$W_q(\mathrm{P} \to \mathrm{P}') = \vec{F}_q^E \cdot d\vec{s} = (q\vec{E}) \cdot d\vec{s}$$
$$= q(\vec{E} \cdot d\vec{s}) = qE \cos\theta \, ds, \tag{25.36}$$

where we have assumed that the force displacement is small enough that $\vec{E}$ can be considered constant between P and P′. Note that θ is the angle between $\vec{E}$ and the s axis, so $E \cos\theta$ is the component of the electric field along the s axis. We can write $E \cos\theta = E_s$, and equating the two expressions for the electrostatic work done on the particle, Eqs. 25.35 and 25.36, we get

$$-q \, dV = qE_s \, ds \tag{25.37}$$

or

$$E_s = -\frac{dV}{ds}. \tag{25.38}$$

In other words, the component of the electric field along the s axis is given by the negative of the derivative of the potential with respect to s. The faster V varies (the more closely spaced the equipotentials), the greater the magnitude of the electric field.

Equation 25.38 gives only the component of the electric field along the (arbitrary) axis s. To determine all the components of the electric field, we must repeat this procedure for each of the three Cartesian coordinates:

$$E_x = -\frac{\partial V}{\partial x}, \quad E_y = -\frac{\partial V}{\partial y}, \quad E_z = -\frac{\partial V}{\partial z}. \tag{25.39}$$

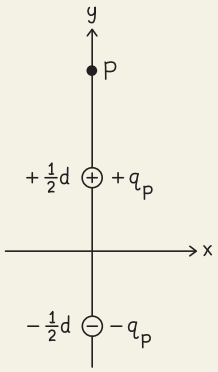
Note the partial derivatives; these are necessary because the function $V(x, y, z)$ depends on all three Cartesian coordinates. When you take the partial derivative with respect to one coordinate, just remember to keep the other coordinates constant. (For example, if $V = x^2y$, then $\partial V/\partial x = 2xy$, $\partial V/\partial y = x^2$, and $\partial V/\partial z = 0$.)

Once the components of the electric field are determined, we can write the electric field in vectorial form:

$$\vec{E} = -\frac{\partial V}{\partial x}\hat{\imath} - \frac{\partial V}{\partial y}\hat{\jmath} - \frac{\partial V}{\partial z}\hat{k}. \tag{25.40}$$

Equation 25.40 then tells us how to obtain the electric field from the potential.

25.16 Apply Eq. 25.40 to the potential you obtained for the uniform field between two parallel charged plates in Example 25.5, and verify that you get the correct expression for the electric field between the plates.



QUANTITATIVE TOOLS

EXAMPLE 25.8 The electrostatic potential and electric field due to a dipole

A permanent dipole consists of a particle carrying a charge $+q_p$ at $x = 0, y = +\frac{1}{2}d$ and another particle carrying a charge $-q_p$ at $x = 0, y = -\frac{1}{2}d$. Use the electrostatic potential at a point P on the axis of the dipole to determine the electric field at that point.

❶ **GETTING STARTED** I begin by making a sketch of the dipole (**Figure 25.27**). I place the dipole along my y axis, with the midpoint of the dipole length at the origin, so that the particles are at the coordinates given in the problem. I choose a point P on the positive y axis, and I let the y coordinate of P be y. Because the two charged particles lie on the y axis, the electric field they create at P must be directed along the y axis.

Figure 25.27

❷ **DEVISE PLAN** The potential at P is the sum of the potentials due to the individual charged particles. To calculate these potentials, I can use Eq. 25.30. Once I have calculated the potential at P, I can use Eq. 25.40 to determine the electric field.

❸ **EXECUTE PLAN** The potential at P is

$$V_P = \frac{1}{4\pi\epsilon_0}\Sigma\frac{q_n}{r_{nP}} = \frac{1}{4\pi\epsilon_0}\left[\frac{+q_p}{y-\frac{1}{2}d} + \frac{-q_p}{y+\frac{1}{2}d}\right]. \quad (1)$$

Now I use this result to determine the electric field. Because I am working with the y axis, I work with the y component of Eq. 25.40:

$$E_y = -\frac{\partial V}{\partial y} = \frac{1}{4\pi\epsilon_0}\left[\frac{q_p}{(y-\frac{1}{2}d)^2} - \frac{q_p}{(y+\frac{1}{2}d)^2}\right]. \checkmark$$

Because the electric field at P is directed along the y axis, the other components of the electric field are zero: $E_x = E_z = 0$. ✔

❹ **EVALUATE RESULT:** This is the same result as in Eq. 23.11. (Remember $k = 1/(4\pi\epsilon_0)$.)

In comparing the derivation in Example 25.8 with the derivation of the electric field in Section 23.6, note that the calculation of the electric field via the potential does not involve any vector addition. The scalar nature of the potential therefore greatly simplifies calculations.

25.17 Calculate the electric field at any point on the axis of a thin charged disk from the potential we obtained in Example 25.7. Compare your answer to the result we obtained by direct integration in Section 23.7.

Chapter Summary

Energy and work (Sections 25.1, 25.2, 25.4)

Concepts **Electric potential energy** is the potential energy associated with the relative positions of charged objects.

The **electrostatic work** done by an electric field on a charged particle as the particle moves from one position to another is independent of the path taken and depends on only the particle's initial and final positions.

The constant electric field created by stationary charged objects is sometimes called an *electrostatic field*.

Quantitative Tools If two particles carrying charges q_1 and q_2 are separated by a distance r_{12}, their **electric potential energy** U^E is

$$U^E = \frac{q_1 q_2}{4\pi\epsilon_0}\frac{1}{r_{12}}, \tag{25.8}$$

where U^E is taken as zero at infinite separation. The electric potential energy of a system of charged particles is the sum of the potential energies of all possible particle pairs. For three particles, the energy is

$$U^E = \frac{q_1 q_2}{4\pi\epsilon_0}\frac{1}{r_{12}} + \frac{q_1 q_3}{4\pi\epsilon_0}\frac{1}{r_{13}} + \frac{q_2 q_3}{4\pi\epsilon_0}\frac{1}{r_{23}}. \tag{25.14}$$

Electrostatic potential (Sections 25.2, 25.3, 25.5)

Concepts The **potential difference** between points A and B in an electrostatic field is equal to the negative of the electrostatic work per unit charge done by the field on a charged particle as it moves from A to B.

An **equipotential surface** is a surface over which the electrostatic potential is constant. The electric field lines associated with a stationary charge distribution are always perpendicular to the equipotential surfaces for the charge distribution. The electrostatic work done on a charged particle moving along an equipotential surface is zero.

An electrostatic field is directed from points of higher potential to points of lower potential. The electric force pushes positively charged particles toward regions of lower potential, whereas it pushes negatively charged particles toward regions of higher potential.

Quantitative Tools If we set the zero of potential at infinity, the potential $V(r)$ at a distance r from a particle carrying a charge q is

$$V(r) = \frac{1}{4\pi\epsilon_0}\frac{q}{r}. \tag{25.21}$$

Potential is measured in **volts:**

$$1\ \text{V} \equiv 1\ \text{J/C}. \tag{25.16}$$

If we set the zero of potential at infinity, the potential at a point P due to a group of n charged particles of charge q_n at distances $r_{n\text{P}}$ from point P is

$$V_\text{P} = \frac{1}{4\pi\epsilon_0}\sum_n \frac{q_n}{r_{n\text{P}}}. \tag{25.30}$$

The work W_q done on a charged particle q by an electric field $\vec{E}$ as the particle moves from point A to point B is

$$W_q(\text{A}\to\text{B}) = q\int_\text{A}^\text{B} \vec{E}\cdot d\vec{\ell}. \tag{25.24}$$

The potential difference V_AB between points A and B due to an electrostatic field $\vec{E}$ is

$$V_\text{AB} \equiv \frac{-W_q(\text{A}\to\text{B})}{q} = -\int_\text{A}^\text{B} \vec{E}\cdot d\vec{\ell}. \tag{25.25}$$

For any electrostatic field,

$$\oint \vec{E}\cdot d\vec{\ell} = 0. \tag{25.32}$$

Continuous charge distributions (Section 25.6)

Quantitative Tools At any point P, the potential due to an extended charged object is

$$V_P = \frac{1}{4\pi\epsilon_0}\int \frac{dq_s}{r_{sP}}, \tag{25.34}$$

where r_{sP} is the distance from the infinitesimal charge element dq_s to P and the integral is taken over the object. (See the Procedure box "Calculating the electrostatic potentials of continuous charge distributions" on page 895.)

If a thin rod of length ℓ carries a uniformly distributed charge q, the potential due to the rod at any point P on a line that runs perpendicular to the rod and passes through either end is

$$V_P = \frac{1}{4\pi\epsilon_0}\frac{q}{\ell}\ln\left(\frac{\ell + \sqrt{\ell^2 + d^2}}{d}\right),$$

where d is the distance from P to the rod.

If a thin disk of radius R carries a uniform surface charge density σ, the potential due to the disk at any point P on a line that runs perpendicular to the plane of the disk and passes through the disk center is

$$V_P = \frac{\sigma}{2\epsilon_0}(\sqrt{z^2 + R^2} - |z|),$$

where z is the distance from P to the disk.

Calculating the electrostatic field from the potential (Section 25.7)

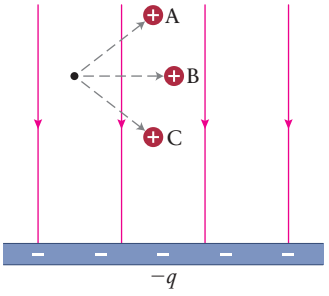
Quantitative Tools If we know the potential due to a charge distribution, we can use the equation

$$\vec{E} = -\frac{\partial V}{\partial x}\hat{\imath} - \frac{\partial V}{\partial y}\hat{\jmath} - \frac{\partial V}{\partial z}\hat{k} \tag{25.40}$$

to calculate the value of the electrostatic field due to the distribution at any point P(x, y, z).

We can also calculate individual components of the electric field from the potential. For example, $E_x = -\partial V/\partial x$ and $E_r = -\partial V/\partial r$.

Questions and Problems



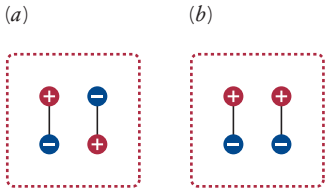
For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

25.1 Electric potential energy

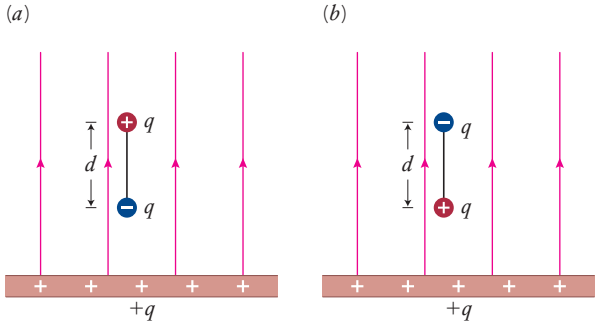
1. What orientation of an electric dipole in a uniform electric field has the greatest electric potential energy? What orientation has the least? (Let the system comprise both the electric dipole and the sources of the uniform electric field.) •
2. Identical positively charged objects A, B, and C are launched with the same initial speed from the same position above a negatively charged sheet that produces a uniform electric field. The directions of the initial velocities are shown in Figure P25.2. Assuming the objects do not interact with one another, rank them in order of their speeds at the instant they reach the sheet, greatest speed first. •

Figure P25.2



3. You release three balls simultaneously from the same height above the floor. The balls all carry the same quantity of surplus positive charge, but they have different masses: 1 kg, 2 kg, and 3 kg. In addition to the gravitational field due to Earth, there is a uniform electric field

directed downward. Assume that the balls are far enough apart that they have negligible influence on one another and that air resistance can be ignored. (*a*) Which ball has the greatest speed when it reaches the floor? (*b*) If all three were negatively charged and at least one will hit the floor, which ball would reach the floor first? ••



4. A proton, a deuteron (a hydrogen nucleus containing one proton and one neutron), and an alpha particle (a helium nucleus consisting of two protons and two neutrons) initially at rest are all accelerated through the same distance in the uniform electric field created by a very large charged plate. Compare their final (*a*) kinetic energies, (*b*) momentum magnitudes, (*c*) speeds, and (*d*) time intervals needed to cover the distance. (*e*) How do the changes in electric potential energy compare? ••
5. A proton, a deuteron (a hydrogen nucleus containing one proton and one neutron), and an alpha particle (a helium nucleus consisting of two protons and two neutrons) initially at rest are all accelerated for the same time interval in the uniform electric field created by a very large charged plate. Compare their final (*a*) kinetic energies, (*b*) momentum magnitudes, (*c*) speeds, and (*d*) distances traveled. (*e*) How do the changes in electric potential energy compare? ••
6. Consider an isolated system of two identical electric dipoles as in Figure P25.6. For which orientation is the electric potential energy smaller? ••

Figure P25.6

7. A dipole carrying charges $+q$ and $-q$ separated by a distance d is rotated 180° in a uniform electric field (Figure P25.7). What is the change in electric potential energy associated with this rotation? (Consider a system comprising both the dipole and the sources of the electric field.) ••

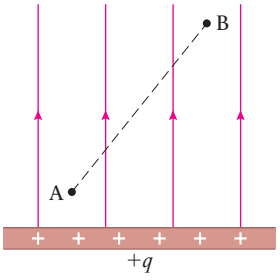


Figure P25.7

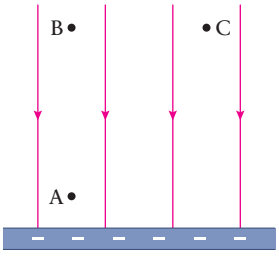
25.2 Electrostatic work

8. In an electrostatic field, path 1 between points A and B is twice as long as path 2. If the electrostatic work done on a negatively charged particle that moves from A to B along path 1 is W_1, how much work is done on this particle if it later goes from A to B along path 2? •
9. A point charge $q_1 = +5.70\ \mu\text{C}$ is fixed at the origin of a coordinate plane. How much electrostatic work is done by the electric force on a second point charge $q_2 = -3.40\ \mu\text{C}$ when it moves from the point $x = 25.0$ cm to the point $x = 37.0$ cm? •
10. A pair of electrons is fixed at certain positions (e_1 at the origin while e_2 is at point *a*) and carries an electric potential energy of 4.8×10^{-5} J. To move the second charge electron to a different location (point *b*) it requires -2.1×10^{-5} J amount of work. Find the electric potential energy of the pair of electrons when the second electron is at point *b*. •
11. Points A and B are on the same electric field line. If an electron is released and moves from A to B, (*a*) is the field directed from A to B or from B to A? (*b*) Is the potential difference between points A and B positive or negative? ••
12. In three separate experiments, an object is moved from point A to point B in the uniform electric field of a large charged plate (Figure P25.12). The object is at rest in both the initial and final positions. Object 1 carries charge $+q$ and has mass m; object 2 carries charge $+q$ and has mass $2m$; object 3 carries charge $-q$ and has mass m. Rank the objects in order of the changes their displacements produce in the electric potential energy of the object-plus-plate system, greatest change first. ••

Figure P25.12

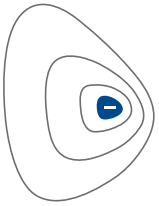


13. Electrostatic work W is done on a charged particle as the particle travels from point A to point B in an electric field. You then apply a force to move the particle back to A, increasing its kinetic energy by an amount equal to $2W$. How much work did you do? ••
14. Points A, B, and C form the vertices of a triangle in a nonuniform electrostatic field. The electrostatic work done on a particle of charge q as the particle travels from A to B is W_{AB}, and that done on the particle as it travels from A to C is $W_{AC} = -W_{AB}/2$. How much electrostatic work is done on the particle as it travels from B to C? ••
15. In the presence of an electrostatic field, you find that you must do positive work on an electron to move it from point A to point B without changing its kinetic energy. (*a*) Considering just the electron as our system, has the system's electric potential energy increased, decreased, or remained the same? (*b*) What if your system consists of

both the electron and the charged particles that are the source of the electrostatic field? (*c*) Is the electrostatic potential difference between A and B positive, negative, or zero? ●●

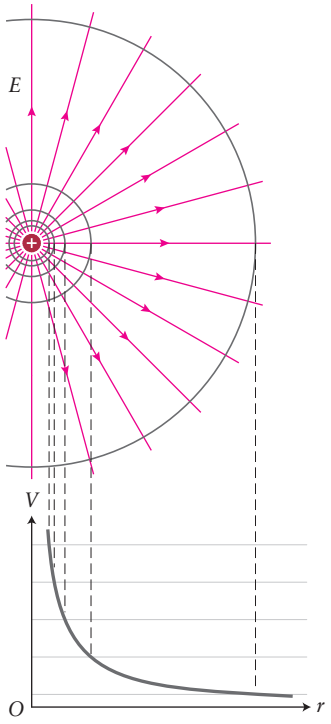
16. In the presence of an electrostatic field, you find that you must do positive work on a proton to move it from point A to point B without changing its kinetic energy. (*a*) Considering just the proton as your system, have you increased, decreased, or left unchanged its electric potential energy? (*b*) What if your system consists of both the proton and the charged particles that are the source of the electrostatic field? (*c*) Is the potential difference between A and B positive, negative, or zero? ●●
17. An electron moves from point A to point B under the influence of an electrostatic field in which the potential difference between A and B is negative. (*a*) If your system includes both the electron and the particles generating the electrostatic field, does the system's electric potential energy increase, decrease, or remain the same? (*b*) Does the electron's kinetic energy increase, decrease, or remain the same? (*c*) How would the answers in parts *a* and *b* change if your system included only the electron? ●●
18. A proton moves from point A to point B under the influence of an electrostatic field in which the potential difference between A and B is negative. (*a*) If your system includes both the proton and the particles generating the electrostatic field, does the system's electric potential energy increase, decrease, or remain the same? (*b*) Does the proton's kinetic energy increase, decrease, or remain the same? (*c*) How would the answers in parts *a* and *b* change if your system included only the proton? ●●
19. Four objects are moved in various ways in the electrostatic field of Figure P25.19. Rank the following motions in order of the amount of electrostatic work done on the object, smallest amount first: (*a*) an object carrying charge $+q$ is moved from A to B, (*b*) an object carrying charge $+q$ is moved from A to C, (*c*) an object carrying charge $+q$ is moved from B to C, (*d*) an object carrying charge $-q$ is moved from A to B. ●●

Figure P25.19



20. Points A, B, C, and D are at the corners of a square area in an electric field, with B adjacent to A and C diagonally across from A. The potential difference between A and C is the negative of that between A and B and twice that between B and D. In terms of the potential difference between A and B, what is the potential difference (*a*) between B and C, (*b*) between C and D, and (*c*) between A and D? ●●●

25.3 Equipotentials

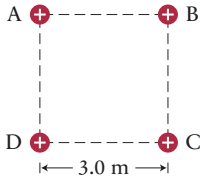


21. Can equipotential lines ever cross? ●
22. Can you draw an equipotential surface through a position where the electric field vanishes? ●
23. Describe the equipotential surfaces associated with an infinitely long charged wire that has a uniform linear charge density. ●
24. Sketch some equipotential lines for the electric field line pattern of an electric dipole. ●●
25. Sketch some electric field lines and equipotential lines associated with two identical charged particles spaced horizontally. ●●
26. Some equipotential lines surrounding a negatively charged object are shown in Figure P25.26, where the potential difference between any two adjacent lines is the same. (*a*) In which region is the electric field magnitude greatest? (*b*) What is the direction of the electric field in that region? (*c*) Which equipotential line has the greatest potential? ●●

Figure P25.26

27. You determine that it takes no (net) electrostatic work to move a charged object from point A to point B along a particular path. (*a*) Can you conclude that A and B are on the same equipotential surface? (*b*) Can you say that the path is part of an equipotential surface that includes A and B? Justify your answers. ●●
28. Figure P25.28 shows that the spacing between equipotential surfaces surrounding a charged particle increases with radial distance r away from the particle. (*a*) How would the potential have to depend on r in order to make the spacing between equipotential surfaces uniform? (*b*) How would the electric field depend on r in that case? ●●

Figure P25.28



25.4 Calculating work and energy in electrostatics

29. Particle A, located at the origin, carries a charge of 6.0 nC. (*a*) What is the electrostatic potential (relative to zero potential at infinity) at a position $r = 8.0$ cm from particle A? (*b*) With particle A held in place, how much work must be done by an external force to bring particle B, also carrying a 6.0-nC charge, from infinity to a distance $r = 8.0$ cm from particle A? (*c*) Particle B is returned to infinity, and particle A is moved to $r = 8.0$ cm and held there. How much work must be done by an outside agent to bring particle B from infinity to the origin? •

30. An electron is released from rest in a uniform electric field of magnitude 4.0×10^3 N/C. What is the electrostatic work done by the electric field on the particle after it has traveled 6.0 m? ••

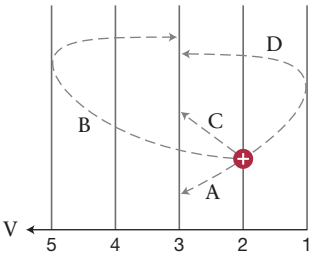
31. Particles A, B, C, and D in Figure P25.31 each carry a charge of magnitude 3.0 nC. Calculate the electric potential energy for the charge distribution in this 3.0-m square (*a*) if all the charges are positive; (*b*) if B, C, and D are positive and A is negative; (*c*) if B and C are positive and A and D are negative; and (*d*) if A and C are positive and B and D are negative. ••

Figure P25.31

32. An electron and a proton are fixed at the vertices of an equilateral triangle with sides of length *a*. (*a*) What is the potential (relative to zero at infinity) at the apex of the triangle. (*b*) Find the work required to move a particle with charge *Q* from infinity to the center of the line joining the fixed electron and proton? ••

33. Six particles, each carrying a charge of 2.0 nC, are equally spaced along the equator of a sphere that has a radius of 0.40 m. What is the electrostatic potential (relative to zero at infinity) (*a*) at the center of the sphere and (*b*) at either pole of the sphere? ••

34. An electron and a proton are held 2 m apart. The midpoint between the electron and the proton sets the origin of a coordinate system, with the *x* axis pointing toward the proton. (*a*) A second electron is moved to the origin from infinity. How much work does this take? (*b*) Keeping the second electron fixed at the origin, a third electron is sent toward the origin with a velocity of 400 m/s from the location (0 m, 10 m). How close does this electron get to the origin? ••



35. Four objects, each carrying a charge of magnitude *q*, are placed at the corners of a square measuring *d* on each side. Two of the objects are positively charged, and two are negatively charged, with like-charged objects placed at opposite corners of the square. (*a*) Is the electric potential energy associated with this charge distribution positive, negative, or zero? (*b*) Confirm your answer to part *a* by calculating the electric potential energy. ••

25.5 Potential difference

36. (*a*) What is the potential at a point 50 cm away from a point charge with a magnitude of 3.0 nC? (*b*) How would the potential change if you measure the potential at a point twice the distance from the charge? ••

37. Four possible paths for a positively charged object traveling from a 2-V equipotential to a 3-V equipotential are shown in Figure P25.37. Rank the paths in order of the electrostatic work done on the object along each path, greatest value first. •

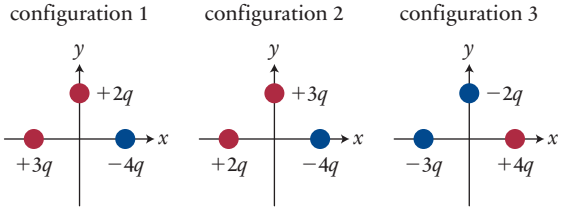
Figure P25.37

38. A conducting sphere with a diameter of 8.00 cm carries a charge of 3.5 nC that is uniformly distributed. Calculate (*a*) the surface charge density of the sphere and (*b*) the electric potential of the sphere relative to the potential far away. ••

39. Two point charges $q_1 = +Q$ and $q_2 = -3Q$ are placed along the *x*-axis, 10 cm apart (q_1 at the origin, q_2 at $x = +10$ cm). (*a*) What is the electric potential at the center of the line connecting the two point charges? (*b*) Could there be a point along the *x*-axis at which the potential is zero? If yes, at what location? If no, why not? •••

40. A particle carrying charge +10.00 nC sets the origin of a rectangular coordinate system. Taking the electrostatic potential to be zero at infinity, locate the distance from the origin of the equipotential surfaces at 20 V, 40 V, 60 V, 80 V, and 100 V. Are these surfaces equally spaced? ••

41. A particle carrying charge $+q$ sets the origin of a rectangular coordinate system. A particle carrying charge $-2q$ is located on the *x* axis at $x = d$. (*a*) Taking zero potential at infinity, at what locations on the *x* axis is the electrostatic potential zero? (*b*) At what locations on the *y* axis is the potential zero? (*c*) Answer the questions of parts *a* and *b* for the case where the object at $x = d$ carries charge $+2q$. ••



42. A positively charged infinite sheet has a surface charge density of $+5.0$ nC/m^2. What is (*a*) the electric field at a distance 0.10 m from the sheet and (*b*) the potential difference between two points located at distances of 0.30 m and 0.50 m from the sheet? (*c*) A +3.0 nC charged particle is initially at a distance 0.50 m from the sheet. How much work must an external force do to move this particle to a distance of 0.30 m from the sheet? (*d*) Taking the

potential to be zero at the sheet, at what distances from the sheet are the equipotential surfaces having potential of magnitudes 20 V, 40 V, and 60 V? ●●

43. An infinite sheet has a uniform positive surface charge. Points A and B are located at distances of 5.0 cm and 10.0 cm from the sheet, respectively. (*a*) Is the potential difference $V_B - V_A$ positive or negative? If the magnitude of this potential difference is 20.0 V, what is (*b*) the electric field in the region containing A and B and (*c*) the numerical value of the charge density on the sheet? ●●

44. Figure P25.44 shows three configurations of charged particles. All the particles are the same distance from the origin. Rank the configurations in terms of (*a*) the electrostatic potentials at the origin, greatest first, and (*b*) the electric potential energies of the three-particle system, greatest first. ●●

Figure P25.44

45. Two parallel conducting plates are 0.10 m apart and carry equal and opposite charges. They are large enough relative to the 0.10-m separation distance that we can assume the electric field between them is uniform. The potential difference between them is 500 V. An electron is released from rest at the negative plate. (*a*) Draw the electric field between the plates, indicating the sign of the charge on each plate and which plate is at the higher electrostatic potential. (*b*) What is the magnitude of the electric field between the plates? (*c*) What is the change in the potential energy of the system comprising the plates and the electron when the electron moves from the negative plate to the positive plate? (*d*) How much work is done by the electric field on the electron as it makes this trip? (*e*) What is the electron's kinetic energy when it reaches the positive plate? ●●

46. Two parallel conducting plates carry equal and opposite charges. The plates are large relative to the distance between them. The potential difference between them is 15.0 V, and the separation between them is 2 cm. (*a*) What is the numerical value of the surface charge density on the plates? (*b*) How much work is done by the electric field on an electron as it moves from the negative plate to the positive plate? ●●

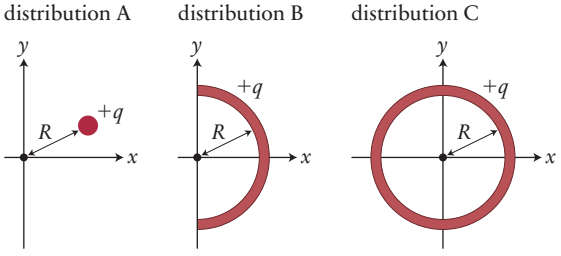
47. Particle 1 carrying charge $+q_1$ is placed on the x axis at $x = -d$. Particle 2 carrying some unknown charge q_2 is placed somewhere on the x axis. The potential energy associated with the charges is $+q_1^2/(2\pi\epsilon_0 d)$, and the electrostatic potential due to the charges is $+q_1/(\pi\epsilon_0 d)$ at the origin and zero at an infinite distance. (*a*) What is the sign of the charge on particle 2? (*b*) What is the magnitude of the charge on particle 2, and where on the x axis was particle 2 placed? Determine all possible answers. ●●

48. Two charged particles are placed near the origin of an xyz coordinate system. Particle 1 carries charge $+q$ and is on the x axis at $x = +d$. Particle 2 carries an unknown charge and is at an unknown location. The magnitude of the electric field at the origin is $q/(2\pi\epsilon_0 d^2)$, and the electrostatic potential at the origin, relative to $V = 0$ at infinity, is $+3q/(4\pi\epsilon_0 d)$. (*a*) If particle 2 is on the x axis, what are its charge and location? (*b*) If particle 2 is on the y axis, what are its charge and location? Determine all possible solutions. ●●●

25.6 Electrostatic potentials of continuous charge distributions

49. A thin disk of radius $R = 5$ cm has uniform surface charge density $\sigma = 8$ nC/m^2. Calculate the potential (relative to zero at infinity) on the axis that runs through the disk center and is perpendicular to the disk face at distances (*a*) 5.0 mm, (*b*) 2 cm, and (*c*) 1 m. ●

50. A point charge $q = +5$ nC is at the center of a thick conducting spherical shell of internal radius 10 cm and external radius 12 cm. (*a*) What is the magnitude and direction of the electric field at the inner and outer surfaces of the shell? (*b*) What is the electrostatic potential on the inner and outer surfaces of the shell, and at a point located at 5 cm from the center of the shell, relative to zero at infinity? ●



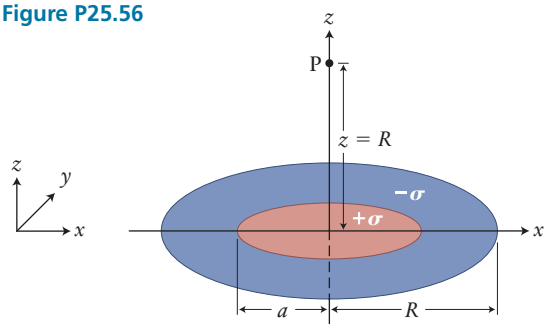
51. An infinitely long positively charged wire has a linear charge density $\lambda = 3$ nC/m. Calculate the electrostatic potential at distances of (*a*) 1.0 m, (*b*) 2.0 m, and (*c*) 6 m from the wire, assuming zero potential 4 m from the wire. ●●

52. A particle carrying charge $+q$ is placed at the center of a thick-walled conducting shell that has inner radius R and outer radius $2R$ and carries charge $-4q$. A thin-walled conducting shell of radius $3R$ carries charge $+4q$ and is concentric with the thick-walled shell. Defining $V = 0$ at infinity, calculate all distances from the particle at which the electrostatic potential is zero. ●●

53. Four uniformly charged nonconducting rods, each of length ℓ and carrying charge $+q$, are arranged into a square of side length ℓ. At the center of the square, what are (*a*) the magnitude of the electric field and (*b*) the electrostatic potential? ●●

54. Figure P25.54 shows three charge distributions. In A, a particle carrying a charge $+q$ is located a distance R from the origin. In B, $+q$ charge is spread uniformly over

Figure P25.54



a semicircle of radius R centered at the origin. In C, $+q$ charge is spread uniformly over a circle of radius R centered at the origin. Rank these distributions in terms of (*a*) the electric field magnitude at the origin, smallest first, and (*b*) the electrostatic potential at the origin, smallest first. (*c*) Using infinity as the location where the electrostatic potential is zero, write an expression for the electrostatic potential at the origin in distribution B. ●●

55. A particle carrying charge $q_p = +10$ nC is located at $y_p = 0.030$ m on the y axis of an xy coordinate system. A nonconducting rod of length $\ell = 0.10$ m carrying charge $q_r = -10$ nC lies on the x axis, extending from $x = 0$ to $x = 0.10$ m. Write an expression for the electrostatic potential for any position along the y axis. ●●

56. A disk of radius R has positive charge uniformly distributed over an inner circular region of radius a and negative charge uniformly distributed over the outer annular (ring-shaped) region (Figure P25.56). The surface charge density on the inner region is $+\sigma$, and that on the annular region is $-\sigma$. The electrostatic potential at P, located on the central perpendicular axis a distance $z = R$ from the disk center, is zero. What is a in terms of R? ●●●

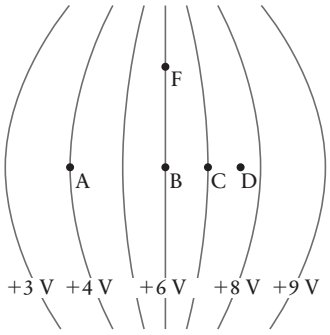
Figure P25.56

57. The surface charge density on a nonconducting disk of radius R varies with the radius as $\sigma(r) = cr$, where c is a positive constant $(c > 0)$. Derive an expression for the electrostatic potential as a function of position x along an x axis that runs through the disk center and is perpendicular to the disk face, with the disk center at $x = 0$ on this axis. ●●●

58. A very long, solid, positively charged cylinder has a radius R and is made of a nonconducting material. The nonuniform volume charge density is given by $\rho = +ar$, where r is the radial distance away from the long central axis of the cylinder. Calculate the difference in electrostatic potential between a location on the axis and a location on the outer surface of the cylinder. ●●●

25.7 Obtaining the electric field from the potential

59. The electric potential in some region of space is given by $V(x, y, z) = A\left(x^2 - xy + \dfrac{z^3}{y}\right)$, where V is in volts, x, y, z are in meters, and A is a positive constant. Determine the magnitude of the electric field in this region. ●●



60. The electrostatic potential at a particular coordinate is given by $V(x, y) = 3x^2 - 2xy + 5y^2$. Obtain the expression for the electric field. ●

61. A particle carrying a charge of 6 nC is at the center of a thick conducting spherical shell of inner radius 9 cm and outer radius 10 cm. (*a*) What is the surface charge density on the outer surface of the shell? (*b*) What is the electrostatic potential (relative to zero at infinity) on the outer surface of the shell? (*c*) Compute the potential difference ΔV between the outer surface of the shell and a point A located at a distance $d = 1$ mm outside it. (*d*) Use the approximate expression $E = \Delta V/d$ to calculate the electric field at the surface of the shell. Compare your expression with what you would have obtained by considering the shell as an infinitely wide conducting plane carrying the same charge density. (*e*) Evaluate the error you made compared to the exact result for the electric field at A. ●●

62. Two particles, each carrying positive charge q, are on the y axis, one at $y = +a$ and the other at $y = -a$. (*a*) Calculate the potential for any point on the x axis. (*b*) Use your result in part *a* to determine the electric field at any point on the x axis. ●●

63. Figure P25.63 shows a two-dimensional slice through a set of equipotential surfaces. (*a*) At which of the locations marked A, B, C, and D is the magnitude of the electric field greatest? (*b*) Is the magnitude of the electric field greater at B or at F? (*c*) Sketch some electric field lines in relation to these equipotential surfaces. ●●

Figure P25.63

64. A particle carrying 3.00 nC of positive charge is at the origin of a rectangular coordinate system, and a particle carrying 3.00 nC of negative charge is on the x axis at $x = 6.00$ m. (*a*) Calculate the potential on the x axis at $x = 3.00$ m, relative to zero potential at infinity. (*b*) Calculate the electric field on the x axis at $x = 3.00$ m. (*c*) Calculate the potential on the x axis at $x = 3.01$ m. (*d*) Compute $\Delta V/\Delta x$ for ΔV between $x = 3.00$ m and $x = 3.01$ m, and $\Delta x = 0.01$ m, and compare your result with your result in part *b*. ●●

65. A ring of radius a carrying a uniformly distributed positive charge q is located in the yz plane of a rectangular coordinate system, with the center of the ring at the origin. (*a*) Sketch a graph of the electrostatic potential $V(x)$ as a function of distance along the x axis. (*b*) At what position is $V(x)$ a maximum? (*c*) What is E_x at this position? ●●●

66. Consider a spherically symmetrical distribution of charged particles. The magnitude of charge for the distribution is q, and the radius of the distribution is R. The electrostatic potential varies with radial distance r away from the center of the distribution. For $r > 2R$, $V(r) = -q/(4\pi\epsilon_0 r)$;

for $R < r < 2R$, $V(r) = -q/(8\pi\epsilon_0 R)$; and for $r < R$, $V(r) = -3q/(4\pi\epsilon_0 r) + 5q/(8\pi\epsilon_0 R)$. (*a*) What is the electric field in these three regions? Use $V(\infty) = 0$ in your calculations. (*b*) Describe a set of objects that could produce an electrostatic potential that behaves in this way. •••

Additional Problems

67. An electron travels from point A to point B in an electrostatic field and gains kinetic energy. (*a*) Is the electrostatic work done on the electron positive, negative, or zero? (*b*) Is the potential at A higher than, lower than, or the same as the potential at B? •

68. A proton travels from point A to point B in an electrostatic field and gains kinetic energy. (*a*) Is the electrostatic work done on the proton positive, negative, or zero? (*b*) Is the potential at A higher than, lower than, or the same as the potential at B? •

69. Calculate E_x for each potential: (*a*) $V(x) = a + bx$, $a = 4000$ V, $b = 6000$ V/m. (*b*) $V(x) = ax + b/x$, $a = 1500$ V/m, $b = 2000$ V·m. (*c*) $V(x) = ax - bx^2$, $a = 2000$ V/m, $b = 3000$ V/m^2. (*d*) $V(x) = -2000$ V (independent of x). •

70. Consider an isolated, uniformly charged spherical shell of radius R carrying positive charge q. Point A is on the shell, point B is a distance $2R$ from the center, point C is a distance $R/2$ from the center, and point D is at the center. Is the potential difference positive or negative (*a*) between A and B, (*b*) between A and C, (*c*) between A and D? ••

71. You are sketching equipotentials for a positively charged particle, having defined $V = 0$ at infinity. If you draw the 5.0-V equipotential as a circle with a radius of 50 mm, what is the radius of (*a*) the 10-V equipotential and (*b*) the 2.0-V equipotential? ••

72. A uniformly charged rod of length ℓ and charge $+q$ lies on the x axis of a Cartesian coordinate system, extending from the origin to $x = -\ell$. What is the electric potential due to this rod at a position on the positive x axis that is a distance d from the origin? ••

73. A solid sphere of radius R is concentric with a spherical shell that carries charge $+q_{\text{shell}}$ and has an inner radius of $2R$ and outer radius of $3R$. If the electrostatic potential at the common center of the sphere and shell is the same as the potential at infinity, what is the charge q_{sphere} on the solid sphere (*a*) if the sphere is conducting and (*b*) if the sphere is nonconducting and has a uniform charge distribution throughout it? •••

74. You really like your new job at the atomic physics lab. Your boss casually mentions that the electron in a helium ion (He^+) emits energy in the form of radiation as it jumps from an orbit that has a radius of 0.42 nm to an orbit that has a radius of 0.24 nm. You wonder if any more information is needed in order to figure out the energy carried off by the emitted radiation. If not, calculate the magnitude of that energy. ••• CR

75. You have always wondered exactly how strong is the interaction called the *strong nuclear interaction*, and you suspect that an element like uranium could make a good test case. You begin to wonder if the electric potential energy discussed in this chapter might provide a path to an answer. As you search for a starting point, you return to Example 25.4, which examines the energy associated with holding the hydrogen atom together. But there is only one proton in the hydrogen nucleus, whereas a uranium nucleus has 92 protons, separated from one another by about 2×10^{-15} m. Clearly something must be able to hold all those protons so close to one another. How strong is this interaction? ••• CR

76. Two charged objects 1 and 2 are held a distance r apart. Object 1 has mass m and charge $+2q$, and object 2 has mass $2m$ and charge $+q$. The objects are released from rest. Assume that the only force exerted on either object is the electric force exerted by the other object. (*a*) When the objects are in motion, what is the ratio of their kinetic energies K_2/K_1? When the objects are a distance $4r$ apart, what is the speed of (*b*) object 1 and (*c*) object 2? When the objects are very far apart, what is the speed of (*d*) object 1 and (*e*) object 2? •••

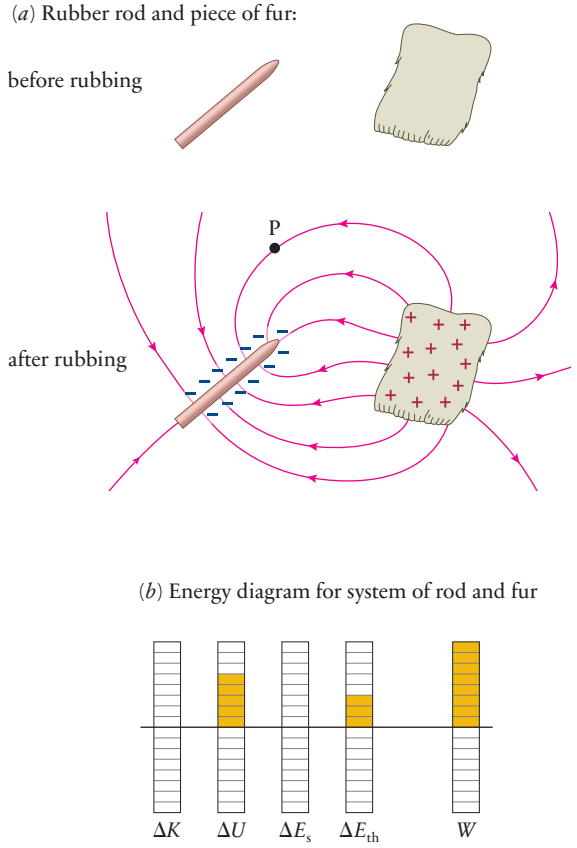
This chapter deals with generating and storing electric potential energy. To produce charged objects, positive and negative charge carriers must be pulled apart and then kept separate. Work is required to pull apart charge carriers, just as work is required to stretch a spring. In each case, this work results in energy storage in the system. We now look at what kind of changes in energy are involved in the separation of positive and negative charge carriers and how charge carriers that have been separated can be stored in simple arrangements of conductors.

26.1 Charge separation



Whenever objects are "charged" (by separating strips of Scotch tape, rubbing objects against each other, using batteries, etc.), the basic phenomenon is the same: Some process (pulling, rubbing, chemical reactions) separates positive and negative charge carriers from one another. As a concrete example, consider a rubber rod and a piece of fur. If you rub the two together and then separate them, they become oppositely charged because the rod pulls electrons away from the fur: The rod ends up with a surplus of electrons and the fur with a deficit. Provided none of the electrons on the rod leak away (to the air, your hand, etc.), the magnitude of the negative charge on the rod is equal to that of the positive charge on the fur.

What is the change in energy associated with this charge separation? Consider the rubber-fur system in its initial and final states (**Figure 26.1a**). To separate the positive and negative charge carriers, they must be pulled apart against an attractive electric force, just as the ends of a stretched spring are pulled apart against an elastic force. Because work must be done on the rod-fur system, the electric potential energy of the system is greater in the final state. This energy is supplied by you while you rub the two objects together and then increase their separation. Not all of the energy you put into the system goes into electric potential energy; the friction involved in the rubbing not only produces charge separation but also heats up the rod and the fur, so part of the work you do on the system increases the thermal energy. An energy diagram for the rod-fur system is shown in Figure 26.1*b*.

26.1 Suppose you repeat the charging (starting again with uncharged rod and fur), but this time you rub longer and twice as much charge accumulates at each point on the two objects. How do the following quantities compare to what they were after the first charging: (*i*) the direction and magnitude of the electric field at point P in Figure 26.1*a*; (*ii*) the potential difference between two fixed points on the rod and the fur; and (*iii*) the electric potential energy in the rod-fur system?

Checkpoint 26.1 highlights the essence of this chapter. Be sure not to confuse *potential difference* and *electric potential energy*:

Figure 26.1 When we charge a rubber rod and a piece of fur by rubbing them together, we do work to separate charge and hence increase the electric potential energy of the system comprising the rod and fur.

- The system's electric potential energy depends on the configuration of the positive and negative charge carriers in the system.
- The potential difference between points on the rod and the fur is a measure of the electrostatic work done on a particle carrying a unit of charge (not part of the system) while moving between those points.

In the next section we examine the proportionality between potential difference and charge separation in detail. In this section we concentrate on the relationship between charge separation and electric potential energy.

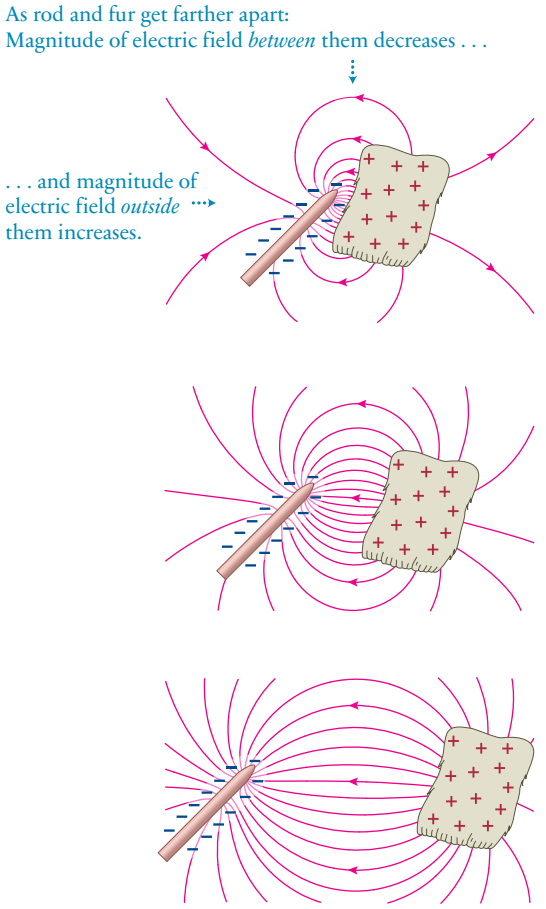
The crucial point to take away from Checkpoint 26.1 is:

Positive work must be done on a system to cause a charge separation of the positive and negative charge carriers in the system. This work increases the system's electric potential energy.

26.2 Will doubling the separation distance between the charged rod and fur in Figure 26.1*a* increase, decrease, or not change the potential energy of the rod-fur system?

The amount of stored electric potential energy depends on the amount of charge that is separated and the distance that separates the charge carriers. More charge or a greater separation means more electric potential energy is

CONCEPTS



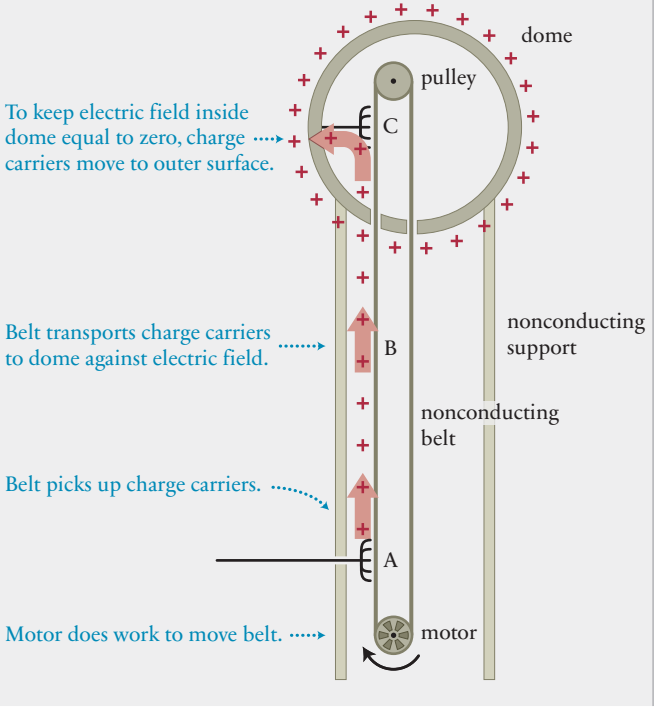
stored. These arguments apply to *all* devices that separate charge, such as Van de Graaff generators (see the box below) and batteries (see Section 26.4). Once electric potential energy has been generated by separating charge carriers, this energy can be used for other processes, such as lighting a lamp, operating a radio, and so on.

Every **charge-separating device** (or **charging device**) has some mechanism that moves charge carriers *against* an electric field—a process that requires work to be done on the system of charge carriers. For the rod-fur system, this work is mechanical and is supplied by the person doing the rubbing and separating the objects. In a battery, chemical reactions drive charge carriers through a region where the electric field opposes their motion.

26.3 If you include the person doing the rubbing in the system considered in Figure 26.1, what is the resulting energy diagram?

Where is the electric potential energy of the rod-fur system stored? As you may recall from Section 7.2, potential energy is stored in reversible changes in the configuration of interacting components of a system. Electric potential energy, therefore, is associated with the configuration of the charge carriers in a system. A look at the field line pattern suggests an alternative view, however. **Figure 26.2** shows how the electric field line pattern changes as the distance between the charged rod and the fur increases. Note how more of the space around the system becomes filled with field lines

Figure 26.2 Change in the electric field line pattern as the distance between the rod and fur increases.



Van de Graaff generator

Figure 26.3 shows a schematic diagram of a Van de Graaff generator—a mechanical device invented in the 1930s by Robert J. Van de Graaff to separate large amounts of electrical charge. The basic principle is extremely simple: A nonconducting belt delivers charge carriers to a hollow conducting dome that rests on a nonconducting support. Machines of this type are used to generate the very large potential differences required in particle accelerators and for the generation of x rays.

Operation of the generator involves three important steps. The first step is a transfer of charge carriers to the belt at A. This transfer can be done by literally "spraying" charged particles onto the belt or simply by rubbing the rubber belt against some appropriate material.

The second step transports the charge carriers to the dome. This step is possible because the belt is nonconducting, so the charge carriers are not mobile—they are stuck to the belt, which is driven by a motor around a pulley inside the dome. The motor must do work on the charge carriers to move them against the electric field of the dome. (In the example shown in the diagram, positive charge carriers at B

Figure 26.3 Schematic diagram of a Van de Graaff generator.

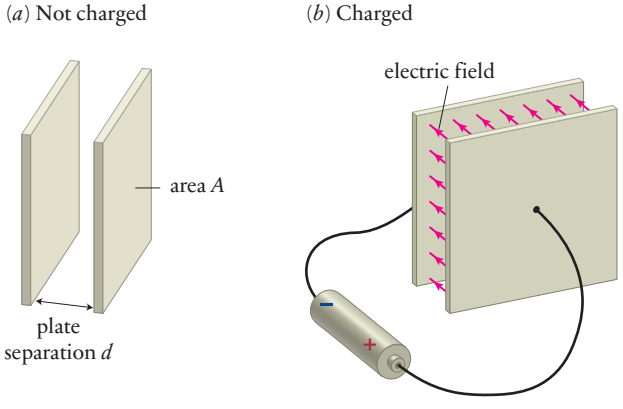
CONCEPTS

must be transported upward against the downward electric field of the positively charged dome.)

The third step transfers the charge carriers from the belt onto the dome. As we saw in Section 24.5, the electric field inside a hollow conductor is always zero and any charge inside a conductor moves toward the outer surface. Therefore, once the charge carriers are inside the dome, they tend to move to the outer surface of the dome. For this purpose, a comb of conducting needles is placed close to the belt at C. If the charge carriers on the belt are electrons, the electrons hop onto the comb and move via the connecting wire toward the outside of the metal dome, causing the dome to acquire a negative charge. Alternatively, the charge carriers on the belt can be positively ionized air molecules, in which case electrons in the comb are attracted toward the ions. These electrons then jump from the comb onto the belt, neutralizing the ions on the belt while leaving a positive charge behind on the outside of the dome.

This huge double Van de Graaff generator, located at the Boston Museum of Science, was built in South Dartmouth, Massachusetts, for the MIT Physics Department in 1931. The oppositely charged pair of generators can produce potential differences of up to 5,000,000 V between the two 4.5-m domes.

(indicating that the magnitude of the electric field there increases), while the density of the field lines between the rod and the fur decreases. Thus, as the distance between the rod and the fur changes, the electric potential energy changes and the electric field changes.



As we shall see later in this chapter, we can relate a change in the electric potential energy of a system to a change in the system's electric field (integrated over all of space), which suggests that the electric potential energy of a system is stored in its electric field. In other words, the electric potential energy of the rod-fur system is spread throughout the space around it. As long as the two objects are held stationary, the field is stationary, so the exact "location" of the energy is not very important because there is no way we can determine it experimentally. If we shake the charged rod or fur, however, the shaking causes a wavelike disturbance in the electric field. This disturbance propagates away from the rod or fur and carries with it energy that we can detect. For now we don't need to concern ourselves with such waves. It suffices to know that electric fields store electric potential energy.

26.2 Capacitors

Any system of two charged objects, such as the rod-fur system in the preceding section, stores electric potential energy. To study how much electric potential energy can be stored in a system of two objects, let's begin by considering the simple arrangement of two parallel conducting plates shown in **Figure 26.4*a***. A system for storing electric potential energy that consists of two conductors is called a **capacitor**; the arrangement in Figure 26.4*a* is called a *parallel-plate capacitor*.

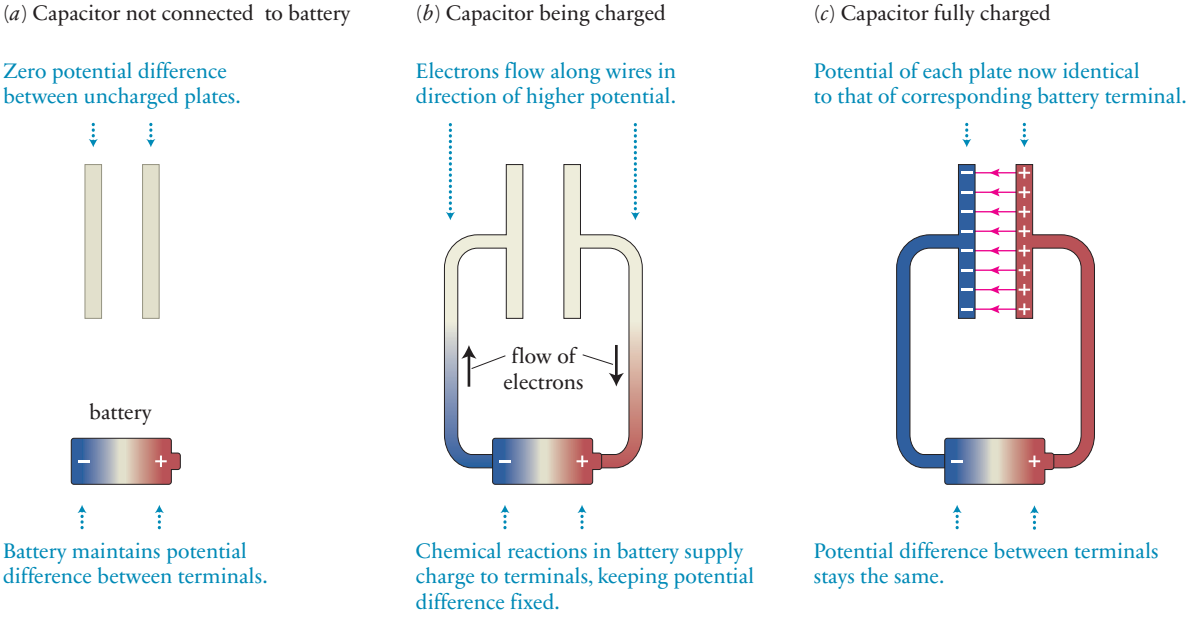


Figure 26.4*b* illustrates a simple method for charging such a capacitor. Each plate is connected by a wire to a terminal of a battery, which maintains a fixed potential difference between its terminals. **Figure 26.5** on the next page shows what happens when the connection is made between the battery and the capacitor. If the capacitor plates are far enough away from the battery, the potential difference between the plates initially is zero (Figure 26.5*a*). Immediately after the wires are connected, there is a

Figure 26.4 A parallel-plate capacitor.

CONCEPTS

Figure 26.5 Charging a capacitor. (Think of the plates as an edge-on version of those shown in Figure 26.4.)

potential difference between the ends of each wire. This difference in potential causes electrons (which are mobile in metal) in the wires to flow as indicated by the arrows in Figure 26.5*b*. A positive charge builds up on the plate connected to the positive terminal, and a negative charge of equal magnitude builds up on the other plate. As electrons leave one plate and accumulate on the other, the potential difference between the plates changes. This process continues until the potential is the same at both ends of each wire—that is, when the potential difference between the plates is equal to that between the terminals of the battery (Figure 26.5*c*). Because there is no longer any potential difference from one end of the wire to the other, the flow of electrons stops and the capacitor is said to be *fully charged*. In the process of achieving this state, the battery has done work on the electrons; this work has now become electric potential energy stored in the capacitor.

The time interval it takes to fully charge a capacitor depends on the properties of the capacitor, the battery, and the way the capacitor is connected to the battery. Typically, only a fraction of a second is needed for charging, although the time interval it takes to charge very large capacitors can be minutes (more on this in Chapter 32).

CONCEPTS

26.4 (*a*) Suppose that we disconnect the wires from the plates after the capacitor is charged as shown in Figure 26.5*c*. How does the potential difference between the plates after the wires are disconnected compare to that just before they are disconnected? (*b*) If we replace the battery in Figure 26.5 by a battery that maintains a greater potential difference between its terminals, is the magnitude of the charge on the plates greater than, smaller than, or the same as when the first battery is connected?

When a capacitor is not connected to a conductor, as in Checkpoint 26.4*a*, it is said to be *isolated*. For an isolated capacitor, the *quantity of charge on each plate* is fixed because the charge carriers have nowhere to go. In contrast, for a capacitor that is connected to a battery, the *potential difference across the capacitor* is fixed—the charge carriers on the plates always adjust themselves in such a way as to ensure that the potential difference across the capacitor is equal to that across the battery terminals.

Figure 26.6 shows the electric fields of two isolated charged parallel-plate capacitors. The field is nearly

Figure 26.6 Effect of plate separation distance in relation to plate area on the field of a parallel-plate capacitor.

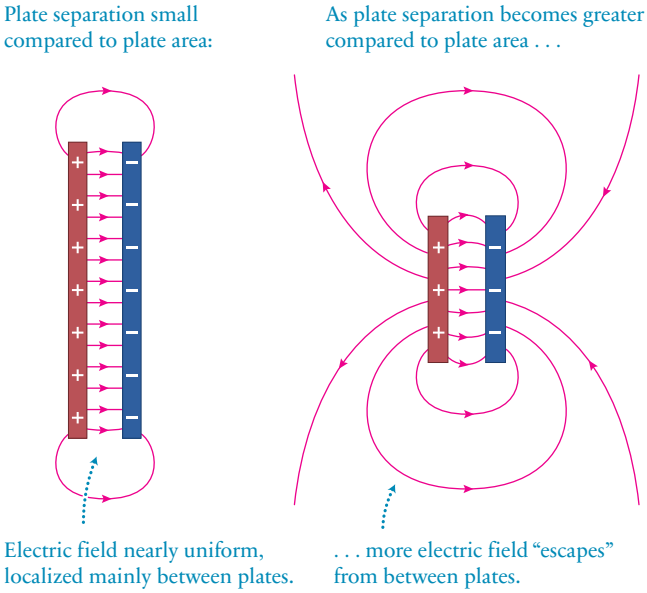

Figure 26.7 Doubling the charge on a parallel-plate capacitor.

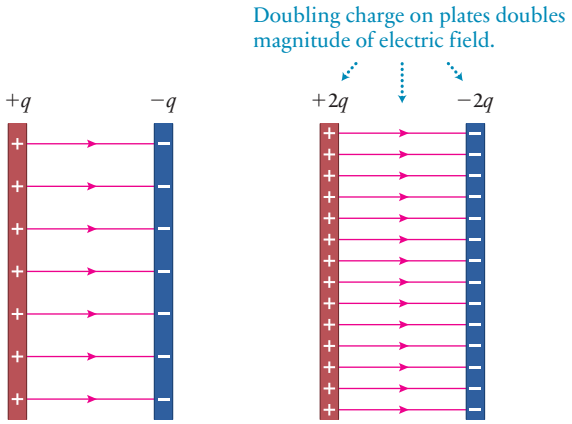

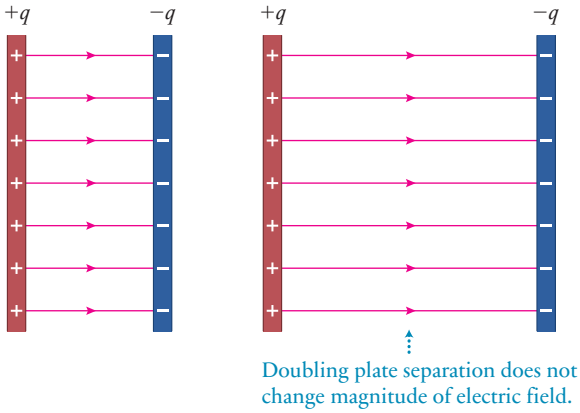

Figure 26.8 Doubling the plate separation distance of a parallel-plate capacitor.

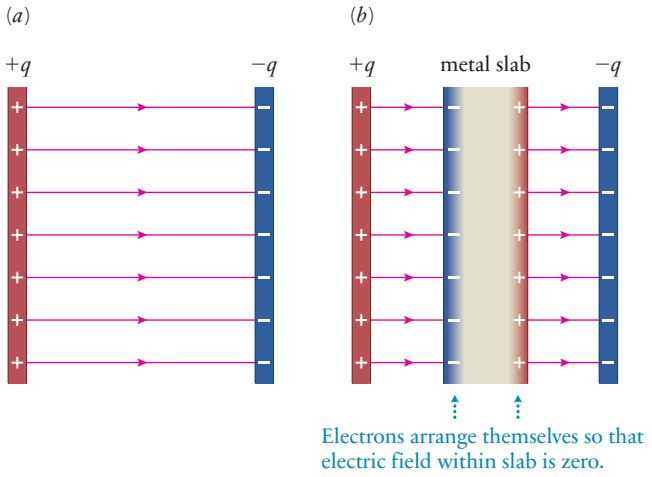
uniform in the region between the plates, but it is nonuniform at the edges. When the spacing between the plates is small compared to the area of the plates, the effect of the nonuniform field is negligible: The electric field is confined almost entirely to the region between the plates, and for all practical purposes we can consider this field to be uniform. When discussing parallel-plate capacitors, we shall ignore the nonuniform fields at the edges and assume the electric field is entirely uniform between the plates. This simplification is justified by the geometry of most capacitors used in electronic applications.

Let us now examine the relationship between the magnitude of the charge on the plates of a parallel-plate capacitor and the potential difference between them. **Figure 26.7** shows an isolated parallel-plate capacitor carrying a positive charge $+q$ on one plate and a negative charge $-q$ on the other. If we double the magnitude of the charge on each plate, then the electric field between the plates doubles, too (see Checkpoint 23.14). Consequently, the electric force exerted on a charged particle between the plates doubles, so the electrostatic work done in moving a charged particle from one plate to the other also doubles. According to Eq. 25.15, the potential difference between the plates doubles as well. In other words, the potential difference between the plates is proportional to the magnitude of the charge on the plates.

What happens if we increase the plate separation of an isolated parallel-plate capacitor, as illustrated in **Figure 26.8**? The electric field remains the same because it is determined by the surface charge density on the plates, which doesn't change (see Checkpoint 23.14). Because the distance between the plates increases, however, the electrostatic work done in moving a charged particle from one plate to the other increases—more work is required to move the particle over a greater distance—so the potential difference between the plates increases too, confirming the result we obtained in Example 25.5.

26.5 Suppose the two capacitors in Figure 26.8 are each connected to a 9-V battery. (*a*) Which of the two capacitors stores the greater amount of charge? (*b*) If, instead of the separation distance increasing, the area of the plates of the capacitor is halved and then the capacitor is connected to a 9-V battery, does the capacitor store more charge, less charge, or the same amount of charge as before the area of the plates was halved?

As Checkpoint 26.5 illustrates, the geometry of the capacitor determines its capacity to store charge. In general:



For a given potential difference between the plates of a parallel-plate capacitor, the amount of charge stored on its plates increases with increasing plate area and decreases with increasing plate separation.

Does this mean that we can increase the amount of charge stored on a parallel-plate capacitor indefinitely simply by making the plate separation infinitesimally small? The answer is *no*, because if the plate spacing is decreased while the potential difference between the capacitor plates is fixed, the charge on each plate increases and thus the magnitude of the electric field in the capacitor increases. When the electric field is about 3×10^6 V/m, the air molecules between the plates become *ionized* and the air becomes conducting, allowing a direct transfer of charge carriers between the plates. Once such a so-called **electrical breakdown** occurs, the capacitor loses all its stored energy in the form of a spark.

The electrical breakdown of air will occur between the charged dome of a Van de Graaff generator and a nearby metal object, as shown in the box on page 910. The breakdown limits the maximum potential difference across a capacitor and thus the maximum amount of charge that can be stored on the capacitor. The electric field at which electrical breakdown occurs is called the *breakdown threshold*.

CONCEPTS

Figure 26.9 Inserting a conducting slab between the plates of a parallel-plate capacitor.

The breakdown threshold can be raised by inserting a nonconducting material between the capacitor plates. As we shall see in the next section, such a nonconducting material also greatly increases the amount of charge that can be stored by a capacitor. To understand why this is so, we begin by considering a simpler situation: the insertion of a conductor between the plates of a parallel-plate capacitor.

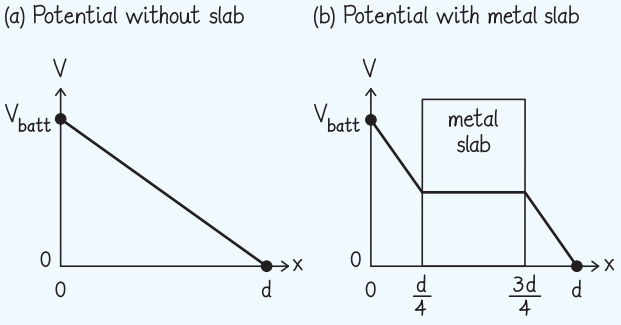
Figure 26.9*a* shows an isolated charged capacitor. Suppose we now insert a conducting slab between the plates of this capacitor (Figure 26.9*b*). As we saw in Section 24.5, the charge carriers in the conductor rearrange themselves in such a fashion as to eliminate the field inside the bulk of the conductor.

CONCEPTS

26.6 Suppose the capacitor in Figure 26.9*a* is charged and then disconnected from the battery. (*a*) As the conducting slab is inserted in the capacitor, as in Figure 26.9*b*, does the amount of charge on the capacitor plates increase, decrease, or stay the same? (*b*) How much charge accumulates on each side of the slab, once it is inserted? (*c*) What is the potential difference across the conducting slab? (*d*) As the slab is inserted, does the magnitude of the potential difference between the capacitor plates increase, decrease, or stay the same?

As Checkpoint 26.6 demonstrates, the effect of the slab is to make the electric field in part of the space between the capacitor plates zero, thus reducing the magnitude of the potential difference between the plates for a given amount of charge on them. As the next example shows, the converse of this fact is that, for a given potential difference between its plates, the capacitor can store more energy with the slab inserted than it can without the slab. In other words, the slab increases the capacitor's capacity to store charge.

EXAMPLE 26.1 Metal-slab capacitor



Suppose the capacitor in Figure 26.9 has a plate separation distance d and the plates carry charges $+q$ and $-q$ when the capacitor is connected to a battery that maintains a potential difference V_{batt} between its terminals. If a metal slab of thickness $d/2$ is inserted midway between the plates while the battery remains connected, what happens to (*a*) the magnitude of the electric field between the plates and (*b*) the quantity of charge on the plates?

1 GETTING STARTED I am given the plate separation distance and plate charges for a capacitor connected to a battery, and I must determine how the electric field magnitude between the plates and the quantity of charge on each plate change when a metal slab is inserted. Because the capacitor remains connected to the battery, the potential difference across the capacitor is fixed. Because the slab is conducting, the electric field inside the slab is always zero.

2 DEVISE PLAN The electric field magnitude determines the electrostatic work, which in turn determines the potential difference between the plates (which I know). To determine how the electric field magnitude changes when the metal slab is inserted, therefore, I must first determine how the potential between the plates changes when the slab is inserted. Once I know the electric field, I can determine how the slab affects the charge on the plates because I know that the magnitude of the electric field between the plates is proportional to the surface charge density σ (see Checkpoint 23.14, $E = 4k\pi\sigma$).

3 EXECUTE PLAN To compare the potentials before and after the slab is inserted, I must plot V as a function of position between the plates (**Figure 26.10**). I choose my x axis to be parallel to the electric field, with the positive plate at $x = 0$ and the negative plate at $x = d$ as the zero of potential. In the absence of the metal slab, the field is uniform between the plates, and so the potential decreases linearly from $x = 0$ to $x = d$ (Figure 26.10*a*). Because the electric field inside the slab is zero, the potential does not vary across the slab (it is an equipotential; see Section 25.3). Because the battery keeps the potential at each plate constant, the potential-versus-distance curve must take on the zigzag form shown in Figure 26.10*b*.

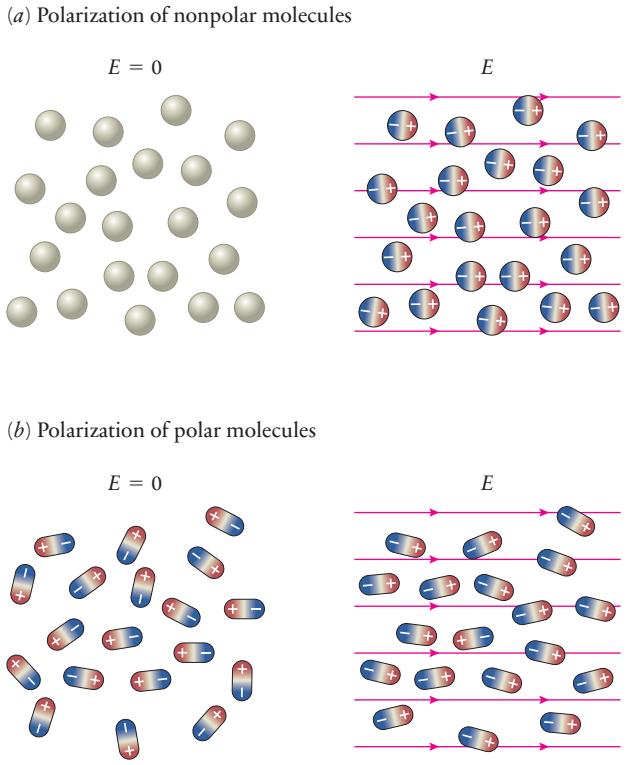
Figure 26.10

(*a*) Insertion of the metal slab affects the electric field between the plates because the slab is an electrical conductor and so the electric field inside it must always be zero. However, because V_{batt} is constant, I know that the electrostatic work, $W_q = F_d^E = qV_{batt}$, done on a particle carrying a charge q to move the particle from one plate to the other must be the same whether or not the slab is in place there. Because no electrostatic work is done to move the particle through the slab where the electric field is zero, the field outside the slab must be greater to make up for the smaller distance over which the particle is moved. More precisely, because the distance over which the electric field is nonzero is reduced to $d/2$, the magnitude of the field must be twice what it was before the slab was inserted. ✔

(*b*) If the field doubles, then the charge per unit area must also double. Given that the area of the plates does not change, this means that the charge on the plates must double. ✔

4 **EVALUATE RESULT** Inserting the metal slab with the battery connected is equivalent to halving the separation distance between the plates while keeping the potential difference constant. I know from Checkpoint 26.5 that, for a constant potential difference, the quantity of charge stored on a capacitor increases with decreasing plate separation, as I found.

26.7 (*a*) Does the position of the slab in Figure 26.9 affect the potential difference across the capacitor? Consider, in particular, the case in which the slab is moved all the way to one side and makes electrical contact with one of the plates. (*b*) Sketch the potential $V(x)$ as a function of x, with the slab off-center.



26.3 Dielectrics

As we just saw, decreasing the space inside an isolated charged capacitor where the electric field is nonzero increases its capacity to store electrical charge for a given potential difference across its plates. With a conducting slab inserted, however, the gap between either plate and the slab face nearest it is smaller than the plate-to-plate gap before the slab was inserted. Because a decreased gap with the potential difference held constant means E increases, we still have the problem of electrical breakdown.

Suppose, however, that we insert a nonconducting material—a **dielectric**—between the plates of a capacitor. As we discussed in Section 22.4, the electric field between the plates of the capacitor polarizes the dielectric. What effect does this polarization have? To answer this question we must first look in more detail at what happens in a polarized dielectric material.

We should distinguish between two general types of dielectric materials. A *polar* dielectric consists of molecules that have a permanent electric dipole moment;

Figure 26.11 Polarization of nonpolar and polar molecules in an electric field.

each molecule is electrically neutral, but the centers of its positive and negative charge distributions do not coincide (see Section 23.4). The atoms or molecules in a *nonpolar* dielectric have no dipole moment in the absence of an electric field.

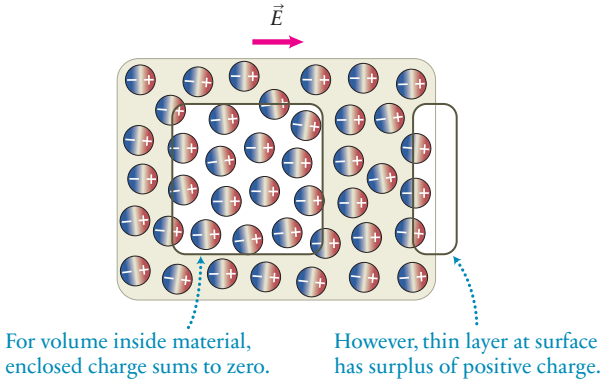
Figure 26.11*a* shows the polarization of a nonpolar dielectric. In the presence of an electric field, the electrons in a nonpolar dielectric are displaced in the direction opposite to $\vec{E}$, inducing a dipole moment on each molecule.

26.8 Why are the electrons displaced in a direction *opposite* the electric field?

The polarization of a polar dielectric is shown in Figure 26.11*b*. In the absence of an electric field, the individual molecules' dipole moments are randomly aligned, so the material as a whole is not polarized. In the presence of an electric field, however, the molecular dipoles are subject to a torque (see Section 23.8) that tends to align the dipoles with the electric field, giving rise to a macroscopic polarization. In general, the polarization of polar dielectrics is much greater than that of nonpolar ones because the permanent dipole moments of the molecules in a polar dielectric are much greater than the induced dipole moments in a nonpolar dielectric.

CONCEPTS

Figure 26.12 The reason a polarized dielectric exhibits a macroscopic polarization.



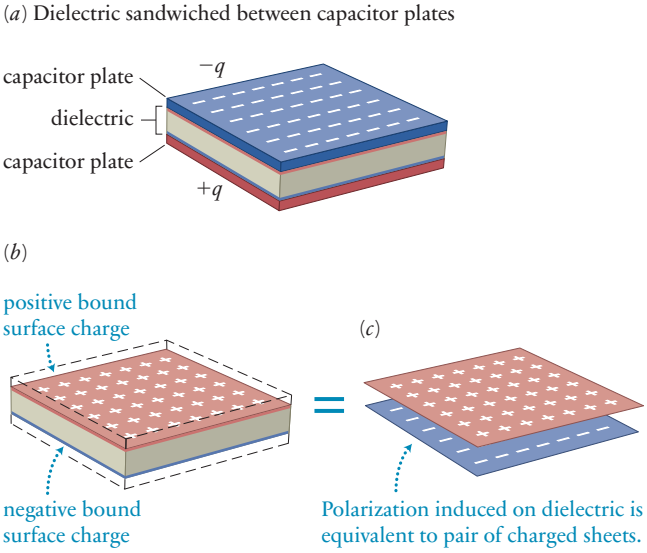


Figure 26.12 illustrates the effect of the uniform polarization of the atoms or molecules in a polar or nonpolar dielectric. The charge enclosed by any volume that lies entirely inside the polarized dielectric is zero: The positive and negative charge carriers may not coincide exactly, but on average they occur in equal numbers. However, this is not true for a small volume at the surface of the dielectric. In the volume on the right in Figure 26.12, for example, a surplus of positive charge appears at the surface of the material. Thus, a polarized dielectric has a very thin sliver of surplus positive charge on one side and a sliver containing an equal amount of surplus negative charge on the other side (see also Figure 22.21). The surface charge on either side of the polarized dielectric is said to be **bound** because the charge carriers that cause it are not free to roam around in the material. In contrast, the charge on the capacitor plates is **free** because the charge carriers that cause it can move around freely. From a macroscopic point of view, a uniformly polarized dielectric differs from an unpolarized dielectric only by the presence of this bound surface charge.

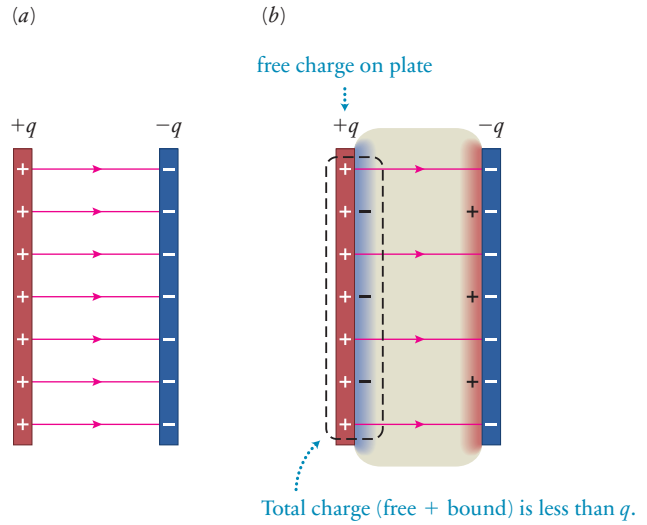
What is the effect of the bound surface charge on the electric field inside the capacitor? Consider a dielectric slab inside an isolated charged capacitor (**Figure 26.13a**). The dielectric is polarized by the electric field of the capacitor; that is, a positive bound surface charge appears on the surface near the negatively charged capacitor plate, and a negative bound surface charge appears on the other side (Figure 26.13*b*). Imagine now that we could "lock in" the polarization and consider just the slab by itself. Except for two sheets of charge at the top and bottom, the bulk of the dielectric is neutral. Thus, for all practical purposes, the polarized dielectric is equivalent to two very thin sheets carrying opposite charge (Figure 26.13*c*).

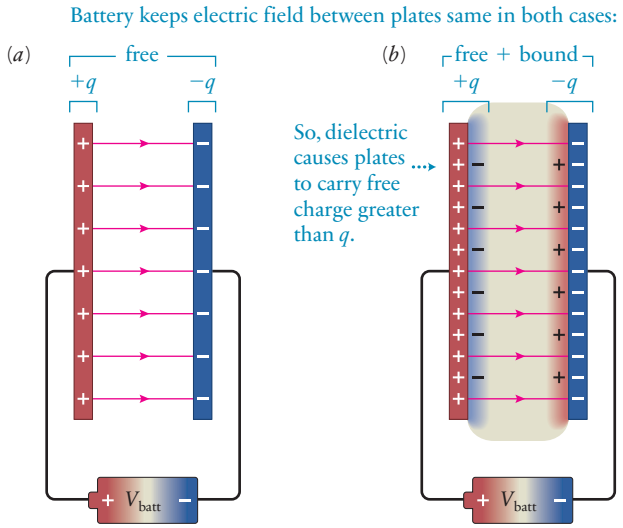


26.9 (*a*) In which direction does the electric field due to the bound surface charge point at a location above the top surface in Figure 26.13*c*? (*b*) In which direction does it point at a location between the top and bottom surfaces?

Figure 26.13 The polarization induced on a dielectric in a parallel-plate capacitor is equivalent to two thin sheets carrying opposite charge.

We can now obtain the electric field of the capacitor with the dielectric by superposition: It is equal to the electric field of the capacitor without the dielectric, plus the electric field of the polarized dielectric by itself. As you found in Checkpoint 26.9, the direction of the electric field due to the polarized dielectric is opposite that of the capacitor, so the presence of the dielectric decreases the electric field strength in the capacitor. Alternatively, we can say that each of the bound surface charges compensates for part of the free charge on the adjoining capacitor plate, so, in effect, the total charge (free and bound) on each side of the capacitor is reduced (**Figure 26.14**). This

Figure 26.14 The presence of a polarized dielectric reduces the strength of the electric field between the plates of an isolated capacitor.



CONCEPTS

reduction in charge, in turn, gives rise to a smaller electric field inside the capacitor. For some dielectric materials, the field inside can be reduced by a factor of several thousand.

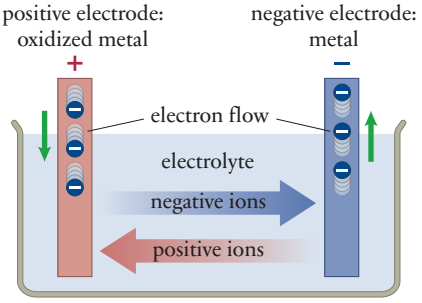
26.10 (*a*) If the magnitude of the bound surface charge on the dielectric slab in Figure 26.14*b* were equal to the magnitude of the free charge on the capacitor plates, what would be the electric field inside the capacitor? (*b*) Could the magnitude of the bound surface charge ever be *greater* than the magnitude of the free charge on the plates?

Figure 26.15 shows what happens when a dielectric-filled capacitor is connected to a battery. The battery keeps the potential difference between the capacitor plates the same regardless of the presence of the dielectric. Because the electric field in the capacitor is equal to the potential difference divided by the distance between the plates (see Example 25.5), it follows that, as long as the capacitor is connected to the battery, the electric field must be the same regardless of the dielectric. The electric field can be the same only if the distribution of charge causing the electric field is the same. In other words, regardless of the presence of the dielectric, we must have the same amount of total charge (free and bound) on each side of the capacitor. Let the magnitude of the free charge on the capacitor plates without the dielectric be q. As shown in Figure 26.15*b*, the polarization of the dielectric causes a negative bound surface charge next to the positive capacitor plate; the sum of the free charge on the conductor and the adjoining bound surface charge must still be equal to $+q$. Similarly, the sum of the negative free charge on the opposite plate and the positive bound surface charge on the adjoining dielectric still must be $-q$. Consequently, the magnitude of the free charge on each plate by itself can be much greater than without the dielectric. This extra charge is supplied by the battery.

Figure 26.15 The presence of a polarized dielectric increases the charge on the plates of a capacitor connected to a battery.

26.11 Given that the electric field is the same in both capacitors in Figure 26.15, which stores the greater amount of electric potential energy?

If the answer to Checkpoint 26.11 surprises you—after all, the electric fields are the same in the two capacitors—remember that the amount of *charge separation* is not the same. The charge on the capacitor plates polarizes the dielectric, and this polarization is the result of charge separation in the molecules of the dielectric. Thus, instead of empty space without charge separation between the capacitor plates, we now have (in addition to a greater charge on the plates) a lot of additional charge separation on the microscopic scale. Most of the energy stored in the capacitor is not due to the separation of charge on the plates, but to the separation of charge in the dielectric between the plates. The pulling apart of the positive and negative charge distributions in the dielectric increases the electric potential energy stored in the dielectric, much like stretching a spring by pulling its ends apart stores elastic potential energy. This tells us that an electric field of a given magnitude in a dielectric stores more energy than an equal field in vacuum.



26.4 Voltaic cells and batteries

CONCEPTS

Electric potential energy is generated by separating charged particles. Earlier in this chapter we discussed two means of accomplishing such charge separation: charging by rubbing and the Van de Graaff generator. Another common way to generate electric potential energy is by means of a *voltaic cell*, the first of which was constructed by Alessandro Volta in around 1800. Assemblies of voltaic cells are called *batteries*. A standard 9-V alkaline battery, for example, consists of six 1.5-V cells connected together. While there are many types of voltaic cells and batteries, all have a common operating principle: Chemical reactions turn chemical energy into electric potential energy by accumulating electrons on one side of the cell (the negative terminal) and removing electrons from the other side (the positive terminal).

The general principle of a voltaic cell is illustrated in **Figure 26.16** on the next page. Two conducting terminals, or *electrodes*, are submerged in an *electrolyte*—a solvent that contains mobile ions. One electrode is usually

Figure 26.16 General operating principle of a voltaic cell. Electrons flow when the cell is connected to an electronic device.

made from an oxidized metal; the oxidized metal reacts by accepting positive ions from the electrolyte and electrons from the electrode. The other electrode is generally metallic; it oxidizes by taking in negative ions and giving up electrons. Because of these reactions, a surplus of electrons builds up on the metallic terminal and a deficit of electrons builds up on the oxidized-metal terminal, causing a potential difference between the two. The reactions stop when the potential difference between the electrodes reaches a certain value called the *cell potential difference*. This value is determined by the type of chemicals in the cell and is typically on the order of a few volts. As we saw in Section 25.5, this potential difference can be used to do electrostatic work on charge carriers when a battery is connected to some device—such as a light bulb, a motor, or a capacitor.

As long as the cell is not connected to anything and its chemicals do not deteriorate, the cell remains in the same state indefinitely. When the cell is connected to a capacitor or to some other device, however, the surplus of electrons is removed from the negative electrode and electrons are supplied to the positive electrode. Then the chemical reactions resume in order to maintain the cell potential difference between the terminals. As the reactions proceed, the electrolyte becomes more dilute and the compositions of the electrodes change. The cell is exhausted when all the ions in the electrolyte have been depleted. For some types of cells, the chemical reactions can be reversed by supplying a potential difference to the terminals of the cell; electric potential energy is then converted back to chemical energy. Such cells are used in rechargeable batteries, which can be reused repeatedly to store and recover electric potential energy.

As we noted in Section 26.1, any charge-separating device involves the motion of charge carriers in the opposite direction of an electric field. This is where work is done on the charge carriers and where some form of energy is converted to electric potential energy. Inside a voltaic cell, electrons must be pulled away from the positively charged terminal and deposited onto the negatively charged terminal. This process occurs at the surface of the electrodes where the chemical reactions take place. The chemical reactions move charge carriers in the opposite direction of electric forces. The chemical energy released in the reactions provides the energy necessary to move the charge carriers against the electric field. The work done per unit charge is called the **emf** (pronounced e-m-f)* of the device:

> **The emf of a charge-separating device is the work per unit charge done by nonelectrostatic interactions in separating positive and negative charge carriers inside the device.**

All charge-separating devices—batteries, voltaic cells, generators, solar cells—have some *nonelectrostatic* means to separate charge carriers and thereby create a potential difference across the terminals of the device.

26.12 As electrons leave one terminal and are added to the other, ions in the electrolyte must flow in the direction indicated in Figure 26.16 to maintain an even distribution of charge. What must be the direction of the electric field in the bulk of the electrolyte to cause this flow?

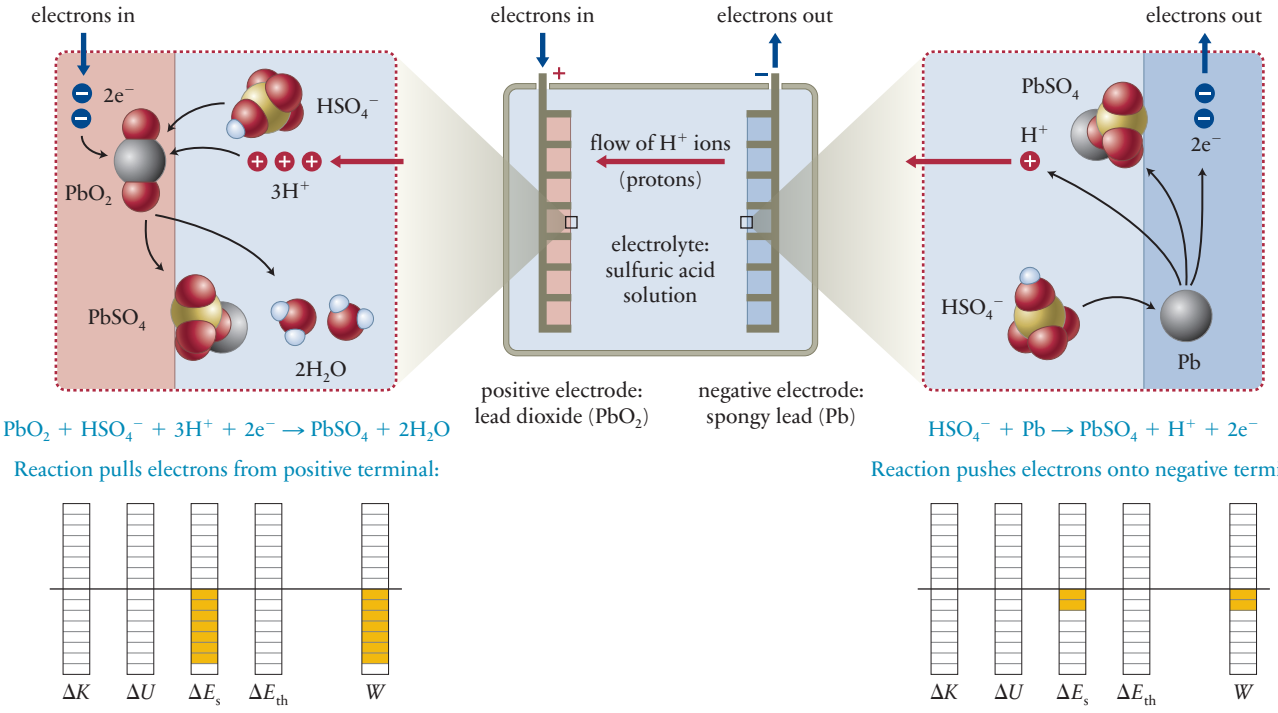


Figure 26.17 illustrates the operation of a lead-acid cell used in automobile batteries. A "12-V" automobile battery consists of six such cells, each producing a potential difference of 2.1 V, for a total of 12.6 V at full charge. The negative electrode of a lead-acid cell is composed of spongy lead (Pb) packed on a metal grid; the positive electrode contains lead dioxide (PbO_2) packed on a metal grid. The electrodes are immersed in sulfuric acid and chemical reactions convert the lead, the lead dioxide, and the sulfuric acid into lead sulfate ($PbSO_4$) and water. For every molecule of lead sulfate that is produced in these reactions, one electron is removed from the positive terminal and one is added to the negative terminal. The left and right sides of Figure 26.17 show energy diagrams for the species undergoing chemical reactions at each of the electrodes. For each reaction, the chemical energy of the species involved in the reaction decreases; this energy is used to do work on the electrons in the electrodes.

26.13 Given that the cell does *positive* work on the electrons, why is it that the work in both energy diagrams in Figure 26.17 is *negative*?

*emf stands for *electromotive force*, a misnomer because this quantity bears no relation to the concept of force. For this reason we shall always refer to this quantity by its abbreviation, rather than its original meaning.

CONCEPTS

Self-quiz

1. Consider again Figure 26.2 and imagine moving one more electron from the fur to the rod. (*a*) Is the work that must be done on the rod-fur system to accomplish this transfer positive, negative, or zero? (*b*) Is the electrostatic work positive, negative, or zero? (*c*) Does the electric potential energy of the rod-fur system increase, decrease, or remain the same?
2. Figure 22.15 (page 791) shows a person's hair standing out from her head because of "electrostatic charge." Look back at the discussion of Van de Graaff generators and discuss how this can happen when a person touches the globe of the generator but is insulated from the ground.
3. A parallel-plate capacitor is connected to a battery. If the distance between the plates is decreased, do the magnitudes of the following quantities increase, decrease, or stay the same: (*i*) the potential difference between the negative plate and the positive plate, (*ii*) the electric field between the plates, and (*iii*) the charge on the plates?
4. When a dielectric is inserted between the plates of an isolated charged capacitor, do the magnitudes of the following quantities increase, decrease, or stay the same: (*i*) the charge on the plates, (*ii*) the electric field between the plates, and (*iii*) the potential difference between the negative plate and the positive plate?
5. Draw an energy diagram for the process of charging a capacitor with a dielectric as shown in Figure 26.15*b* for the following systems: (*a*) battery, capacitor, and dielectric; (*b*) dielectric only; (*c*) battery and capacitor. Ignore any dissipation of energy.

Answers:

1. (*a*) To displace the electron toward the rod, you must apply a force directed toward the rod. Because the force and force displacement are in the same direction, you (an external agent) must do positive work. (*b*) The electric force exerted on the electron is directed toward the fur, opposite the direction of the force displacement, so the electrostatic work is negative. (*c*) The electric potential energy of the system increases because separating charge carriers increases a system's electric potential energy.
2. If a person is in contact with the globe of the generator but insulated from the ground, then the person acts as an extension of the globe. Electrical charge spreads out over the surface of the person, including the surface of each hair as well. Because each hair has a surplus of the same type of charge, the hairs repel each other and stand out, getting as far away from each other as possible.
3. (*i*) Stays the same. The battery keeps the potential difference across the capacitor constant. (*ii*) To keep a constant potential difference when the distance between the plates decreases, the magnitude of the electric field between the plates must increase because $Ed = V_{\text{batt}}$ (see Example 25.5). (*iii*) For the magnitude of the electric field to increase, the charge on the plates must increase.
4. (*i*) Because the capacitor is isolated, the charge on the plates must remain the same—there is no path for the charge to travel elsewhere. (*ii*) When the dielectric is inserted, the electric field due to the bound surface charge is in the opposite direction of the electric field due to the free charge on the plates and decreases the magnitude of the electric field between the plates. (*iii*) Because the magnitude of the electric field decreases and the separation between the plates is constant, the magnitude of the potential difference between the negative plate and the positive plate must also decrease.
5. See **Figure 26.18**. (*a*) During charging, a decrease in source energy (from the battery) increases the electric potential energy (more charge separation in the dielectric and on the capacitor plates). (*b*) The electric potential energy of the dielectric increases due to work done on it by the battery and the capacitor. The electric potential energy stored in the dielectric is smaller than that stored in part *a* because some electric potential energy is stored on the capacitor plates. (*c*) The decrease in source energy is the same as in part *a*. The electric potential energy stored on the capacitor is smaller than in part *a* because most of the converted source energy ends up in the dielectric, which is not part of the system considered. This energy leaves the system as negative work.

Figure 26.18

26.5 Capacitance

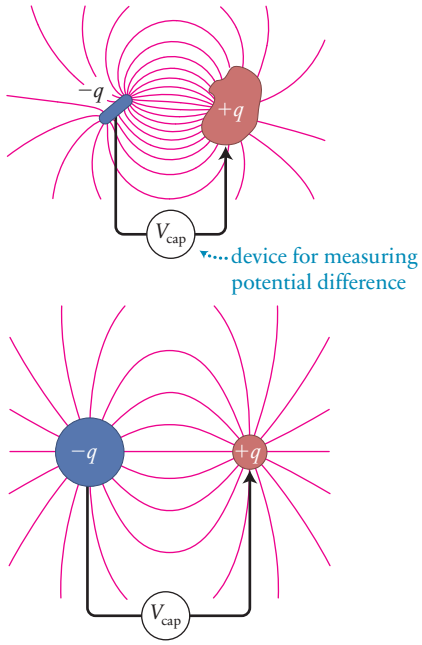

Figure 26.19 shows three capacitors, each one consisting of a pair of conducting objects carrying opposite charges of magnitude q. For each arrangement, the potential difference between the objects is proportional to q; that is, doubling q doubles the potential difference across the capacitor. The ratio of the magnitude of the charge on one of the objects to the magnitude of the potential difference across them is defined as the **capacitance** of the arrangement:

$$C \equiv \frac{q}{V_{\text{cap}}}. \tag{26.1}$$

In Eq. 26.1, q represents *the magnitude of the charge on each conducting object* and V_{cap} is *the magnitude of the potential difference between the conducting objects*. Because both these quantities are positive, C is always positive.

The value of C depends on the size, shape, and separation of the conductors. In Figure 26.19, for example, the values of V_{cap} would typically be different for the three capacitors, even though q is the same for each. Below we'll examine how to determine C for a given set of conductors.

Figure 26.19 The electric fields and potential differences of three different capacitors.

26.14 Two capacitors, A and B, are each connected to a 9-V battery. If $C_A > C_B$, which capacitor stores the greater amount of charge?

The answer to Checkpoint 26.14 suggests a simple interpretation of C. As its name suggests, C represents the capacitor's *capacity to store charge*: The greater C, the greater the amount of charge stored for a given value of V_{cap}.

As you can see from Eq. 26.1, capacitance has SI units of coulomb per volt. This derived unit is given the name **farad** (F), in honor of the English physicist Michael Faraday:

$$1\ \text{F} \equiv 1\ \text{C/V}.$$

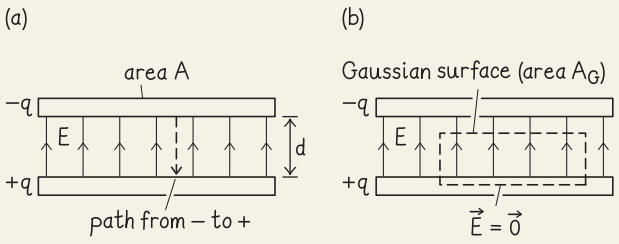
As you will see in Checkpoint 26.15, a capacitance of 1 F is enormous. The capacitance of capacitors commonly found in electronic devices is expressed in microfarads ($1\ \mu\text{F} = 1 \times 10^{-6}$ F) and picofarads ($1\ \text{pF} = 1 \times 10^{-12}$ F).

Figure 26.19 suggests a simple procedure for determining the capacitance of a given set of conductors: Determine the potential difference V_{cap} between the two conductors when they carry some given charge q, and use Eq. 26.1 to calculate C. Note that because conductors are equipotentials, V_{cap} represents the potential difference between *any* two points on the conductors measured along *any* path. The Procedure box below gives one procedure for determining the capacitance of a given set of conductors. In the next examples we apply this procedure to some simple configurations of conductors.

PROCEDURE: Calculating the capacitance of a pair of conductors

To calculate the capacitance of a pair of conductors:

1. Let the conductors carry opposite charges of magnitude q.
2. Use Gauss's law, Coulomb's law, or direct integration to determine the electric field along a path leading from the negatively charged conductor to the positively charged conductor.
3. Calculate the electrostatic work W done on a test particle carrying a charge q_t along this path (Eq. 25.24) and determine the potential difference across the capacitor from Eq. 25.15:
$$V_{\text{cap}} = -W_{q_t}(- \rightarrow +)/q_t.$$
4. Use Eq. 26.1, $C \equiv q/V_{\text{cap}}$, to determine C.



QUANTITATIVE TOOLS

EXAMPLE 26.2 Parallel-plate capacitor

What is the capacitance of a parallel-plate capacitor that has a plate area A and a plate separation distance d?

1 GETTING STARTED I begin by making a sketch of the capacitor, showing the electric field between the plates (**Figure 26.20*a***). The problem doesn't specify the plate shape, so I simply show the capacitor from the side, representing each plate by a horizontal line. If I assume that the separation distance d is small, then the electric field is uniform and confined between the plates.

Figure 26.20

2 DEVISE PLAN I can use the steps of the Procedure box on page 921 to determine the capacitance. The first step is to determine the electric field between the capacitor plates when they carry opposite charges of magnitude q. The second step is to obtain the electrostatic work done on a test particle moved from one plate to the other; I can use Eq. 25.24 to obtain this work. Because the field is uniform, it is most convenient to choose a path along a field line for the path over which the electrostatic work is done. As specified in the Procedure box, the path runs from the negatively charged plate to the positively charged plate. Once I know the electrostatic work, I know the potential difference across the capacitor and so can calculate the capacitance.

3 EXECUTE PLAN Because of the planar symmetry, I can use Gauss's law to determine the electric field. I choose a cylindrical Gaussian surface straddling the surface of the positively charged plate. The cylinder height is less than d, and the area of the end surfaces is A_G (Figure 26.20*b*). The electric flux through this Gaussian surface is zero everywhere except through the top surface, where $\Phi = EA_G$. (The bottom surface is inside the conducting metal plate, where the electric field is zero.)

To apply Gauss's law, I also need to know the charge enclosed by the Gaussian surface. The positive plate carries a charge $+q$ distributed over a surface of area A, so the surface charge density is $\sigma = +q/A$ and the charge enclosed by the Gaussian surface is $q_{enc} = \sigma A_G = (q/A)A_G$. Applying Gauss's law, $\Phi = q_{enc}/\epsilon_0$ (Eq. 24.8), I get

$$EA_G = \frac{q}{\epsilon_0 A} A_G \quad \text{or} \quad E = \frac{q}{\epsilon_0 A} = \frac{\sigma}{\epsilon_0} \tag{1}$$

in agreement with Eq. 24.17.

Now that I know E, I can calculate the electrostatic work required to move a test particle carrying a charge $+q_t$ from the negatively charged to the positively charged plate. The electric force exerted on the test particle is upward in Figure 26.20, and the force displacement is downward because the particle moves from negative plate to positive plate. Because these two vectors point in opposite directions, the electrostatic work done on the test particle is negative, $W_{q_t} = -q_t Ed$, and the potential difference across the capacitor is, from Eq. 25.15,

$$V_{cap} \equiv \frac{-W_{q_t}(- \to +)}{q_t} = \frac{q_t Ed}{q_t} = Ed$$

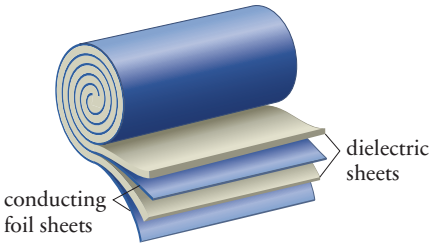
or, substituting E from Eq. 1,

$$V_{cap} = \frac{qd}{\epsilon_0 A}.$$

Note that the potential difference is proportional to the magnitude of the charge on each plate, q. Using the definition of capacitance, I obtain

$$C \equiv \frac{q}{V_{cap}} = \frac{q}{qd/(\epsilon_0 A)} = \frac{\epsilon_0 A}{d}. \checkmark$$

4 EVALUATE RESULT My result agrees with the conclusions we drew in Section 26.2: The capacitance (or quantity of charge stored for a given potential difference) increases with increasing plate area A and decreasing plate separation distance d. Also, I note that the electric field—and therefore the capacitance—do not depend on the plate: Circular or square plates give the same result.



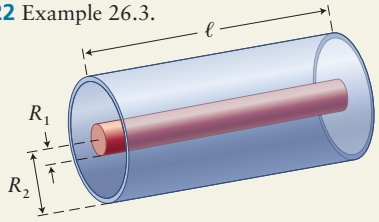
26.15 The plate spacing in a typical parallel-plate capacitor is about 50 μm. (*a*) What is the plate area in a 1-μF capacitor? (*b*) Given that the electric field at which electrical breakdown occurs in air is about 3×10^6 V/m, what is the maximum charge that this capacitor can hold? (*c*) How many electrons does this charge correspond to? (The electron's charge is $e = 1.6 \times 10^{-19}$ C.)

As Checkpoint 26.15 shows, even modest capacitances require very large plate areas. Various techniques are used to keep the overall size of capacitors small, one of which involves rolling up two thin conducting sheets that are separated by thin sheets of a dielectric material (**Figure 26.21*a***). Figure 26.21*b* shows a number of different capacitors used in electronic circuits.

QUANTITATIVE TOOLS

Figure 26.21

(*a*) One way to design a compact capacitor with a large surface area



(*b*) Some capacitors used in electronic circuits

EXAMPLE 26.3 Coaxial cylindrical capacitor

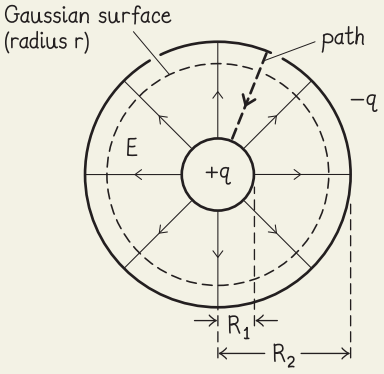


Figure 26.22 shows a *coaxial capacitor* consisting of two concentric metal cylinders 1 and 2, of radii R_1 and $R_2 > R_1$, and both of length $\ell \gg R_2$. Both cylinders are made of metal. What is the capacitance of this arrangement?

Figure 26.22 Example 26.3.

❶ **GETTING STARTED** To determine the capacitance, I must let the two cylinders carry opposite charges of magnitude q, which I assume to be uniformly distributed over each cylinder. If I let cylinder 1 carry a charge $+q$ and cylinder 2 carry a charge $-q$, the electric field points radially outward from cylinder 1 to cylinder 2 (**Figure 26.23**). Because the cylinders are very long relative to their separation distance $R_2 - R_1$, I assume that the electric field is confined to the volume between the cylinders.

Figure 26.23

❷ **DEVISE PLAN** Again I refer to the Procedure box on page 921 to calculate the capacitance. For the path over which electrostatic work is done, I choose a straight path that goes radially from cylinder 2 to cylinder 1.

❸ **EXECUTE PLAN** Because of the cylindrical symmetry, I choose a cylindrical Gaussian surface (Figure 26.23). The length of the Gaussian surface is ℓ_G, and its radius is r ($R_2 > r > R_1$). The electric flux Φ through the curved portion of the Gaussian surface is equal to the product of the electric field strength E_r at a distance r from the common axis of cylinders 1 and 2 and the surface area of the Gaussian surface $A_G = (2\pi r)\ell_G$. Therefore $\Phi = 2\pi r \ell_G E_r$. Because the linear charge density on cylinder 1 is $+q/\ell$, the quantity of charge enclosed by the Gaussian surface is given by the product of the linear charge density and the length of the Gaussian surface: $q_{enc} = +(q/\ell)\ell_G$. Applying Gauss's law, I get

$$2\pi r \ell_G E_r = \frac{q\ell_G}{\epsilon_0 \ell},$$

or $E_r = q/(2\pi\epsilon_0 \ell r)$, in agreement with the result we obtained in Exercise 24.7, $E = 2k\lambda/r$, because $k = 1/(4\pi\epsilon_0)$ and $q/\ell = \lambda$.

Now that I know E_r, I can calculate the electrostatic work required to move a test particle carrying a charge q_t from cylinder 2 to cylinder 1. Integrating the electric force exerted on the test particle over the force displacement from cylinder 2 (negatively charged) to cylinder 1 (positively charged), I get

$$W_{q_t} = \int_{R_2}^{R_1} \frac{qq_t}{2\pi\epsilon_0 \ell r}\, dr.$$

Working out the integral, I obtain

$$W_{q_t} = \frac{qq_t}{2\pi\epsilon_0 \ell}\Big[\ln r\Big]_{R_2}^{R_1} = \frac{qq_t}{2\pi\epsilon_0 \ell}\ln\left(\frac{R_1}{R_2}\right).$$

The potential difference between the negative cylinder 2 and the positive cylinder 1 is thus

$$V_{cap} \equiv \frac{-W_{q_t}}{q_t} = -\frac{q}{2\pi\epsilon_0 \ell}\ln\left(\frac{R_1}{R_2}\right) = \frac{q}{2\pi\epsilon_0 \ell}\ln\left(\frac{R_2}{R_1}\right).$$

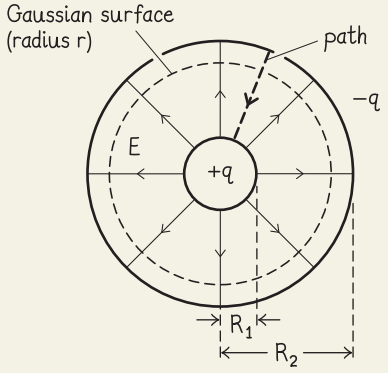
Because $R_2 > R_1$, the logarithm is positive and therefore V_{cap} is positive, as it should be because I am bringing a quantity q_t of positive charge from a location of low potential on negatively charged cylinder 2 to a location of high potential on positively charged cylinder 1.

(Continued)

According to Eq. 26.1, the capacitance of the coaxial capacitor is thus

$$C \equiv \frac{q}{V_{\text{cap}}} = \frac{2\pi\epsilon_0\ell}{\ln(R_2/R_1)}. \checkmark$$

❹ **EVALUATE RESULT** My result shows that the capacitance is proportional to ℓ, which makes sense: The longer the coaxial cylinders, the greater the quantity of charge that can be stored on them. Decreasing R_1 or increasing R_2 is equivalent to increasing the plate separation distance d in a parallel-plate capacitor, which decreases the capacitance. Indeed, my result shows a decreasing capacitance for decreasing R_1 or increasing R_2. (The dependence on R_1 and R_2 is a bit more complicated than the dependence on d in a parallel-plate capacitor because the electric field in the coaxial capacitor is nonuniform and because changing the radii of the cylinders affects their surface areas.)



26.16 Coaxial cables used for cable television typically have a central metallic core of 0.20-mm radius, surrounded by a cylindrical metallic sheath of 2.0-mm radius. The two are separated by a plastic spacer. If the effect of the spacer can be ignored (that is, assuming the two conductors are separated by air), what is the capacitance of a 100-m-long cable?

EXAMPLE 26.4 Spherical capacitor

What is the capacitance of a spherical capacitor consisting of two concentric conducting spherical shells of radii R_1 and $R_2 > R_1$?

❶ **GETTING STARTED** If I let the inner sphere carry a positive charge $+q$ and the outer one a negative charge $-q$, my sketch of the capacitor looks identical to the sketch of the coaxial capacitor of Example 26.3 (**Figure 26.24**). The calculation, however, will not be the same because now the electric field has spherical, not cylindrical, symmetry.

Figure 26.24

❷ **DEVISE PLAN** For the path over which electrostatic work is done, I choose a straight path that goes radially from the outer sphere to the inner sphere. The outer sphere does not contribute to the electric field between the spheres because the field inside a hollow conductor is always zero (see Section 24.5). The electric field created by the inner sphere is the same as that created by a charged particle (Eq. 24.15, $E = kq/r^2$), so I can use this expression to follow steps 3 and 4 in the Procedure box on page 921.

❸ **EXECUTE PLAN** The electrostatic work done in moving a test particle carrying a charge q_t from the outer sphere to the inner sphere is

$$W_{q_t}(- \to +) = \int_{R_2}^{R_1} \frac{qq_t}{4\pi\epsilon_0 r^2}\, dr.$$

Working out the integral, I get

$$W_{q_t}(- \to +) = -\frac{qq_t}{4\pi\epsilon_0}\left[\frac{1}{r}\right]_{R_2}^{R_1} = -\frac{qq_t}{4\pi\epsilon_0}\left[\frac{1}{R_1} - \frac{1}{R_2}\right].$$

The potential difference between the outer and inner spheres is thus

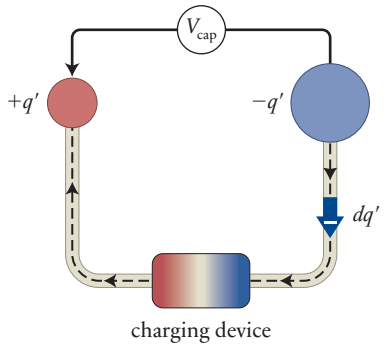
$$V_{\text{cap}} \equiv \frac{-W_{q_t}(- \to +)}{q_t} = \frac{q}{4\pi\epsilon_0}\left[\frac{1}{R_1} - \frac{1}{R_2}\right],$$

so the capacitance is

$$C \equiv \frac{q}{V_{\text{cap}}} = 4\pi\epsilon_0\left[\frac{1}{R_1} - \frac{1}{R_2}\right]^{-1} = 4\pi\epsilon_0\left[\frac{R_2 - R_1}{R_1 R_2}\right]^{-1}$$

$$= 4\pi\epsilon_0\left[\frac{R_1 R_2}{R_2 - R_1}\right]. \checkmark$$

❹ **EVALUATE RESULT** I expect the capacitance to go up as the separation distance $R_2 - R_1$ between the spheres decreases, and this is just what my result shows. If I increase the spheres' radii while keeping their separation distance $R_2 - R_1$ fixed, the surface area $A = 4\pi R^2$ of each sphere increases and the capacitance should increase, in agreement with my result.



26.17 (*a*) To calculate the "capacitance" of an isolated sphere, evaluate the result we obtained in Example 26.4 in the limit that R_2 goes to infinity. (*b*) What is the capacitance of the spherical metal dome of a Van de Graaff generator that has a radius of about 2.5 m. (*c*) Given that air breaks down in an electric field with a magnitude of about 3.0×10^6 V/m, what is the maximum amount of charge that can be stored on the dome before the air breaks down?

QUANTITATIVE TOOLS

26.6 Electric field energy and emf

How much electric potential energy is stored in a charged capacitor? To answer this question, consider a simple capacitor consisting of two conducting objects. In order to charge the capacitor, some charge-separating device must transfer charge from one conductor to the other (Figure 26.25). During this transfer, the charge-separating device does work on the capacitor and this energy ends up as electric potential energy "stored in the capacitor."* One complication in the calculation of the work done by the charge-separating device is that as the magnitude of the charge on each conductor increases, the potential difference increases too, so the work required to transfer a unit of charge increases.

Figure 26.25 To determine the electric potential energy stored in a capacitor, we calculate the energy required to transfer charge from one conductor to the other.

Let us therefore break down the transfer of charge from one conductor to the other into small increments of charge dq', so that the potential difference is essentially constant during the transfer of a single increment. Consider some instant during the charging when the magnitude of the charge on each conductor is q'. The potential difference between the negative and positive conductors is then given by Eq. 26.1: $V_{cap} = q'/C$. As an additional increment of charge dq' is moved from the negative to the positive conductor, the electrostatic work done on it is $dW = -dq'V_{cap}$ (Eq. 25.17). Because the charge-separating device must do work on charge carriers against the electric force, the work done by the charge-separating device on the charge carriers is the negative of the electrostatic work, so the change in electric potential energy of the capacitor during the transfer is

$$dU^E = -dW = V_{cap}\,dq' = \frac{q'}{C}\,dq'. \tag{26.2}$$

When the magnitude of the charge on each conductor has increased from zero to its final value q, the electric potential energy stored in the capacitor is

$$U^E = \int dU^E = \int_0^q \frac{q'}{C}\,dq' = \frac{1}{C}\int_0^q q'\,dq' = \tfrac{1}{2}\frac{q^2}{C}. \tag{26.3}$$

Often it is more convenient to express the electric potential energy not in terms of the magnitude of the charge q on the capacitor, but in terms of the potential difference across it:

$$U^E = \tfrac{1}{2}\frac{q^2}{C} = \tfrac{1}{2}CV_{cap}^2 = \tfrac{1}{2}qV_{cap}. \tag{26.4}$$

Note that Eqs. 26.3 and 26.4 hold for any type of capacitor, regardless of the configuration of the conductors. All that enters into these expressions besides the charge or the potential difference is the capacitance, which depends on the size, shape, and the separation of the conductors.

26.18 A 1.0-μF parallel-plate capacitor with a plate spacing of 50 μm is charged up to the breakdown threshold. (*a*) If the electric field in the air between the capacitor plates is 3.0×10^6 V/m, how much energy is stored in the capacitor? Express your answer in joules. (*b*) How high must you raise this book ($m \approx 2$ kg) to increase the gravitational potential energy of the Earth-book system by the same amount?

As we discussed in Section 26.1, we can imagine electric potential energy to be stored either in the configuration of charge in the capacitor or in the electric field. We can use Eq. 26.4 and our knowledge about the

*We are assuming that there is no dissipation of energy, so that all the work done on the system ends up as electric potential energy. In practice this is a reasonable assumption.

QUANTITATIVE TOOLS

electric field in a capacitor to relate electric potential energy to the electric field. From Example 25.5 we know that the magnitude of the potential difference between the plates of a parallel-plate capacitor is given by Ed, so, using the expression for C in Example 26.2 and Eq. 26.4, we can write for the electric potential energy stored in a parallel-plate capacitor

$$U^E = \tfrac{1}{2} C V_{\text{cap}}^2 = \tfrac{1}{2}\left(\frac{\epsilon_0 A}{d}\right)(Ed)^2 = \tfrac{1}{2}\epsilon_0 E^2 (Ad). \tag{26.5}$$

The term in parentheses on the right side, Ad, is equal to the volume of the space between the capacitor plates—that is, the region to which the electric field is confined. Therefore, the energy per unit volume stored in the electric field—the **energy density** of the electric field—is

$$u_E \equiv \frac{U^E}{\text{volume}} = \tfrac{1}{2}\epsilon_0 E^2. \tag{26.6}$$

Although we derived this expression for the special case of a parallel-plate capacitor, it holds true for any electric field in vacuum. Any given region of space where a uniform electric field is present can be viewed as containing an amount of electric potential energy equal to $\frac{1}{2}\epsilon_0$ times the square of the magnitude of the electric field in that region times the volume. If the electric field is nonuniform, we must subdivide the volume of interest into small enough segments that E can be considered uniform within each segment, then apply Eq. 26.6 to each segment and take the sum of all the contributions. (This corresponds to integrating the energy density over the volume of the region that contains the electric field.)

26.19 A parallel-plate capacitor has plates of area A separated by a distance d. The magnitude of the charge on each plate is q. (*a*) Determine the magnitude of the force exerted by the positively charged plate on the negatively charged one. (*b*) Suppose you increase the separation between the plates by an amount Δx. How much work do you need to do on the capacitor to achieve this increase? (*c*) What is the change in the electric potential energy of the capacitor? (*d*) Moving the plate adds additional space with electric field between the plates. Show that the energy stored in the electric field in this additional space is equal to the work done on the capacitor.

The energy stored in a capacitor is supplied to it by the charging device—such as a generator, a battery, or a solar cell. Inside this device, nonelectrostatic interactions cause a separation of charge by doing work on charged particles. The work per unit charge done by the nonelectrostatic interactions on the charge carriers inside the device is called the emf and is denoted by $\mathscr{E}$:

$$\mathscr{E} \equiv \frac{W_{\text{nonelectrostatic}}}{q}. \tag{26.7}$$

The SI unit of emf is the same as that of potential: the volt. The rating of a battery—1.5 V or 9 V—gives its emf.*

If no energy is dissipated inside the charging device, *all* of the energy can be transferred to charge carriers outside the device. This transfer takes

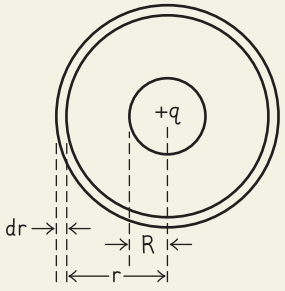
*The term *voltage* is sometimes used to refer to a potential difference or to an emf (such as the rating of a battery). Potential difference, however, is related to *electrostatic* work done on charge carriers, whereas emf deals with *nonelectrostatic* work done on them. Thus, electrostatic work brings opposite charge carriers together, while nonelectrostatic work causes charge separation. To maintain this important distinction, we shall avoid the term *voltage*.

QUANTITATIVE TOOLS

place through electric interactions. In Figure 26.25, for example, electric forces remove electrons from one object and push them onto the other, charging the capacitor. In the absence of any energy dissipation, the nonelectrostatic work done on charge carriers inside the device is equal to the electrostatic work done on charge carriers outside it. Because the electrostatic work per unit charge is the potential difference between the negative and positive terminals of the charging device, we have, for an ideal charging device,

$$V_{\text{device}} = \mathscr{E} \quad \text{(ideal device)}. \tag{26.8}$$

In practice, some energy is always dissipated inside the device, so not all of the nonelectrostatic work done on charge carriers inside the device can be turned into electrostatic work. Consequently, for most devices, $V_{\text{device}} < \mathscr{E}$.



EXAMPLE 26.5 Van de Graaff energy

The radius of the dome on one very large Van de Graaff generator is about 2.5 m, and air breaks down when the field magnitude is about 3.0×10^6 V/m. How much electric potential energy is stored in the electric field surrounding the dome just before the air there breaks down?

❶ **GETTING STARTED** I am given the radius of a Van de Graaff dome and asked to calculate how much potential energy is in the electric field surrounding the dome just before the field causes the air to break down. If I approximate the dome as a uniformly charged spherical shell, then the electric field surrounding it is the same as that surrounding a particle carrying the same charge [Eq. 24.15, $E = q/(4\pi\epsilon_0 r^2)$]. The magnitude of the electric field around the dome is greatest at the dome surface, so I take this E_{surf} value as the maximum value just before the air breaks down.

❷ **DEVISE PLAN** Equation 26.6 gives me the energy density of the electric field around the dome. I can substitute the Eq. 24.15 expression for the electric field of a sphere carrying a charge q into Eq. 26.6 to obtain an expression for the energy density of the electric field at an arbitrary distance r from the dome center. Because the electric field has the same magnitude at any location a distance r from the dome center, I can divide the space outside the dome into a series of thin spherical shells, each of thickness dr and all concentric with the dome (**Figure 26.26**), and then integrate over all shells from $r = R$ to $r = \infty$ to obtain the energy stored in the electric field surrounding the dome in terms of the charge q. I can then use Eq. 24.15 to eliminate q from my result and express the energy stored in terms of E_{surf}, which is given.

Figure 26.26

❸ **EXECUTE PLAN** Substituting Eq. 24.15 into Eq. 26.6, I get

$$u_E = \tfrac{1}{2}\epsilon_0 E^2 = \tfrac{1}{2}\epsilon_0\left(\frac{q}{4\pi\epsilon_0 r^2}\right)^2.$$

The volume of a thin spherical shell of radius r and thickness dr centered on the dome is equal to the surface area of a sphere of radius r times the shell thickness: $(4\pi r^2)dr$. The energy in that volume is thus $dU^E = u_E(4\pi r^2)dr$, and so the electric potential energy in the space around the dome is

$$\begin{aligned} U^E &= \int_R^\infty dU^E = \int_R^\infty u_E(4\pi r^2)\,dr \\ &= \tfrac{1}{2}\epsilon_0\int_R^\infty\left(\frac{q}{4\pi\epsilon_0 r^2}\right)^2(4\pi r^2)dr = \frac{q^2}{8\pi\epsilon_0}\int_R^\infty \frac{1}{r^2}\,dr \\ &= \frac{q^2}{8\pi\epsilon_0}\left[\frac{-1}{r}\right]_R^\infty = \frac{q^2}{8\pi\epsilon_0 R}. \end{aligned} \tag{1}$$

Now I have an expression for U^E, the quantity I must determine, but I have no value for q. Given that the electric field at the dome surface is given by Eq. 24.15, $E_{\text{surf}} = q/(4\pi\epsilon_0 R^2)$, I can rearrange this expression to $q = E_{\text{surf}}(4\pi\epsilon_0 R^2)$ and rewrite Eq. 1 as $U^E = 2\pi\epsilon_0 E_{\text{surf}}^2 R^3$. Because E_{surf} is the maximum electric field magnitude around the dome, I know that this magnitude must be the breakdown value for air. Substituting the values given, I get

$$\begin{aligned} U^E &= 2\pi[8.85\times10^{-12}\,\text{C}^2/(\text{N}\cdot\text{m}^2)](3.0\times10^6\,\text{V/m})^2(2.5\,\text{m})^3 \\ &= 7.8\,\text{kJ}. \checkmark \end{aligned}$$

❹ **EVALUATE RESULT** As a check on my work, I can calculate the electric potential energy of the charge stored on the dome using Eq. 26.4. In Checkpoint 26.17, you found that the capacitance of an isolated sphere is $C_{\text{sphere}} = 4\pi\epsilon_0 R$ and that the potential of a sphere is related to the electric field at its surface by $V_{\text{cap}} = ER$. Therefore $U^E = \frac{1}{2}CV_{\text{cap}}^2 = 2\pi\epsilon_0 R^3 E_{\text{surf}}^2$, which is the same result I obtained.

QUANTITATIVE TOOLS

26.20 To store electric potential energy, the flash unit on a typical camera uses a 100-μF capacitor charged to a potential difference of 300 V. When the flash is fired, the energy in the capacitor is released to a bulb in a burst of about 1.0-ms duration. (*a*) How much energy is stored in the fully charged capacitor before it is fired? (*b*) What is the average power of the flash firing?

26.7 Dielectric constant

As we saw in Section 26.3, the capacitance of a capacitor can be increased by inserting a dielectric between the two conductors. For example, inserting a slab of mica between the plates of an isolated charged capacitor (**Figure 26.27**) decreases the potential difference across the capacitor by a factor of 5. This tells us that the mica reduces the electric field inside the isolated capacitor by a factor of 5. By definition, the magnitude of the potential difference V_0 across the isolated capacitor without a dielectric divided by the magnitude of the potential difference V_d with the dielectric is called the **dielectric constant** κ:

$$\kappa \equiv \frac{V_0}{V_d}. \tag{26.9}$$

Given that the magnitude q_0 of the charge on each plate of the isolated capacitor is not affected by the dielectric, we see from Eqs. 26.9 and 26.1 that

$$\kappa \equiv \frac{V_0}{V_d} = \frac{V_0/q_0}{V_d/q_0} = \frac{1/C_0}{1/C_d} = \frac{C_d}{C_0}, \tag{26.10}$$

where C_d is the capacitance of the capacitor with the dielectric and C_0 that without a dielectric. Therefore, the capacitance changes by the factor κ when a dielectric is inserted:

$$C_d = \kappa C_0. \tag{26.11}$$

The dielectric constant is always greater than or equal to 1 ($\kappa \geq 1$). It is greater than 1 with a dielectric in place because the presence of a dielectric decreases the electric field inside the capacitor. The greater the polarization of the dielectric material, the more reduced the electric field inside the dielectric and the greater the dielectric constant κ. **Table 26.1** gives the dielectric constants for several commonly used dielectric materials.

Figure 26.27 The potential difference across an isolated parallel-plate capacitor is greater (*a*) without a dielectric between the plates than it is (*b*) with a dielectric.

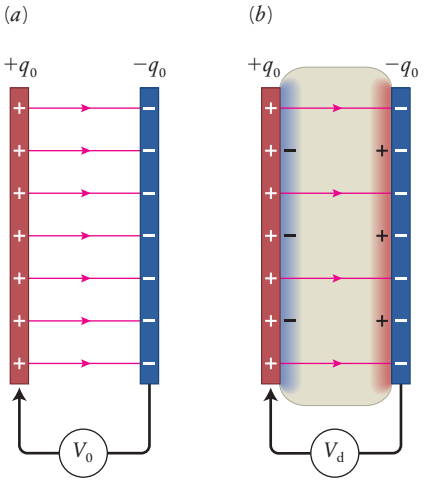


Table 26.1 Dielectric properties

Material	Dielectric constant κ	Breakdown threshold E_{max} (V/m)
Air (1 atm)	1.00059	3.0×10^6
Paper	1.5–3	4.0×10^7
Mylar (polyester)	3.3	4.3×10^8
Quartz	4.3	8×10^6
Mica	5	2×10^8
Oil	2.2–2.7	
Porcelain	6–8	
Water (distilled, 20°C)	80.2	$6.5–7 \times 10^7$
Titania ceramic	126	8×10^6
Strontium titanate	322	
Barium titanate	1200	8×10^7

The dielectric constant for vacuum—that is, no material between the plates—is unity (one) by definition. Because air is very dilute, the dielectric constant of air is nearly unity as well. If the dielectric is composed of polar molecules that can align themselves (such as the water molecules in liquid water), then the overall polarization is much greater than in nonpolar dielectrics, so the dielectric constant is large. For some polar materials, the dielectric constant can be in the thousands.

The electric field $\vec{E}$ inside the dielectric is the superposition of the electric field due to the free charge on the plates, $\vec{E}_{\text{free}}$, and the electric field due to the bound surface charge on the dielectric, $\vec{E}_{\text{bound}}$: $\vec{E} = \vec{E}_{\text{free}} + \vec{E}_{\text{bound}}$ (**Figure 26.28a**). We designate the magnitude of the free charge on the capacitor plates by q_{free} and the magnitude of the bound charge on the surfaces of the dielectric by q_{bound} (Figures 26.28*b* and *c*). With this notation, both q_{free} and q_{bound} are always positive. Using the expression for the electric field of a sheet of charge, we can thus write for the magnitude of the electric field inside the capacitor in the absence of a dielectric

$$E_{\text{free}} = \frac{\sigma_{\text{free}}}{\epsilon_0} = \frac{q_{\text{free}}}{\epsilon_0 A}, \tag{26.12}$$

where $\sigma_{\text{free}} = q_{\text{free}}/A$ is the magnitude of the free surface charge density and A is the area of either capacitor plate. Likewise, the magnitude of the electric field due to the bound surface charge is

$$E_{\text{bound}} = \frac{\sigma_{\text{bound}}}{\epsilon_0} = \frac{q_{\text{bound}}}{\epsilon_0 A}, \tag{26.13}$$

where σ_{bound} is the magnitude of the bound surface charge density. Because $\vec{E}_{\text{free}}$ and $\vec{E}_{\text{bound}}$ point in opposite directions, the magnitude of the electric field $\vec{E}$ inside the dielectric is then

$$E = E_{\text{free}} - E_{\text{bound}} = \frac{\sigma_{\text{free}} - \sigma_{\text{bound}}}{\epsilon_0} = \frac{q_{\text{free}} - q_{\text{bound}}}{\epsilon_0 A}. \tag{26.14}$$

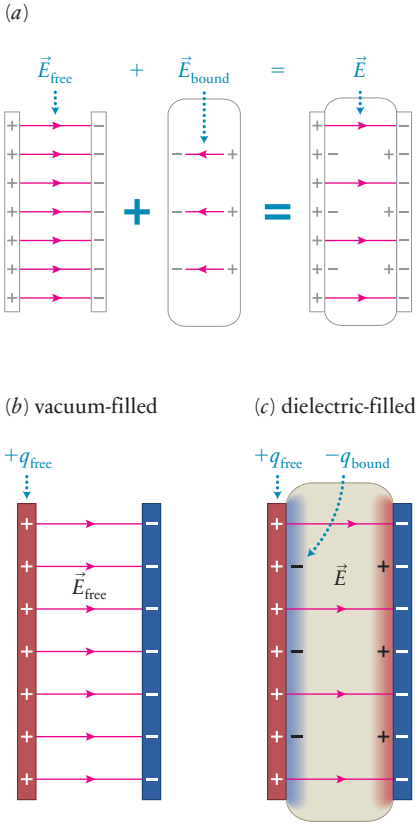
Let us determine the magnitude of the bound charge q_{bound}. If the plate separation is d, we can write Eq. 26.10 in the form

$$\kappa \equiv \frac{V_0}{V_d} = \frac{E_{\text{free}}\, d}{E\, d} = \frac{E_{\text{free}}}{E}, \tag{26.15}$$

where E_{free} is the magnitude of the electric field due to the free charge only, and E is the magnitude of the electric field inside the dielectric. In other words, the dielectric reduces the electric field by the factor κ: $E = E_{\text{free}}/\kappa$. Substituting Eqs. 26.12 and 26.14 into this expression, we get

$$\frac{q_{\text{free}}}{\kappa \epsilon_0 A} = \frac{q_{\text{free}} - q_{\text{bound}}}{\epsilon_0 A} \tag{26.16}$$

or



$$\frac{q_{\text{free}}}{\kappa} = q_{\text{free}} - q_{\text{bound}}. \tag{26.17}$$

Solving this expression for q_{bound}:

$$q_{\text{bound}} = \frac{\kappa - 1}{\kappa} q_{\text{free}}. \tag{26.18}$$

Because κ is always greater than 1 in the presence of a dielectric, we see that the magnitude of the bound surface charge is always smaller than the magnitude of the free charge that causes it.

Figure 26.28 (*a*) The electric field inside a dielectric-filled capacitor is the vector sum of the electric field due to the charged plates and that due to the polarized dielectric. (*b*) and (*c*) Bound and free charge on a vacuum-filled and a dielectric-filled isolated parallel-plate capacitor.

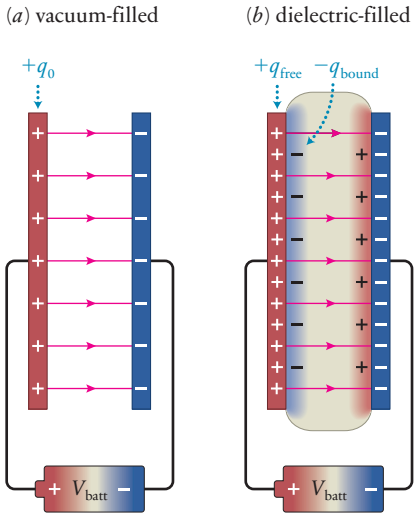


Figure 26.29 Bound and free charge on a vacuum-filled and a dielectric-filled parallel-plate capacitor connected to a battery.

Next we consider the situation of a capacitor connected to a battery (**Figure 26.29**). In this situation, the potential difference across the capacitor is constant, but the charge on the plates changes when the dielectric is inserted. As we have seen in Section 26.3, the electric field inside the dielectric must be the same as before the dielectric was inserted. In other words, the sum of the free and bound charges must still be equal to q_0; that is, $q_0 = q_{free} - q_{bound}$ (Figure 26.29). Because the definition of capacitance involves only the charge on the capacitor plates, we can write

$$C_d \equiv \frac{q_{free}}{V_d} \tag{26.19}$$

and likewise

$$C_0 \equiv \frac{q_0}{V_0}. \tag{26.20}$$

Note the difference between q_{free} and q_0. Even though both represent free charge, they are not equal because when the dielectric is inserted, the battery increases the charge on the plate in order to maintain a constant potential difference across the capacitor, so $q_{free} > q_0$. Because $C_d = \kappa C_0$ (Eq. 26.11), we see from Eqs. 26.19 and 26.20 that the dielectric increases the charge on the capacitor plates by the factor κ:

$$q_{free} = \kappa q_0. \tag{26.21}$$

26.21 (*a*) In Figure 26.29, what is the magnitude of q_{bound}? Express your answer in terms of q_0 and the properties of the dielectric. (*b*) What is the bound surface charge density on the dielectric? Express your answer in terms of the electric field E.

EXAMPLE 26.6 Capacitor with dielectric

A parallel-plate capacitor consists of two conducting plates with a surface area of 1.0 m^2 and a plate separation distance of 50 μm. (*a*) Determine the capacitance and the energy stored in the capacitor when it is charged by connecting it to a 9.0-V battery. (*b*) With the capacitor fully charged and disconnected from the battery, a 50-μm-thick sheet of Mylar is inserted between the plates. Determine the potential difference across the capacitor and the energy stored in it. (*c*) If the Mylar-filled capacitor is connected to the battery, how much work does the battery do to fully charge the capacitor?

❶ **GETTING STARTED** I am given information about a capacitor and a battery used to charge it. From this information, I must determine the capacitance and the energy stored in the capacitor with and without a sheet of Mylar between the plates connected to the battery, and determine what happens to the potential with and without a sheet of Mylar between the plates and with and without the battery connected to the capacitor. When connected to the capacitor, the battery maintains a constant potential across the capacitor. When the battery is not connected to the capacitor, the charge on the plates remains constant.

❷ **DEVISE PLAN** To calculate the energy stored in the capacitor I can use Eq. 26.4; I calculated the capacitance of a parallel-plate capacitor in Example 26.2. When the dielectric is added, the potential and the capacitance are given by Eqs. 26.9 and 26.11. From Table 26.1, I see that the dielectric constant of Mylar is $\kappa = 3.3$.

❸ **EXECUTE PLAN** (*a*) Using the result of Example 26.2, I get

$$C = \frac{[8.85 \times 10^{-12}\ \mathrm{C^2/(N \cdot m^2)}](1.0\ \mathrm{m^2})}{50 \times 10^{-6}\ \mathrm{m}}$$

$$= 0.18 \times 10^{-6} \frac{\mathrm{C^2}}{\mathrm{N \cdot m}} = 0.18\ \mu\mathrm{F}, \checkmark$$

and Eq. 26.4 gives

$$U^E = \tfrac{1}{2} C(V_0)^2 = \tfrac{1}{2} (0.18\ \mu\mathrm{F})(9.0\ \mathrm{V})^2 = 7.2\ \mu\mathrm{J}. \checkmark$$

(*b*) Because of the bound surface charge on the dielectric, the electric field between the capacitor plates decreases, and so the potential difference across the capacitor decreases, too. From the definition of the dielectric constant (Eq. 26.9), I have

$$V_d = \frac{V_0}{\kappa} = \frac{9.0\ \mathrm{V}}{3.3} = 2.7\ \mathrm{V}, \checkmark$$

QUANTITATIVE TOOLS

where I obtained my value for κ from Table 26.1. To calculate the energy in the presence of the dielectric, I must first obtain an expression for the capacitance of the dielectric-filled capacitor. Substituting the expression for the capacitance of a parallel-plate capacitor (see Example 26.2) into Eq. 26.11 yields

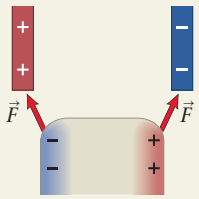
$$C_d = \kappa C_0 = \frac{\kappa \epsilon_0 A}{d}$$

$$= \frac{(3.3)[8.85 \times 10^{-12}\ \mathrm{C^2/(N \cdot m^2)}](1.0\ \mathrm{m^2})}{50 \times 10^{-6}\ \mathrm{m}}$$

$$= 0.58\ \mu\mathrm{F}.$$

The stored energy is thus

$$U^E = \tfrac{1}{2} C V_d^2 = \tfrac{1}{2} (0.58\ \mu\mathrm{F})(2.7\ \mathrm{V})^2 = 2.1\ \mu\mathrm{J}. \checkmark$$



(*c*) The energy stored in the fully charged dielectric-filled capacitor is

$$U^E = \tfrac{1}{2} C V_{batt}^2 = \tfrac{1}{2} (0.58\ \mu\mathrm{F})(9.0\ \mathrm{V})^2 = 24\ \mu\mathrm{J}.$$

From part *b* I know that before it was connected to the battery, the capacitor stored 2.1 μJ, and so the work done by the battery in charging the capacitor must be 24 μJ − 2.1 μJ = 22 μJ. ✔

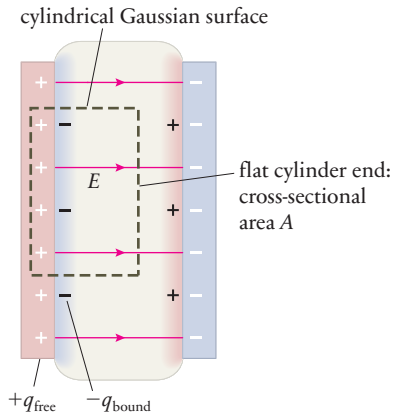
4 EVALUATE RESULT My answers to parts *a* and *b* show that the amount of energy stored decreases when the dielectric is inserted. That makes sense because, as the dielectric is brought near the plates, the charged plates induce a polarization on the dielectric and consequently it is pulled into the space between the plates (**Figure 26.30**). Therefore, the capacitor does *positive* work on whoever is holding the dielectric, and the energy in the capacitor decreases as the dielectric enters the space between the plates. This work is equal to the difference in energy between parts *a* and *b*: $W = 7.2\ \mu\mathrm{J} - 2.1\ \mu\mathrm{J} = 5.1\ \mu\mathrm{J}$. My answer to part *c* is about three times greater than the value I calculated for U^E in part *a*, which is what I expect given that the capacitance is increased by the factor $\kappa = 3.3$ once the dielectric is inserted.

Figure 26.30

26.22 Verify that in the solution to part *a* of Example 26.6, (*a*) the ratio of units $\mathrm{C^2/(N \cdot m)}$ is equivalent to the unit F and (*b*) the product of units $\mathrm{F \cdot V^2}$ is equivalent to the unit J.

26.8 Gauss's law in dielectrics

Can we apply Gauss's law to calculate the electric fields inside dielectric materials? The answer is *yes*, because Gauss's law is a fundamental law that follows directly from the $1/r^2$ dependence of Coulomb's law. Thus, the presence of a dielectric cannot affect its validity.



Consider the situation illustrated in **Figure 26.31**. To determine the magnitude of the electric field E inside the dielectric, we consider the cylindrical Gaussian surface with cross-sectional area A shown in the figure. The electric flux is zero except through the right flat surface of the cylinder, so

$$\oint \vec{E} \cdot d\vec{A} = EA. \qquad (26.22)$$

The charge enclosed by the Gaussian surface is not just the enclosed charge on the plate—we must also take into account the enclosed bound charge on the dielectric. The enclosed charge is thus $q_{enc} = q_{free,\,enc} - q_{bound,\,enc}$, and Gauss's law then gives

$$\oint \vec{E} \cdot d\vec{A} = EA = \frac{q_{free,\,enc} - q_{bound,\,enc}}{\epsilon_0}. \qquad (26.23)$$

Figure 26.31 A cylindrical Gaussian surface used to calculate the electric field inside a dielectric-filled parallel-plate capacitor.

QUANTITATIVE TOOLS

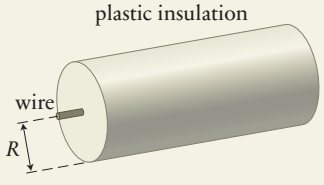
In this form, Gauss's law is not very useful, because in order to extract E from Eq. 26.23, we need to know the magnitude of the bound surface charge. Generally, we don't know the contribution from the bound charge in a given situation.

Substituting the relationship between the free and bound charges (Eq. 26.18), however, we can rewrite Eq. 26.23 in the form

$$\oint \vec{E} \cdot d\vec{A} = \frac{q_{\text{free, enc}}}{\epsilon_0 \kappa}. \tag{26.24}$$

This result—Gauss's law in dielectrics—is remarkable. The left side contains the electric flux of the electric field *inside the dielectric*. We can obtain this field, however, just by accounting for the enclosed *free* charge (and we already know how to deal with that charge). This relationship is valid because the effect of the bound charge is completely accounted for by the dielectric constant in the denominator. As Eq. 26.17 shows, dividing q_{free} by κ gives the difference of the free and bound charges.

Because the dielectric constant affects the value of the electric field, **Gauss's law in matter** is usually written in the form



$$\oint \kappa \vec{E} \cdot d\vec{A} = \frac{q_{\text{free, enc}}}{\epsilon_0}. \tag{26.25}$$

This form of Gauss's law is very general: Even though we derived it for the special case of a parallel-plate capacitor, it holds in any situation, even one without a dielectric. In the absence of matter (that is, in vacuum), $\kappa = 1$, and because there is no bound charge we have $q_{\text{free, enc}} = q_{\text{enc}}$. Then Eq. 26.25 becomes identical to the familiar form of Gauss's law (Eq. 24.8).

EXAMPLE 26.7 Electric field surrounding a charged insulated wire

A thin, long, straight wire is surrounded by plastic insulation of radius R and dielectric constant κ (Figure 26.32). The wire carries a uniform distribution of charge with a positive linear charge density λ. If the wire has a diameter d, what is the potential difference between the outer surface of the wire and the outer surface of the insulation?

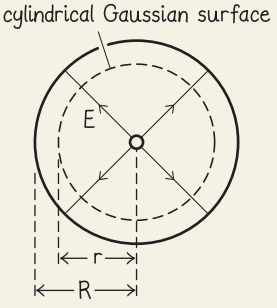


Figure 26.32 Example 26.7.

❶ **GETTING STARTED** The insulation reduces the electric field created by the charge in the wire, so the potential difference between the wire surface and any location a distance R from the wire (in other words, any location on the outer surface of the insulation) is smaller than when there is no insulation around the wire.

❷ **DEVISE PLAN** The potential difference between two locations A and B can be obtained from Eq. 25.25, $V_{AB} = -\int_A^B \vec{E} \cdot d\vec{\ell}$, but using this expression requires me to know the electric field. To calculate the electric field inside the insulation, I can apply Eq. 26.25 to a cylindrical Gaussian surface that has radius r and length L and is concentric with the wire, as shown in Figure 26.33.

Figure 26.33

QUANTITATIVE TOOLS

3 EXECUTE PLAN Because of the cylindrical symmetry of the wire, the electric field has the same magnitude E everywhere on the curved region of the Gaussian surface. The electric flux through that region of the Gaussian surface is equal to the product of the electric field at a distance r from the wire and the surface area: $\Phi = EA = E(2\pi rL)$ (Eq. 3 in Exercise 24.7). The free charge enclosed by the cylinder is λL, and with these substitutions Eq. 26.25 becomes

$$\kappa E(2\pi rL) = \frac{\lambda L}{\epsilon_0}$$

and

$$E = \frac{\lambda}{2\pi\kappa\epsilon_0 r}. \qquad (1)$$

Substituting this expression for E into Eq. 25.25, I obtain for the potential difference between the outer surface of the wire and the outer surface of the insulation

$$V_{dR} = -\int_{d/2}^{R} \vec{E}\cdot d\vec{r} = -\frac{\lambda}{2\pi\kappa\epsilon_0}\int_{d/2}^{R}\frac{1}{r}\,dr$$
$$= -\frac{\lambda}{2\pi\kappa\epsilon_0}\ln\frac{2R}{d}. \checkmark$$

4 EVALUATE RESULT Because $\ln(2R/d)$ is positive, the potential difference is negative, as it should be because I am moving away from the positively charged wire. As an additional check, if I set $\kappa = 1$ in Eq. 1, my result for the electric field becomes identical to the result I obtained for a thin wire without insulation in Exercise 24.7.

26.23 Show that, if you account for the free and bound charges, Gauss's law in vacuum (Eq. 24.8) yields the same result for the electric field outside the insulation as Gauss's law in matter (Eq. 26.25) does.

Chapter Summary

Capacitors (Sections 26.1, 26.2, 26.5)

Concepts A **charge-separating device** (such as a battery) has some mechanism that moves charge carriers *against* an electric field. The work done in this process increases the system's electric potential energy.

A **capacitor** consists of a pair of conducting objects separated by a nonconducting material or vacuum. The objects store electric potential energy once charge has been transferred from one to the other.

A *parallel-plate capacitor* consists of two parallel conducting plates of surface area A separated by a gap of width d. The electric field is uniform between the plates.

A *coaxial capacitor* consists of two coaxial conducting cylinders of radii R_1 and $R_2 > R_1$ and length $\ell \gg R_2$.

A spherical capacitor consists of two concentric conducting spherical shells of radii R_1 and $R_2 > R_1$.

Quantitative Tools The conducting objects in a capacitor carry charges of equal magnitude q but opposite sign. The charge separation produces a potential difference of magnitude V_{cap} between the objects. The **capacitance** C of this arrangement is

$$C \equiv \frac{q}{V_{\text{cap}}}. \tag{26.1}$$

Capacitance is measured in **farads** '(F),' where

$$1\ \text{F} \equiv 1\ \text{C/V}.$$

The capacitance of a *parallel-plate capacitor* is

$$C = \frac{\epsilon_0 A}{d}.$$

The capacitance of a *coaxial capacitor* is

$$C = \frac{2\pi\epsilon_0 \ell}{\ln(R_2/R_1)}.$$

The capacitance of a spherical capacitor is

$$C = 4\pi\epsilon_0\left[\frac{R_1 R_2}{R_2 - R_1}\right].$$

Electric field energy and emf (Sections 26.4, 26.6)

Concepts The **energy density** of an electric field is the energy per unit volume stored in the field.

The **emf** of any charge-separating device is the work per unit charge done by nonelectrostatic interactions in separating positive and negative charge carriers.

Quantitative Tools The electric potential energy U^E stored in a capacitor is

$$U^E = \tfrac{1}{2}\frac{q^2}{C} = \tfrac{1}{2}CV_{\text{cap}}^2 = \tfrac{1}{2}qV_{\text{cap}}. \tag{26.4}$$

In air or vacuum, the **energy density** u_E of an electric field is

$$u_E = \tfrac{1}{2}\epsilon_0 E^2. \tag{26.6}$$

The **emf** $\mathscr{E}$ of a charge-separating device is

$$\mathscr{E} \equiv \frac{W_{\text{nonelectrostatic}}}{q}. \tag{26.7}$$

Dielectrics (Sections 26.3, 26.7, 26.8)

Concepts A **dielectric** is a polarizable nonconducting material. A *polar* dielectric is made up of molecules that have a permanent dipole moment, whereas a *nonpolar* dielectric consists of molecules that do not have a dipole moment in the absence of an electric field.

Quantitative Tools The **dielectric constant** κ of a material between capacitor plates is

$$\kappa \equiv \frac{V_0}{V_{\text{d}}}, \tag{26.9}$$

where V_0 is the potential difference across the capacitor without the dielectric and V_{d} is the potential with the dielectric in place.

A dielectric inserted between the plates of a capacitor becomes polarized by the electric field of the capacitor. This polarization gives the two faces of the dielectric thin layers of charge of equal magnitude but opposite sign. This charge is **bound** because the charge carriers are not free to move. The charge on the capacitor plates is **free** because the charge carriers are free to move.

If a capacitor has capacitance C_0 without a dielectric, its capacitance with a dielectric is

$$C_d = \kappa C_0. \tag{26.11}$$

If q_{free} is the **free charge** on a capacitor, then the **bound charge** q_{bound} is

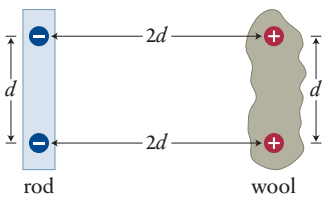
$$q_{bound} = \frac{\kappa - 1}{\kappa} q_{free}. \tag{26.18}$$

Gauss's law in matter is

$$\oint \kappa \vec{E} \cdot d\vec{A} = \frac{q_{free,\,enc}}{\epsilon_0}, \tag{26.25}$$

where $q_{free,\,enc}$ is the free charge enclosed by the Gaussian surface.

Questions and Problems



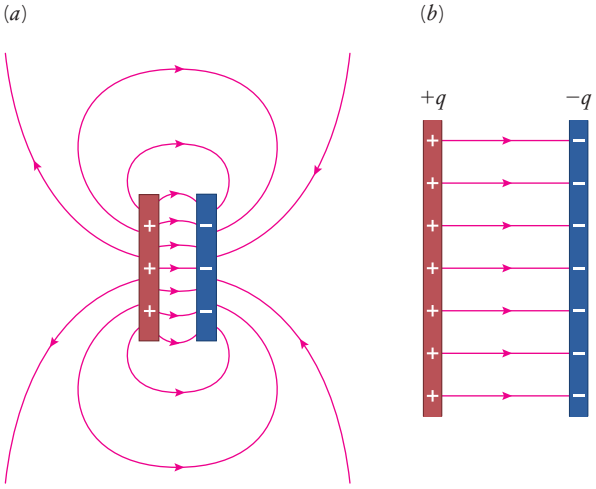
For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

26.1 Charge separation

1. Is it possible separate positive and negative charges unequally in two objects by a charge-separating method or by any mechanical equipment? •
2. Positive work is done on a system containing positively and negatively charged particles. All work goes into changing the electric potential energy of the system. What can be said about the electric field between positively and negatively charged particles? What can be said about the electric field everywhere else? ••
3. If you are designing a Van de Graaff generator, would you prefer to replace the spherical metallic dome with a dome of some other shape to achieve better charge storage? Justify your answer. ••
4. Draw energy diagrams for the processes of separating charge carriers by (*a*) rubbing, (*b*) increasing the separation distance between a positively charged object and a negatively charged object, and (*c*) increasing the separation distance between two positively charged objects. ••
5. A plastic rod is rubbed with wool, producing a distribution of positive and negative surplus charge that is concentrated in two locations on the rod and two on the wool. This distribution can be approximated as two pairs of small balls of charge as shown in Figure P26.5. The distance d is 30.0 mm, and the magnitude of the charge on each ball is 2.00 μC. If 34.0 J of work went into thermal energy as the rod and wool heated up, how much work was done on the system? ••

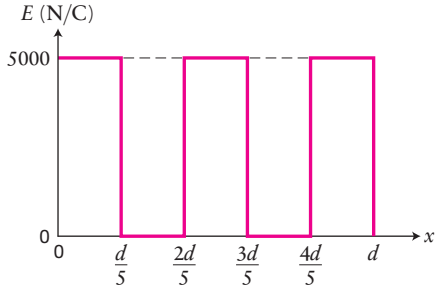
Figure P26.5



6. A piece of wool is used to charge two plastic spheres of negligible radius. When the spheres are held 20 mm apart, they repel each other with 16 N of force. If the wool ends up with a surplus positive charge of 30 μC, what is the charge on each of the two spheres? ••
7. Two 0.0450-kg spheres are identical (including the charge they carry) and are initially pinned in place 200 mm apart. You unpin them and push on each sphere with a force of 0.15 N. After their separation increases to 400 mm, each sphere has a speed of 500 mm/s. What is the charge on each sphere? Is there more than one possible answer? ••
8. A fellow scientist heard that a Van de Graaff generator built 70 years ago could collect 5.0 C of charge on its dome, which had a radius of 1.1 m, and has challenged you to do the same. The belt you plan to use is 100 mm wide and 10.0 m long (5.0 m to go up to the dome, and 5.0 m to come back down). Charging the belt gives it a surface charge density of 45 μC/m^2. How much force must your motor be able to exert on the belt in order to accomplish your goal? If you had more freedom in the design, what changes would you make to make the charging process easier on your motor, and why? Would your changes alter only the force required for your motor, or would they also affect the energy required for charging? State any assumptions you make, and state whether or not they are physically reasonable. •••

26.2 Capacitors

9. The plates of a capacitor are charged using a battery, and they produce an electric field across the separation distance d between them. The two plates are now to be pushed together to a separation of $d/2$. The pushing together can be done either with the battery connected or with it disconnected. Which way would result in the greater electric field magnitude, and by what factor? •
10. Two parallel-plate capacitors have the same plate area. Capacitor 1 has a plate separation twice that of capacitor 2, and the quantity of charge you place on capacitor 1 is twice the quantity you place on capacitor 2. How do the potential differences across each of the two capacitors compare to each other? •



11. Two parallel-plate capacitors have the same plate area. Capacitor 1 has a plate separation twice that of capacitor 2, and the potential difference you impose across the plates of capacitor 1 is twice the potential difference you impose across capacitor 2. How do the quantities of charge stored on the two capacitors compare to each other? •
12. Suppose a capacitor is fully charged by a battery and then disconnected from the battery. The positive plate has a charge $+q$ and the negative plate has a charge $-q$. The plate area is doubled, and the plate separation is reduced to half its initial separation. What is the new charge on the negative plate? ••
13. Explain why there must always be some nonzero electric field outside the plates of a parallel-plate capacitor (Figure P26.13*a*), which means that the idealization shown in Figure P26.13*b*, with all the field lines confined to the region between the plates, can never be exact. (Hint: Consider the potential difference between the plates for paths outside the edges.) ••

Figure P26.13

14. Figure P26.14 is a graph of the electric field between two capacitor plates as a function of distance from the left plate. The distance between the plates is d, the direction of the field is to the right, and a battery is connected to the plates. (*a*) Which plate carries a positive charge? (*b*) How many slabs of material have been inserted between the plates? (*c*) What can you say about the slab(s) inserted? (*d*) Make a graph of the electric field between the plates when the slabs between the plates are removed and the battery remains connected. ••

Figure P26.14

15. When two parallel plates separated by a distance d are connected to a battery that maintains a potential difference of magnitude V between the plates, a charge of magnitude q accumulates on each plate. If the plate separation is increased to $2d$ and the battery is replaced with one that has potential difference $2V$ between the terminals, what is the new charge on each plate? ••
16. Suppose two capacitor plates have an area of 1 cm^2 and are initially separated by 2 mm. Each plate holds 5 μC of charge. How much energy is required to double the plate separation? ••
17. A certain capacitor is fully charged by a battery, such that the positive plate holds a charge $+q$ and the negative plate holds a charge $-q$. The plates of the capacitor are then pulled apart to twice their initial separation. Determine the new charge on the positive plate if (*a*) the battery is kept attached to the capacitor as the separation is increased, and (*b*) the battery is disconnected before the plate separation is increased. ••
18. You need to insert a metal slab between the two plates of a parallel-plate capacitor. The plates are a distance d apart, and a battery maintains a constant potential difference V_{batt} between them. In order to avoid dielectric breakdown, the electric field in any region cannot exceed $4V_{batt}/d$. (*a*) What is the maximum thickness of the metal slab that can be used without causing dielectric breakdown? (*b*) If this maximum thickness is used, does the insertion of the metal slab affect the amount of charge stored on the capacitor? •••

26.3 Dielectrics

19. Either a dielectric or a conductor could be inserted between the plates of a capacitor. (*a*) State at least two similarities between the effects of inserting a dielectric and inserting a conducting slab. (*b*) State at least two differences between the effects of inserting a dielectric and inserting a conducting slab. •
20. A fully charged capacitor initially has an air gap and is disconnected from the battery. A dielectric material is inserted between the plates. What happens to (*a*) the free charge at the surface of the capacitor plates and (*b*) the total charge (free and bound) at the surface of the capacitor plates? •
21. Two parallel-plate capacitors have the same dimensions, but the space between the plates is filled with air in capacitor 1 and with plastic in capacitor 2. The magnitude of the charge on the plates is the same in both capacitors. Compare (*a*) the magnitudes of the electric fields E_1 and E_2 between the plates, (*b*) the potential differences V_1 and V_2 between the plates, and (*c*) the energies stored in the capacitors. ••
22. Two parallel-plate capacitors have the same dimensions, but the space between the plates is filled with air in capacitor 1 and with plastic in capacitor 2. The potential difference between the plates is the same in both capacitors. Compare (*a*) the magnitudes of the electric fields E_1 and E_2 between the plates, (*b*) the magnitudes of the charges on the plates q_1 and q_2, and (*c*) the energies stored in the capacitors. ••

23. A capacitor connected to a battery initially holds a charge of $+q$ on its positive plate and $-q$ on its negative plate. The electric field between the plates is initially $\vec{E}$. A dielectric material is then inserted that polarizes in such a way as to produce an electric field of $-0.50\vec{E}$ (where the – sign indicates that this field opposes the initial field $\vec{E}$). Determine the new charge stored on the positive plate. ••
24. A parallel-plate capacitor with air between the plates and plate separation distance d is connected to a battery that maintains a potential difference V_{batt} between the plates. Sketch a graph of V as a function of x when x is defined as position between the plates, running from $x = 0$ at the surface of the positively charged plate to $x = d$ at the surface of the other plate. Plot the points $x = 0, x = d/4, x = d/2, x = 3d/4$, and $x = d$. A slab that is made of a dielectric material and has a thickness of $d/2$ is inserted between the plates such that the midpoint of the slab thickness is at the position $d/2$ in the space between the plates. Sketch a graph of $V(x)$ for the capacitor now. Comment on how your graph is affected by the magnitude of the bound charge induced on the surface of the dielectric slab. ••
25. A capacitor initially has a charge of magnitude q on each plate. When a dielectric is inserted between the plates, the bound surface charge on the two dielectric surfaces facing the plates has a magnitude $q/4$. What is the ratio of the electric field magnitude in the empty capacitor to the electric field magnitude in the capacitor with the dielectric (*a*) if the battery stays connected to the plates and (*b*) if the battery is removed before the dielectric is inserted? ••
26. A capacitor has a plate area of 0.0045 m^2 and a charge of magnitude q on each plate. The space between plates has been filled with a dielectric that has a bound surface charge of magnitude $3q/4$ on either side. When the dielectric material is removed, the electrical breakdown of air is observed between the plates. What is the smallest possible value of q? ••
27. The night before an exam, your study partner asks what you can do to a parallel-plate capacitor to avoid the problem of the electrical breakdown of air. You answer that a nonconducting dielectric material can be inserted. Your friend is confused as to why other things wouldn't work. Why wouldn't it help, for example, to add a conducting slab? Why isn't increasing plate separation also a valid answer? After all, moving charge carriers very far apart must decrease their effect on the air between them. Why do these alternatives not work? •••

26.4 Voltaic cells and batteries

28. The term *emf* (electromotive force) represents work done per unit charge. Why, then, is it termed erroneously as "force" (or electromotive force)? •
29. A 10-V battery is used for a capacitor to get charged with air inside the plates. If the air is replaced with mica, will the voltage of the battery reduce if it is given that mica has higher dielectric constant value than air? •
30. What limits the lifetime of a battery? •
31. The reactions in a lead-acid battery are

$$\text{Positive terminal:}\quad PbO_2 + HSO_4^- + 3H^+ + 2e^- \rightarrow PbSO_4 + 2H_2O$$

$$\text{Negative terminal:}\quad HSO_4^- + Pb \rightarrow PbSO_4 + H^+ + 2e^-$$

If a certain battery supplies 1.0×10^8 electrons per second to the negative terminal and the battery contains 3.00 moles of electrolytic solution (which means the solution contains 3.00 moles of HSO_4^-), what fraction of the solution undergoes a chemical reaction each second? ••
32. One electrode in an alkaline battery is zinc, and the other is manganese dioxide. Fill in the blank for the chemical reaction (*a*) at the zinc electrode: $Zn + 2OH^- \rightarrow ZnO + ____ + 2e^-$ and (*b*) at the manganese electrode: $2MnO_2 + H_2O + ____ \rightarrow Mn_2O_3 + 2OH^-$. (*c*) Which electrode is positive and which is negative? ••
33. Suppose that the metal electrodes in a battery are shaped like large parallel plates and are 2.00 mm apart so that they are essentially a parallel-plate capacitor. If the battery supplies a potential difference of 1.5 V between the electrodes, what is the surface charge density on the electrodes (before anything has been connected to the battery)? ••

26.5 Capacitance

34. A capacitor having capacitance 10 pF is connected to a 9-V battery. If you consider a cylindrical Gaussian surface around the capacitor, calculate the net electric flux through it when the capacitor is operational. •
35. Can you increase the capacitance of a parallel plate capacitor to infinity? Explain your answer. •
36. A parallel-plate capacitor initially has capacitance C. What is the capacitance after each of the following single changes is made: (*a*) plate separation distance doubled, (*b*) dielectric material inserted, (*c*) potential difference across plates doubled, (*d*) plate area halved, (*e*) applied emf increased until plate charge doubles. •
37. A coaxial capacitor consisting of an inner wire and an outer cylindrical shell has a length of 50 cm and an outer diameter of 4 mm. When connected to a 16.0-V battery, this capacitor can hold 3 nC of charge on the wire. What is the wire radius? ••
38. How is Farad is a high unit of measuring the capacitance? Explain your argument by considering a parallel-plate capacitor having a plate separation of (*d*) 20 cm and plate area Am^2. ••
39. One way to double the capacitance of a parallel-plate capacitor is to reduce the plate separation distance by a factor of 2. Doubling the capacitance of a spherical capacitor is a bit more complex, though. (*a*) If you had a spherical capacitor consisting of two concentric spherical shells of radii R_{inner} and $R_{outer} > R_{inner}$, you could

double the capacitance by changing the radius of the outer shell from R_{outer} to some value d. What is d in terms of R_{inner} and R_{outer}? (*b*) You could also double the capacitance by changing the radius of the inner shell from R_{inner} to some value d. What is d in terms of R_{inner} and R_{outer}? (*c*) Repeat parts *a* and *b* for a capacitor consisting of two long concentric cylindrical shells of radii R_{inner} and $R_{outer} > R_{inner}$. ••

40. A spherical capacitor consists of two concentric conducting spherical shells of radii R and $2R$. (*a*) How long would a coaxial cylindrical capacitor made of two concentric cylindrical conductors of radii R and $2R$ have to be in order to have the same capacitance as the spherical capacitor? (*b*) What plate separation distance would be required for a parallel-plate capacitor made of two circular conductors each of radius R in order to have the same capacitance as the spherical capacitor? ••

41. Two small, irregularly shaped conducting objects, one carrying charge $+q$ and one carrying charge $-q$, are placed on an x axis at $x = -4.0$ m and $x = +4.0$ m, respectively. Between the objects, the electric field on the x axis is given by $E(x) = aq(x^2 + b)$, where a and b are constants. (*a*) What are the standard units of a and b? (*b*) What is the capacitance of this configuration? •••

42. The expression for the capacitance of a parallel-plate capacitor that has plates of area A separated by a distance d is given in Example 26.2. (*a*) Show that the expression for a spherical capacitor, given in Example 26.4, reduces to the expression for a parallel-plate capacitor in the limit that R_1 approaches R_2, with $d = R_2 - R_1$. (*b*) Show that the expression for a cylindrical capacitor, given in Example 26.3, reduces to the expression for a parallel-plate capacitor in the limit that R_1 approaches R_2, with $d = R_2 - R_1$. (Hint: You might find the Taylor series expansion of $\ln(1 + x)$ useful.) •••

26.6 Electric field energy and emf

43. In a parallel plate capacitor, transfer of 2×10^{36} electrons takes place when connected to a 12-V battery. Estimate the energy stored in the capacitor. •

44. Suppose a certain battery has an internal emf of 15 V but the potential difference across its terminals is only 80% of that value. If that battery is connected to a 47 μF capacitor, how much energy is stored when the capacitor is fully charged? •

45. A parallel-plate capacitor connected to a battery maintaining a potential difference V across the capacitor initially stores electric potential energy U_i^E. If the plate area is doubled and the battery is replaced with one that maintains a potential difference of $2V$ across the capacitor, how much electric potential energy is stored now? •

46. Two parallel-plate capacitors 1 and 2 are identical except that capacitor 1 has charge $+q$ on one plate and $-q$ on the other, and capacitor 2 has charge $+2q$ on one plate and $-2q$ on the other. Compare the two capacitors based on their (*a*) capacitance, (*b*) potential difference between the plates, (*c*) electric field magnitude between the plates, and (*d*) energy stored. ••

47. Three parallel-plate capacitors are separately connected to identical batteries. Capacitor 1 has a plate area A and a plate separation d. Capacitor 2 has a plate area $2A$ and a plate separation d. Capacitor 3 has a plate area A and a plate separation $2d$. Rank the three capacitors, largest first, based on (*a*) capacitance, (*b*) charge stored, (*c*) electric field magnitude between the plates, (*d*) energy stored, and (*e*) energy density. ••

48. Three parallel-plate capacitors each store the same amount of charge. Capacitor 1 has a plate area A and a plate separation d. Capacitor 2 has a plate area $2A$ and a plate separation d. Capacitor 3 has a plate area A and a plate separation $2d$. Rank the three capacitors, largest first, based on their (*a*) capacitance, (*b*) potential difference between the plates, (*c*) electric field magnitude between the plates, (*d*) energy stored, and (*e*) energy density. ••

49. (*a*) A spherical capacitor consists of two concentric conducting spheres of radii R and $2R$. If the two spheres carry charges of $+q$ and $-q$, what is the average energy density inside the capacitor in terms of R and q? (*b*) A cylindrical capacitor of length ℓ consists of two coaxial conducting cylinders of radii R and $2R$. If the two cylinders carry charges of $+q$ and $-q$, what is the average energy density inside the capacitor? ••

50. A parallel-plate capacitor has plates of area A. The plates are initially separated by a distance d, but this distance can be varied. If the capacitor is connected to a battery, what should the plate separation be if you want to quadruple (*a*) the capacitance, (*b*) the charge stored, (*c*) the energy stored, and (*d*) the energy density? ••

51. A parallel-plate capacitor has plates of area A. The plates are initially separated by a distance d, but this distance can be varied. If the capacitor is charged by a battery and the battery is then removed so that the capacitor is isolated, what should the plate separation be if you want to quadruple (*a*) the capacitance, (*b*) the charge stored, (*c*) the energy stored, and (*d*) the energy density? ••

52. A parallel-plate capacitor has an initial charge q and a plate separation distance d. How much work must you do, in terms of q, d, and plate area A, to increase the separation distance to $3d$ if (*a*) the capacitor is isolated and (*b*) the capacitor is connected to a battery? (*c*) The work you do is positive in both cases. Explain why in one situation the electric potential energy increases and in the other it decreases. •••

26.7 Dielectric constant

53. If you are constructing a parallel-plate capacitor, having air and paper as the dielectric medium between the plates, which dielectric material within the plates will make the capacitor act better? Justify your answer. •

54. The potential difference across the plates of a parallel-plate capacitor is gradually increased. (*a*) What happens when the breakdown threshold is exceeded? (*b*) If you want to increase the potential difference before breakdown occurs, what capacitor variables might you change? •

55. (*a*) Make a list of ways to increase the capacitance of a parallel-plate capacitor. (*b*) Does *Increase quantity of charge stored* or *Decrease potential difference* belong on the list? •

56. When you remove a dielectric slab from between the plates of a charged isolated capacitor, what happens to the energy stored in the capacitor? Why does this happen to the stored energy? ••

57. Two parallel-plate capacitors are identical except that capacitor 1 has vacuum between the plates and capacitor 2 has a dielectric slab of dielectric constant κ filling the space between the plates. The capacitors are connected to identical batteries. Compare the two based on (*a*) capacitance, (*b*) charge stored, (*c*) energy stored, (*d*) electric field magnitude, and (*e*) energy density. ••

58. Two parallel-plate capacitors are identical except that capacitor 1 has vacuum between the plates and capacitor 2 has a dielectric slab of dielectric constant κ filling the space between the plates. Each capacitor is isolated (that is, not connected to a battery), and they store equal quantities of charge. Compare the two based on (*a*) capacitance, (*b*) potential difference between the plates, (*c*) energy stored, (*d*) electric field magnitude between the plates, and (*e*) energy density. ••

59. When a dielectric slab completely fills the space between the plates of a parallel-plate capacitor, the magnitude of the bound charge is one-fourth the magnitude of the free charge. (*a*) What is the dielectric constant of the material of which the slab is made? (*b*) If the slab does not fill the space between the plates, but instead has a width equal to half the distance between the plates, does the magnitude of the bound charge change? If so, how? ••

60. If you want to maintain a potential difference of 6000 V between the plates of a parallel-plate capacitor, what is the minimum value of the plate separation if the space between the plates is completely filled by (*a*) a slab of mica and (*b*) a slab of barium titanate? (*c*) What is the ratio of the maximum charges that could be put on a plate of the capacitor in part *b* to the capacitor in part *a*. ••

61. A parallel-plate capacitor with air between its plates can hold 6 pC of charge per volt of potential difference across its plates. When a barium titanate dielectric slab completely fills the space between the plates and the capacitor is connected to a 9.0-V battery, what is the charge that can be stored on the positive plate of the capacitor? ••

62. You are working on charge-storage devices for a research center. Your goal is to store as much charge on a given device as possible. The facilities allow you to generate almost any potential difference V you need, but you are restricted to using a single parallel-plate capacitor. The area and separation distance of the plates are fixed, and the dielectric materials available to you are paper ($\kappa = 3.0$, $E_{max} = 4.0 \times 10^7$ V/m), Mylar ($\kappa = 3.3$, $E_{max} = 4.3 \times 10^8$ V/m), quartz ($\kappa = 4.3$, $E_{max} = 8 \times 10^6$ V/m), and mica ($\kappa = 5$, $E_{max} = 2 \times 10^8$ V/m). What properties of these materials must you consider in choosing the best dielectric for your needs? Rank the materials in order of their ability to meet your needs, first choice first. ••

63. A spherical capacitor has an inner radius of 5 cm and an outer radius of 6 cm. With air between the spheres, the capacitor is connected to a 12-V battery and allowed to charge fully. With the battery still connected, oil ($\kappa = 2.2$ is poured in, filling the volume between the spheres. Calculate the additional work done by the battery throughout the process of filling the capacitor with oil. •••

64. A dielectric slab completely fills the space between the plates of a parallel-plate capacitor. The magnitude of the bound charge on each side of the slab is 75% of the magnitude of the free charge on each plate. The capacitance is $480\epsilon_0\ell$, where ℓ is a constant with dimensions of length, and the maximum charge that can be stored on the capacitor is $240\ell^2\epsilon_0 E_{max}$, where E_{max} is the breakdown threshold. What are (*a*) the dielectric constant for the slab, (*b*) the plate separation distance in terms of ℓ, and (*c*) the plate area in terms of ℓ? •••

26.8 Gauss's law in dielectrics

65. Two very long wires each carry a linear charge density λ. They initially repel each other with a force F. If the wires are immersed in distilled water, with what force do they repel each other? •

66. A solid conducting sphere of radius R and carrying charge $+q$ is embedded in an electrically neutral nonconducting spherical shell of inner radius R and outer radius $2R$. The material of which the shell is made has a dielectric constant of 4.0. (*a*) Relative to a potential of zero at infinity, what is the potential at the center of the conducting sphere? (*b*) If the dielectric constant of the shell doubles, what happens to the potential at the center of the sphere? ••

67. A solid conducting sphere of radius $R = 10$ cm is embedded in an electrically neutral nonconducting spherical shell that has inner radius R, outer radius $2R$, and is made of a material having dielectric constant κ. The potential at the center of the sphere is 540 V. The electric field at the outer surface of the shell is directed away from the surface of the shell, and has a magnitude of 900 V/m. What are (*a*) the dielectric constant of the shell and (*b*) the electric charge on the sphere? ••

68. A conducting sphere has a radius of 2.25 m and carries a positive surplus charge of 35.0 mC. A protective layer of barium titanate is applied to the surface of the sphere to make it safe for laboratory workers nearby. Safety considerations dictate that the potential difference between the surface of the conductor and the outside of the nonconductive layer must be 20,000 V (though this is by no means safe under all conditions). How thick must the protective layer be? •••

Additional Problems

69. (*a*) Explain how treating the electric field lines between two oppositely charged objects as elastic bands can help you to understand what happens to the electric potential energy of the system when you increase the separation distance between the objects. (*b*) Can you think of any limitations to this elastic-band analogy for analyzing field lines? •

70. Why are capacitors used in external defibrillators instead of high-voltage batteries? •

71. Two parallel-plate capacitors have the same plate separation. The plate area of capacitor 1 is twice that of capacitor 2. (*a*) How do the potential differences across the two capacitors compare if the quantity of charge you place on capacitor 1 (q_1) is twice the quantity you place on capacitor (q_2)? (*b*) How do the charge magnitudes on either plate of the two capacitors compare if the potential difference between the plates of capacitor 1 is twice that between the plates of capacitor 2? •

72. During a lightning strike, on the order of 10 C of charge is typically transferred to the ground over a potential difference of 3×10^8 V. (*a*) What is the capacitance of the cloud-ground system? (*b*) How much energy is stored in the system just before the strike? (*c*) As a check on the order of magnitude of your answer for part *b*, convert the energy released in the lightning strike into liters of gasoline (gasoline has a stored chemical energy of 36 MJ/liter). ••

73. Given that charge separation increases the electric potential energy of a system, what can you conclude about the criteria for keeping a system of positively and negatively charged particles in static equilibrium, in the presence of electrostatic interactions only? ••

74. A parallel-plate capacitor in which the plates are extendable is connected to a battery and charged until there is a charge $+q$ on one plate and a charge $-q$ on the other plate. (*a*) With the battery still connected, the area of each plate is doubled by sliding the extension out. How much charge is on each plate now? (*b*) In which case, before the plate area is expanded or after, is more force required to keep the plates apart? Use the elastic-band model described in Problem 69 to explain your answer. ••

75. A parallel-plate capacitor carries a charge $+q$ on one plate and a charge $-q$ on the other plate. Each plate has an area A. How much force, in terms of q and A, does one plate exert on the other? ••

76. When a parallel-plate capacitor has air between its plates and is connected to a 12.0-V battery, its capacitance is 33 n*F*. The capacitor is then submerged in distilled water. What is the charge on the plates (*a*) if the capacitor is submerged with the battery connected and (*b*) if the battery is removed before submersion? ••

77. Your firm uses a large parallel-plate capacitor to store energy, and you measure the electric field strength between the plates to determine the amount of energy stored. During a test run with a new renewable energy source, you realize that the electric field magnitudes being produced are too small to be accurately detected by your equipment. The capacitor plates are fixed in place, and you cannot yet control the energy source to give you a greater potential difference. All you have to work with are four large flat slabs of metal, one $d/2$ thick, one $d/3$ thick, one $d/4$ thick, and one $d/5$ thick, where d is the fixed plate separation distance. You realize that it is necessary to increase E by at least an order of magnitude, but it takes you a while to figure out what to do. How do you increase E sufficiently? ••• CR

78. You are working for a car-battery manufacturer, and your boss complains that to be more competitive, the company needs to produce batteries that will last longer while minimizing the amount of metal or metal oxide used. She is not concerned about the amount of electrolyte used, but the battery must be powerful enough to supply a great deal of energy quickly when needed. What do you think the shape of the electrodes might have to do with battery life and power, starting with what seem to be the extremes: electrodes shaped like sheets similar to parallel plates and rod-shaped electrodes that extend down into the electrolyte solution? ••• CR

79. In the endless endeavor to make electronic devices as small as possible, you have been hired to make a capacitor that has the greatest capacitance possible in a cubic volume of $(10\text{ mm}) \times (10\text{ mm}) \times (10\text{ mm})$. You are allowed to use any capacitor geometry you wish, as well as any combination of geometries. For simplicity, assume a dielectric constant of 1000 (as better materials are found, you can multiply the capacitance appropriately). You begin thinking about the minimum thickness of the conductors and dielectrics, and the scale of about 0.5 μm seems reasonable. There is the question of how to fill the volume while maintaining exactly two conducting surfaces. Describe the capacitor that meets all of these criteria. ••• CR

CONCEPTS

QUANTITATIVE TOOLS

The word *magnetism* is derived from Magnesia, a province where the ancient Greeks mined *magnetite*, a mineral that attracts iron. The interactions between a magnet and a paper clip or a refrigerator door are familiar ones. These interactions may seem to have nothing to do with the subject of earlier chapters, but as we shall see, electricity and magnetism are closely related phenomena. They are two manifestations of one interaction, called the *electromagnetic interaction*. The discovery of the connection between electricity and magnetism in the 19th century opened the door to important technological breakthroughs, such as electric motors and generators, the transmission of radio signals, and the electronics and telecommunications industries.

In this chapter, we discuss interactions between magnets and introduce the concept of a magnetic field. We also begin to explore the connection between electricity and magnetism.

27.1 Magnetism

One simple definition of **magnet** is any object that attracts pieces of iron, such as iron filings or paper clips. Magnets come in many shapes and sizes, as Figure 27.1 shows.

If you examine the surface of a magnet interacting with an object that contains iron, such as a paper clip, you will discover that certain parts of the magnets, called *magnetic poles*, interact more strongly with the paper clip than do other parts of the magnet. Disk-shaped magnets (Figure 27.1*b*) usually have poles on the two faces; paper clips stick to the flat faces but not to the curved surface. Bar magnets (Figure 27.1*c*) have poles at the ends, and most of the length of the bar doesn't interact very strongly with a paper clip. A horseshoe magnet (Figure 27.1*d*) is simply a bent bar magnet with poles at the ends of the bent bar.

Figure 27.1 Magnets come in many shapes and sizes.

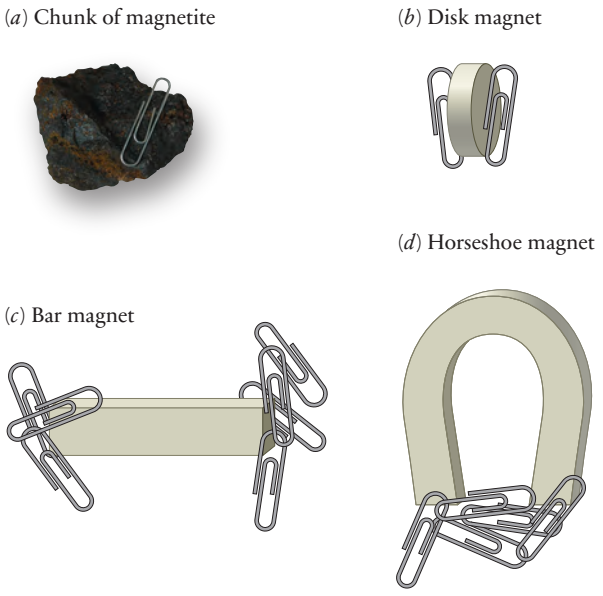

Figure 27.2 The needle of a compass is a small bar magnet that is free to rotate. When the compass is held horizontally, the needle points in the direction of Earth's North Pole. This end of the needle is defined as its north pole N.

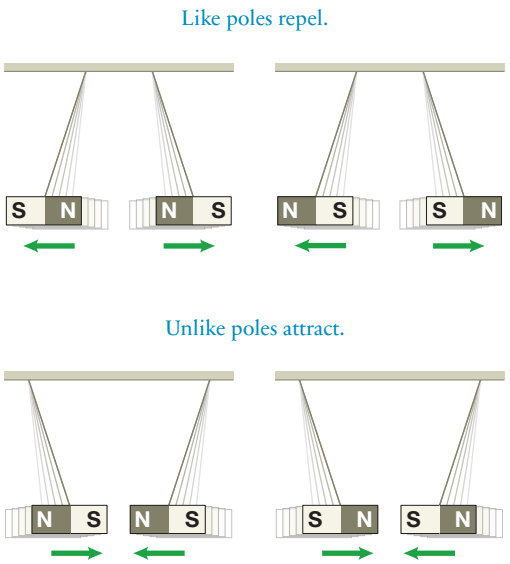
Depending on which of their poles you hold near each another, two magnets can attract or repel without touching. This tells us that these interactions are long-range and that there are two types of magnetic poles. The interaction between magnets is one example of what are called **magnetic interactions.**

When a bar magnet is suspended and free to rotate, it aligns itself so that its poles lie on a line roughly north-south along Earth's surface. This north-south alignment of a freely rotating magnet is the basic operational principle of a compass needle, which is simply a freely rotating magnetic needle (Figure 27.2). This alignment provides a means of distinguishing between the two types of poles:

> **The pole of a freely suspended bar magnet that settles toward north is defined as being the north pole of the magnet (denoted N); the opposite pole is defined as being the south pole of the magnet (denoted S).**

To understand what causes this alignment, we must first examine how one magnetic pole interacts with another. If you hold the poles of two magnets near each other, you discover that the magnetic interaction between the two types of poles follows a rule very similar to that between the two types of charge (Figure 27.3):



> **Like magnetic poles repel each other; opposite magnetic poles attract each other.**

CONCEPTS

27.1 Because we cannot see any obvious difference between the ends of a bar magnet, could it be that *like* poles attract each other and *unlike* poles repel each other?

How do the poles of a magnet interact with objects that are not magnets? For most materials that are not magnets, the answer to this question is: not much if at all. Try picking up a penny, a wooden tooth pick, a piece of

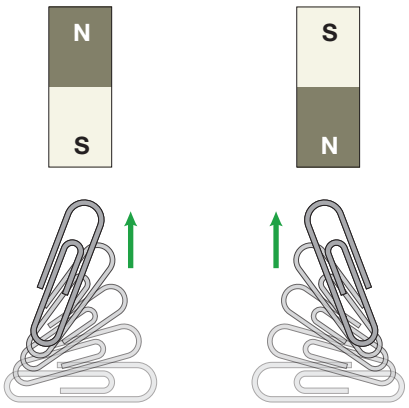
Figure 27.3 Interactions between magnetic poles.

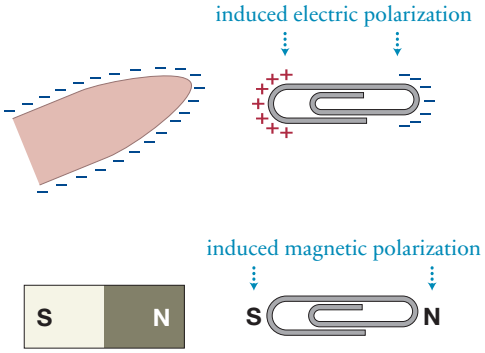
aluminum, or a piece of plastic with a magnet. It won't work. However, both the north pole and the south pole of a magnet attract an iron paper clip (**Figure 27.4**).

Materials attracted by both types of magnetic poles include iron, nickel, cobalt, and certain alloys, such as steel. These materials are called *magnetic materials*. Normally, two objects made from these materials do not interact with each other. For example, one iron paper clip does not attract another one. However, just as a charged object can induce charge polarization on a neutral object, the presence of a magnet induces a **magnetic polarization** in a paper clip or any other object made from a magnetic material (**Figure 27.5**). The poles of the magnet interact with the induced poles of the now-magnetized paper clip.

27.2 (*a*) Is the interaction between a charged object and an electrically neutral object always attractive? Why or why not? (*b*) In Figure 27.4, which type of magnetic pole is induced at the top of each paper clip?

Figure 27.4 Both the north and south poles of a magnet attract an unmagnetized iron object.





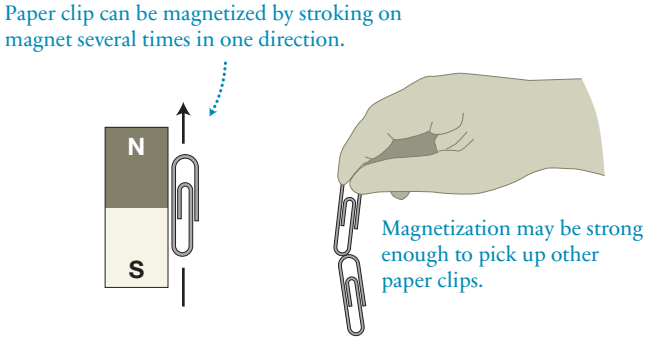


Figure 27.5 Comparing induced electric and magnetic polarization. Magnetic polarization can be induced only in an object made from magnetic material.

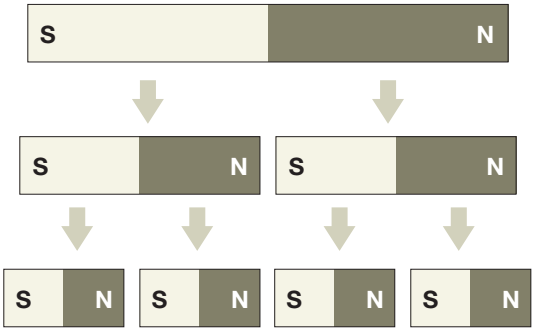
Unlike induced electric polarization, which vanishes as soon as the charged object is removed, some magnetic materials retain their induced magnetic polarization. For example, sewing needles left unmoved for long periods become magnetized by Earth's magnetic field. If you stroke a paper clip several times in the same direction with a magnet, the paper clip remains magnetically polarized even after you remove the magnet. In fact, you may even be able to pick up one paper clip with another (**Figure 27.6**). The clip can be *demagnetized* again—its magnetic polarization undone—by heating it, dropping it, or stroking it with a magnet in random directions.



In addition to the retention of magnetic polarization, there is another fundamental difference between magnetic and electric interactions: It is not possible to isolate one pole of a magnet the way we can separate a positively charged particle and a negatively charged particle from each other. For example, if we cut a bar magnet in two, we see that each of the resulting pieces has two opposite poles (**Figure 27.7** on the next page). The cutting has created an additional *pair* of opposite poles. Remarkably, if we carefully place the two pieces together again, the two new poles seem to vanish. A piece of iron held close to the cut is either not at all or only weakly attracted, as if the two newly formed opposite poles at the cut have "neutralized" each other.

Figure 27.6 If you stroke a paper clip several times in the same direction with a magnet, the clip retains some magnetic polarization.

CONCEPTS

Figure 27.7 When a magnet is cut in two, each piece retains both an N and S pole.

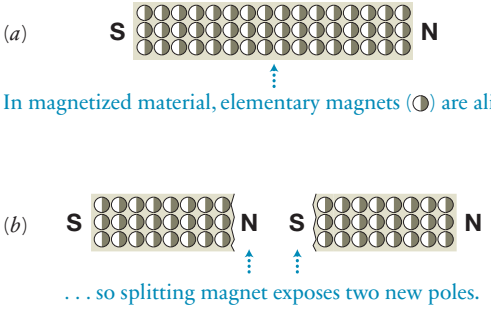
Each of the two halves can again be cut in half, but regardless of how small the pieces into which we divide the bar, each piece always has two poles. As we continue to divide the bar into smaller and smaller pieces, we come to a point where each part is a single atom. Experiments show that the iron, nickel, or cobalt atoms that make up magnets still behave like magnets. Even elementary particles behave like magnets—we shall refer to these as *elementary magnets*. Thus, a magnet consists of a large number of elementary magnets whose alignment is such that their combined effect is reinforced at the poles (**Figure 27.8***a*). Because we cannot cut the elementary magnets, a pair of new poles appears every time we cut through the magnet (Figure 27.8*b*).

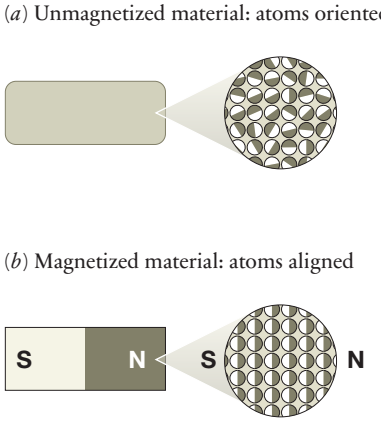
In spite of extensive searches, isolated magnetic poles, called *magnetic monopoles* (say, a north pole in the absence of a south pole), have never been found. Magnetism is therefore not due to magnetic monopoles, the way electricity is due to electrical charge. Although the pole of a magnet is not a monopole, we will occasionally rely on the picture of a bar magnet as a pair of opposite monopoles separated by a small distance to get an intuitive feel for magnetism. We call such an arrangement a **magnetic dipole.**

In an object made of magnetic material, the elementary magnets are randomly oriented relative to one another (**Figure 27.9***a*). Some push or pull in one direction, while others push or pull in other directions. As a result, their effects cancel and the object as a whole does not act like a magnet. When a magnet is brought nearby, however, the elementary magnets in the object align themselves with the poles of the magnet, and the object becomes magnetized (Figure 27.9*b*). With some magnetic materials, the alignment is (partially) maintained even after the nearby magnet is removed, leaving the object magnetized.

You can use this model to visualize demagnetization. If a magnet is heated or handled roughly, the elementary magnets are jarred around and lose their alignment.

Figure 27.8 The concept of elementary magnets explains why cutting a magnet in two reveals new N and S poles.





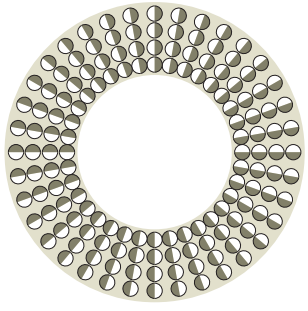


Figure 27.9 (*a*) Unmagnetized and (*b*) magnetized pieces of magnetic material.

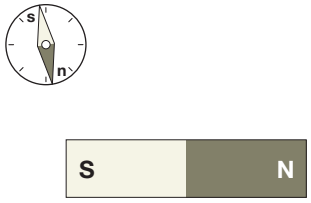
27.3 (*a*) Draw the elementary magnets inside a bar magnet and a horseshoe magnet, using the half-filled-circle format shown in Figures 27.8 and 27.9. (*b*) How many poles does the magnetized ring in **Figure 27.10** have? (*c*) If someone gave you such a ring, how could you verify that it is indeed magnetized as illustrated?

Figure 27.10 A magnetized ring (Checkpoint 27.3).

27.2 Magnetic fields

The long-range nature of magnetic interactions suggests that we can introduce the concept of a **magnetic field,** denoted by $\vec{B}$.* In analogy to the field model for electric interactions, a magnet is surrounded by a magnetic field.

*The unintuitive symbol $\vec{B}$ was introduced early on in the description of magnetism. Whenever you see a B in an illustration or force superscript, remember that it stands for a magnetic field or force. The force exerted by a magnet on a paper clip, for example, is denoted by $\vec{F}^{B}_{mc}$.

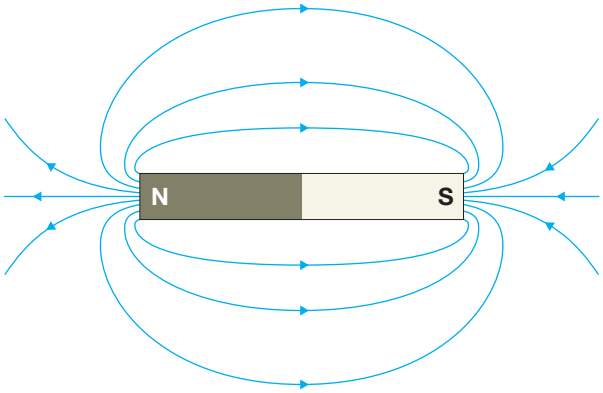


CONCEPTS

Figure 27.11 Effect of a bar magnet on a compass needle.

(*a*) Forces exerted by magnet on poles of compass needle cause a torque.

(*b*) North pole of compass needle points toward south pole of magnet



This magnetic field exerts a force on the poles of another magnet. Because there is no such thing as a "magnetic charge," it is not possible to map out a magnetic field using a "test magnetic charge." We can, however, use a compass to map out the direction of the magnetic field.

27.4 (*a*) Which end of a compass needle is a north pole: the end that points toward Earth's North Pole or the other end? (*b*) If you place a compass near the north pole of a magnet, what happens to the compass needle? (*c*) Is Earth's geographic North Pole a magnetic north pole?

When a compass is placed near a bar magnet as illustrated in **Figure 27.11a**, the south pole of the bar magnet exerts an attractive force on the north pole of the compass needle and a repulsive force on the needle's south pole. These two forces cause a torque that tends to align the needle with its north pole pointing toward the bar magnet's south pole.

27.5 (*a*) What is the effect of the north pole of the bar magnet on the compass needle in Figure 27.11*a*? (*b*) What is the combined effect of the bar magnet's north and south poles on the needle? (*c*) A compass placed in the position shown in Figure 27.11*b* aligns itself in the direction indicated. What is the direction of the vector sum of the forces exerted by the bar magnet's north and south poles on the north pole of the needle? On the south pole of the needle?

Figure 27.13 Magnetic field line pattern surrounding a bar magnet.

We can now use the alignment of a compass needle to map out **magnetic field lines** by placing a compass somewhere near a bar magnet, moving the compass a small distance in the direction of the needle, and repeating this procedure to trace out a line, as illustrated in **Figure 27.12**. At any location, the direction of the magnetic field $\vec{B}$ is tangent to the magnetic field line passing through the location. By convention:

Near a magnet, magnetic field lines point away from north poles and toward south poles.

A more complete diagram of the magnetic field lines outside a bar magnet is shown in **Figure 27.13**. Notice the similarity with an electric dipole field (Figure 24.2).

Magnetic field line patterns outside a magnet can be made visible by sprinkling iron filings on a piece of paper placed over the magnet. The little pieces of iron become magnetized and act like compass needles that align themselves along field lines (**Figure 27.14** on the next page).

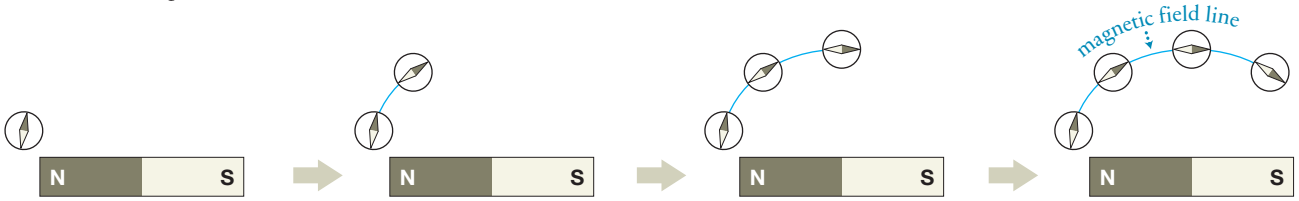
The similarity between electric and magnetic field patterns suggests that we may be able to carry over many of the concepts we developed for electric fields into our study of magnetism. In particular, we can associate a magnetic field magnitude with the density of magnetic field lines:

At every location in a magnetic field line diagram, the magnitude of the magnetic field is proportional to the field line density at that location.

In the field pattern shown in **Figure 27.15*a*** on the next page, for example, the magnitude of the magnetic field is greatest

CONCEPTS

Figure 27.12 A magnetic field line can be traced by moving a compass small distances in the direction in which its needle points.



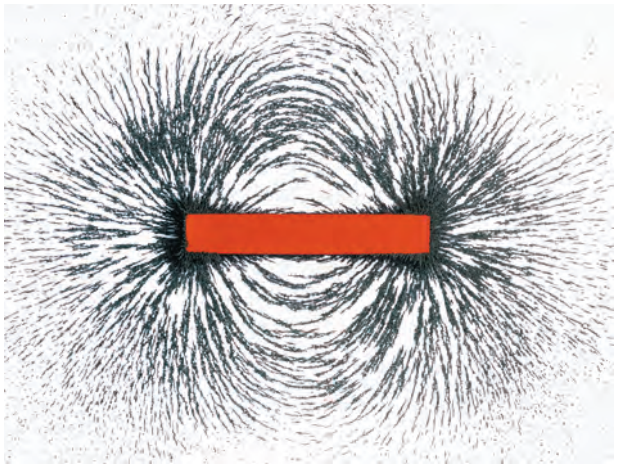


Figure 27.14 The magnetic field line pattern outside a bar magnet made visible by sprinkled iron filings around the magnet.

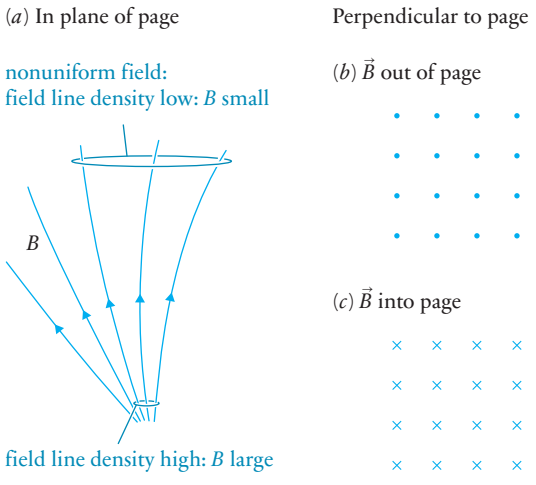


near the bottom and smallest near the top. Occasionally we shall work with magnetic fields that are perpendicular to the plane of the drawing, and so we need to be able to represent them. Figure 27.15*b* and *c* show conventions for representing field lines perpendicular to the page.

In electrostatics, the concept of field line flux led to Gauss's law, and so we may ask ourselves if there is an analogous law for magnetism. The answer is *yes*, but the result is somewhat different from that in electrostatics. To see why, complete this checkpoint.

27.6 (*a*) Consider a single elementary magnet inside a closed surface. Given that elementary magnets are particles without spatial extent, is the magnetic field line flux through the closed surface positive, negative, or zero? (*b*) Does adding a second elementary magnet inside the closed surface change your answer? (*c*) Consider a bar magnet inside a closed surface. Is the magnetic field line flux through the closed surface positive, negative, or zero? (*d*) Does your answer change if the closed surface cuts through the magnet?

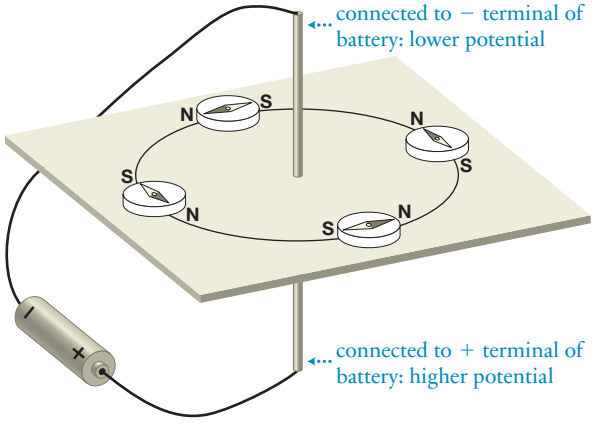
Figure 27.15 Conventions for representing a magnetic field.

The fundamental point of Checkpoint 27.6 is that each field line leaving a closed surface that encloses an elementary magnet reenters the surface somewhere else, so the magnetic field line flux due to an elementary magnet inside a closed surface is zero. Generalizing this statement to a collection of many elementary magnets, we say:

The magnetic field line flux through a closed surface is always zero.

In electrostatics, electric field lines originate or terminate on electrical charge. Because of the absence of magnetic monopoles, however, we have no "magnetic charge" on which magnetic field lines could originate or terminate. Magnetic field lines must therefore always form loops that close on themselves. The statement that the magnetic field line flux through a closed surface is always zero is therefore a direct consequence of the absence of magnetic monopoles.

27.7 What is the direction of the magnetic field lines *inside* the bar magnet of Figure 27.13?



27.3 Charge flow and magnetism

The first indication of a connection between electricity and magnetism came in 1820, when the Danish physicist Hans Christian Ørsted discovered that a flow of charge carriers deflects the needle of a compass. This effect is illustrated in **Figure 27.16**, which shows battery terminals connected to a conducting rod.

The top of the rod in Figure 27.16 is connected to the negative battery terminal, and the bottom is connected to the positive terminal. As we saw in Chapter 26, this means that the bottom of the rod is at a higher potential than the top and an upward-pointing electric field arises inside the rod.*

*In Section 24.5 we concluded that the electric field inside a conductor in electrostatic equilibrium is zero. The rod in Figure 27.16, however, is not in electrostatic equilibrium because the battery maintains a potential difference across it, causing free charge carriers in the rod to move.

Figure 27.16 A flow of charge carriers through a conducting rod causes a circular alignment of compass needles.

CONCEPTS

The upward electric field in the rod exerts a downward electric force on the negatively charged electrons in the rod, causing a flow of charge carriers, called **current,** through the rod. The battery maintains a constant potential difference across the rod by adding electrons at the top of the rod and removing them at the bottom. Consequently, the battery maintains a constant current through the rod.

27.8 (*a*) Is the rod in Figure 27.16 electrically charged while connected to the battery? (*b*) Is there an electric field due to the rod at the positions of the compasses in Figure 27.16?

When the electrons flow through the rod in Figure 27.16, the compass needles align themselves in a circular pattern around the rod. This observation leads to a conclusion:

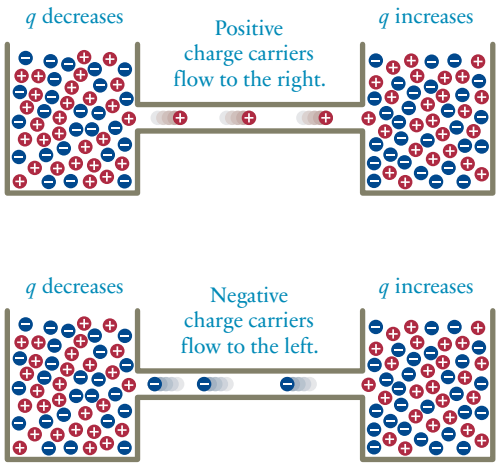
A flow of charged particles causes a magnetic field.

If the direction of the flow is reversed by reversing the battery, the compass needles turn around until they point in the opposite direction. If the flow of charge carriers is stopped, the needles point toward Earth's geographic North Pole, as usual.

27.9 Sketch the magnetic field line pattern in the horizontal plane around the rod in Figure 27.16.

It is important to note that a flow of positive charge carriers in one direction is equivalent to a flow of negative charge carriers in the opposite direction. In **Figure 27.17**, for example, the charge on the right increases and the charge on the left decreases regardless of which flow occurs. Experiments also show that the two types of flow are equivalent in terms of the magnetic field:

Figure 27.17 A flow of positive charge carriers in one direction is equivalent to a flow of negative charge carriers in the other direction.



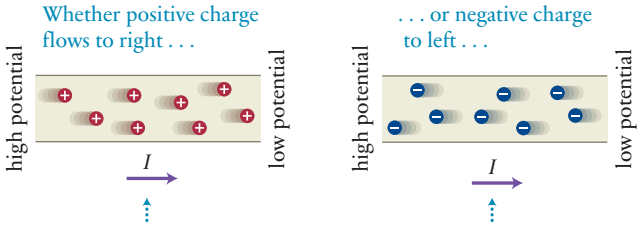


Figure 27.18 By definition, current has the direction in which positive charge carriers would flow, even if it is actually carried by negative charge carriers moving in the opposite direction.

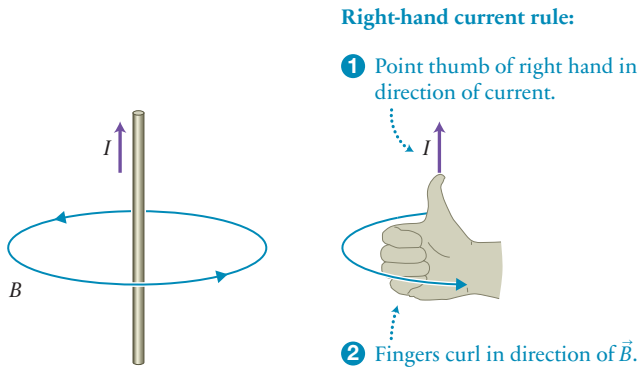
. . . we say *direction of current* is to right (from high to low potential).

A flow of positive charge in one direction produces the same magnetic field as an equal flow of negative charge in the opposite direction.

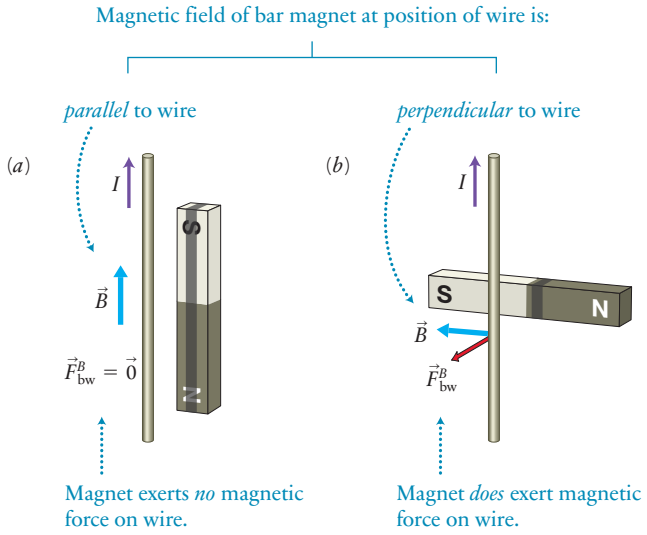
Therefore, regardless of the actual movement of charge carriers through a current-carrying wire, we shall always denote the direction of decreasing potential (that is, the direction in which positive charge carriers would flow) with an arrow labeled with the symbol for current (I) next to the wire, as shown in **Figure 27.18**. We'll call this direction the *direction of current*.



We can now connect the direction of a magnetic field to that of current. **Figure 27.19** shows a single circular magnetic field line for the current-carrying rod from Figure 27.16. As seen from the top, the magnetic field curls in a counterclockwise direction around the rod. The downward flow of negative electrons through the rod corresponds to an upward current, and so the direction of the magnetic field is connected to that of the current by the *right-hand current rule*:

If you point the thumb of your right hand in the direction of current, your fingers curl in the direction of the magnetic field produced by that current.

27.10 Can you replace the current-carrying rod of Figure 27.16 by a magnet and get the same magnetic field?



The relationship between the magnetic field produced by a magnet and that produced by a current-carrying wire

Figure 27.19 The right-hand current rule relates the direction of a current to the direction of the resulting magnetic field.

CONCEPTS

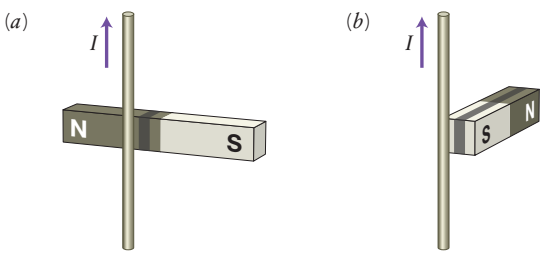
Figure 27.20 The magnetic force exerted by a bar magnet on a current-carrying wire depends on the magnet's orientation.

is not immediately obvious. We shall study this relationship in more detail in the next chapter. Before doing so, however, we still need to answer the question: How does a bar magnet interact with a straight current-carrying wire? The answer, which follows from the experiment illustrated in **Figure 27.20**, describes an interaction that is very different from all the interactions we have encountered so far. When a bar magnet is held parallel to a current-carrying wire, the magnetic field of the magnet at the position of the wire is parallel to the wire (Figure 27.20*a*). In this position, the magnet exerts *no force* on the wire! When we rotate the magnet 90°, so that its long axis is perpendicular to the long axis of the wire, the magnet exerts a repulsive force on the wire (Figure 27.20*b*). The most striking aspect of this interaction is that the direction of the magnetic force is *perpendicular* to the magnetic field.

CONCEPTS

27.11 Use Figure 27.20 to determine the direction of the magnetic force exerted by the magnet on the wire when the magnet is in the orientations shown (*a*) in **Figure 27.21*a*** and (*b*) in Figure 27.21*b*. (Hint: First determine the direction of the magnetic field due to the magnet at the wire; then use the observations from Figure 27.20 to determine the direction of the magnetic force.)

Figure 27.21 Checkpoint 27.11.



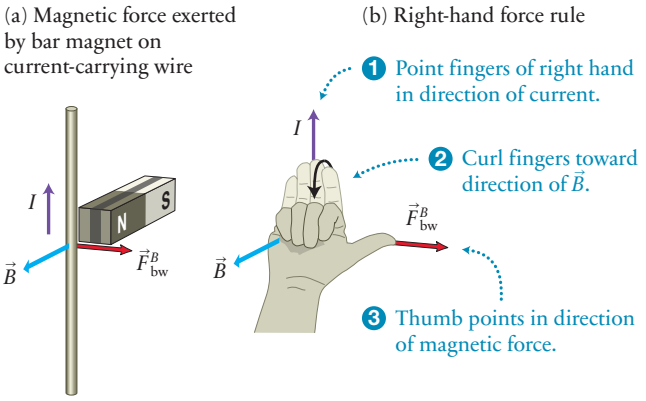


Figure 27.22 When a magnet exerts a force on a current-carrying wire, the right-hand force rule relates the direction of the force to that of the current and the magnet's magnetic field.

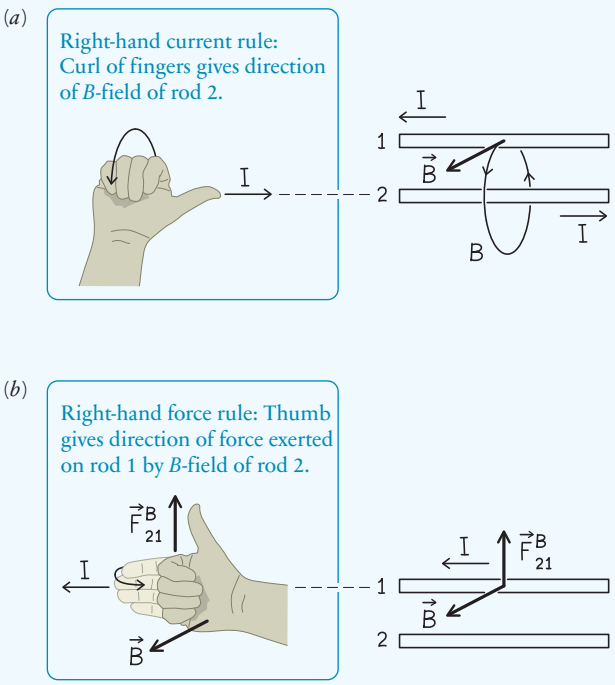
The surprising *sideways* force exerted by the bar magnet on the wire in Figure 27.21*b* (see Checkpoint 27.11) is a result of the fact that the magnetic force exerted by a bar magnet on a current-carrying wire is always at right angles to both the magnetic field and the direction of current. This observation suggests that these three directions can be connected by a right-hand rule. **Figure 27.22** shows that if you orient the fingers of your right hand in the direction of current in such a way that you can curl them so that the fingertips point in the direction of the magnetic field, then your right thumb points in the direction of the magnetic force exerted on the wire. Take a minute to verify the direction of the force in Figure 27.20*b* using this procedure, commonly called the *right-hand force rule*:*

> **The direction of the magnetic force exerted by a magnetic field on a current-carrying wire is given by the direction of the right-hand thumb when the fingers of that hand are placed along the direction of current in such a way that they can be curled toward the magnetic field.**

Table 27.1 summarizes the two right-hand rules we have encountered so far.

Table 27.1 Right-hand rules in magnetism

Right-hand rule	Thumb points along	Fingers curl
current rule	current	along *B*-field
force rule	magnetic force	from current to *B*-field



*There is nothing magical about right hands. You could use your left hand and change the rule to read, "The direction . . . given by the direction of the left-hand thumb when the fingers of that hand are placed along the direction of the magnetic field in such a way that they can be curled toward the direction of current." The same applies to determining the direction of a magnetic field surrounding a current-carrying rod. In Figure 27.19, for instance, orienting your left hand so that the thumb points in the direction *opposite* the direction of current automatically curls the fingers in the direction of the magnetic field. A consistent convention is what is important.

EXAMPLE 27.1 Current-carrying rods

Two parallel rods carry currents in opposite directions. Determine the direction of the magnetic force exerted by each rod on the other rod.

1 GETTING STARTED I begin by making a sketch of the rods, labeling them 1 and 2 and showing the currents in opposite directions (**Figure 27.23**). The current through rod 2 creates a magnetic field at the location of rod 1. This magnetic field exerts a force $\vec{F}_{21}^{B}$ on rod 1. Likewise, the magnetic field created at rod 2 by the current through rod 1 exerts a force $\vec{F}_{12}^{B}$ on rod 2.

Figure 27.23

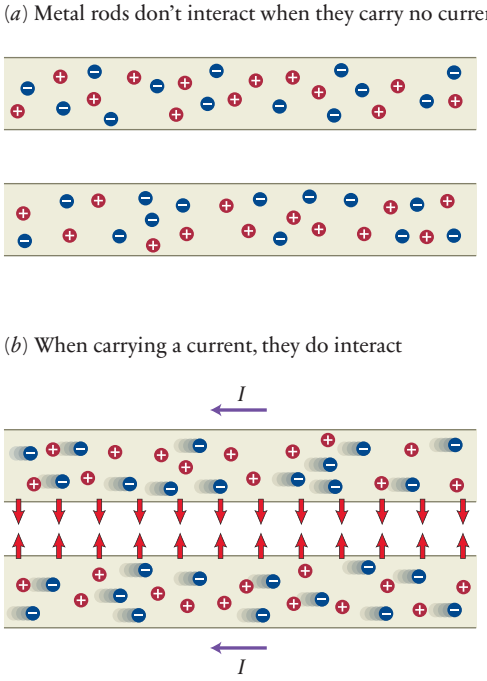
2 DEVISE PLAN To determine the direction of each force, I need to apply the right-hand force rule. To apply this rule, I need to know the direction of the magnetic field created by each rod at the location of the other. I can determine these directions using the right-hand current rule.

3 EXECUTE PLAN I begin with the right-hand current rule to determine the direction of the magnetic field due to the current through rod 2 at the location of rod 1. When I align my right thumb with the direction of current through rod 2, my fingers curl out of the page (Figure 27.23*a*), telling me that this is the direction of the magnetic field due to rod 2. Next I apply the right-hand force rule to determine the direction of the magnetic force $\vec{F}_{21}^{B}$ exerted by rod 2 on rod 1. I align the fingers of my right hand with the current through rod 1 in such a way that they can curl toward $\vec{B}$ (Figure 27.23*b*). My right thumb now points up in the plane of the page, telling me that this is the direction of $\vec{F}_{21}^{B}$. ✔

To determine the direction of the magnetic force $\vec{F}_{12}^{B}$ exerted by rod 1 on rod 2, I again begin with the right-hand current rule, which tells me that, at the location of rod 2, the magnetic field due to rod 1 is directed out of the page. Applying the force rule, I place my fingers along the direction of I_2 and see that curling them in the direction of $\vec{B}$ makes my thumb point downward in the plane of the page, so this is the direction of $\vec{F}_{12}^{B}$. ✔

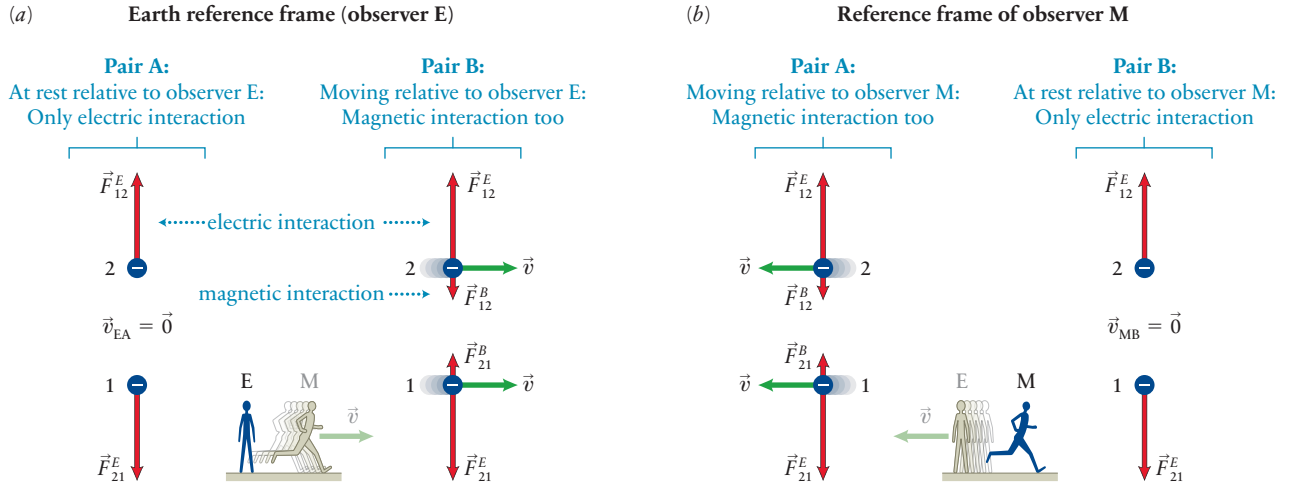
The force $\vec{F}_{21}^{B}$ points upward, the force $\vec{F}_{12}^{B}$ points downward, and therefore the rods repel each other.

4 EVALUATE RESULT It makes sense that the two rods exert forces on each other that point in opposite directions because the forces $\vec{F}_{12}^{B}$ and $\vec{F}_{21}^{B}$ form an interaction pair.



27.12 Determine the directions of the forces exerted by two parallel rods with currents in the same direction.

27.4 Magnetism and relativity



The magnetic interaction between two current-carrying rods is baffling. How can any interaction between the rods depend on the motion of the charge carriers in them? **Figure 27.24*a*** shows a schematic view of the positive and negative charge carriers that make up two parallel metal rods. The electrons in the two rods repel one another, but this repulsion is perfectly balanced by the attraction between the electrons in one rod and the positively charged ions in the other rod. Once the electrons are set in motion, however, this balance appears to be disturbed, and, depending on the signs of the

Figure 27.24 Schematic view of the interaction between two current-carrying rods.

CONCEPTS

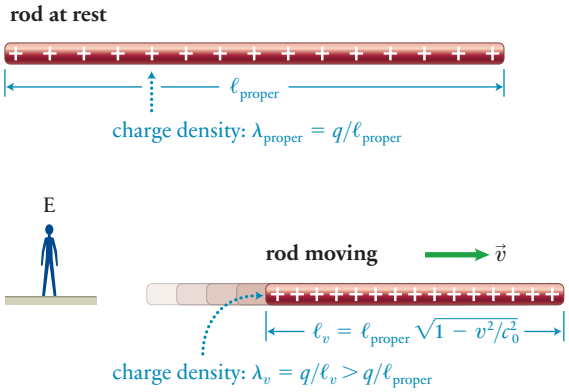
Figure 27.25 A relativistic view of the interaction between two charged particles.

currents, the rods either attract (Figure 27.24*b*) or repel each other.

To analyze this interaction, consider the simpler situation of two pairs of electrons. Relative to Earth, pair A is at rest and pair B is moving at constant velocity $\vec{v}$ (**Figure 27.25*a***). To observer E, who is also at rest relative to Earth, the interaction between the two electrons of pair A is completely described by Coulomb's law: As we saw in Chapter 22, the electrons repel each other due to an electric interaction. According to observer E, the interaction between the electrons of pair B is *different* from that between the pair A electrons. In addition to the Coulomb repulsion, observer E perceives a magnetic interaction between the electrons of pair B because the moving electrons constitute a current.

The conclusions drawn by an observer M moving along with pair B are startlingly different (Figure 27.25*b*). To this observer, pair B is at rest and pair A is moving to the left at constant velocity. Consequently, to M the interaction between the electrons of pair B is purely electric, while that between the electrons of pair A must have a magnetic component as well. This odd conclusion is a direct consequence of the fact that magnetism is motion-dependent and therefore, like velocity, must be relative:

The observed interaction between charge carriers depends on their motion relative to the observer: The interaction can be purely electric, purely magnetic, or a combination of the two.



At first sight, this statement appears to be a violation of the principle of relativity. If reference frame M moves at constant velocity relative to reference frame E, then both observers should agree on their observations (see Section 6.3). The resolution of this problem lies in the fact that the magnetic interaction between two moving charged carriers is a direct consequence of special relativity: *Magnetism is a relativistic effect.*

As explained in Chapter 14, relativistic effects tend to be so extraordinarily small that they cannot be observed under most ordinary conditions. So why is it that we can feel this relativistic effect every time we stick a note to a refrigerator with a magnet? To see why, let us return to the two current-carrying rods in Figure 27.24. Two 1-m-long rods, each 0.5 mm in diameter, contain an immense number of free electrons—more than 10^{22} of them. To appreciate how enormous this number is, imagine that these electrons were not accompanied by an equal number of positively charged ions. The force with which two such collections of unbalanced electrons separated by a distance of 5 mm would repel each other is a phenomenal 10^{19} N—enough to lift up thousands of average-sized mountains. The fact that two electrically neutral metal rods do not exert any force on each other shows how incredibly accurate is the balance between positive and negative charge carriers in matter. In contrast, if we run large currents through the rods—by applying and maintaining a potential difference of, say, several volts across the length of each rod—then the magnetic force exerted by each rod on the other is a mere 10^{-2} N. This small but measurable magnetic force is 10^{21} times smaller than the electric repulsion between the electrons in the rods! Thus, if magnetism is indeed a relativistic effect (see below and Section 27.8 for details), we can now understand why we can so readily observe it. First, the electric force is incredibly large, and so even a small relativistic correction becomes measurable. Second, because electrical charge is so well balanced in all matter, electric forces are balanced, leaving only the small "magnetic" correction. In a sense, therefore, magnetism provides the most direct observation of a relativistic effect!

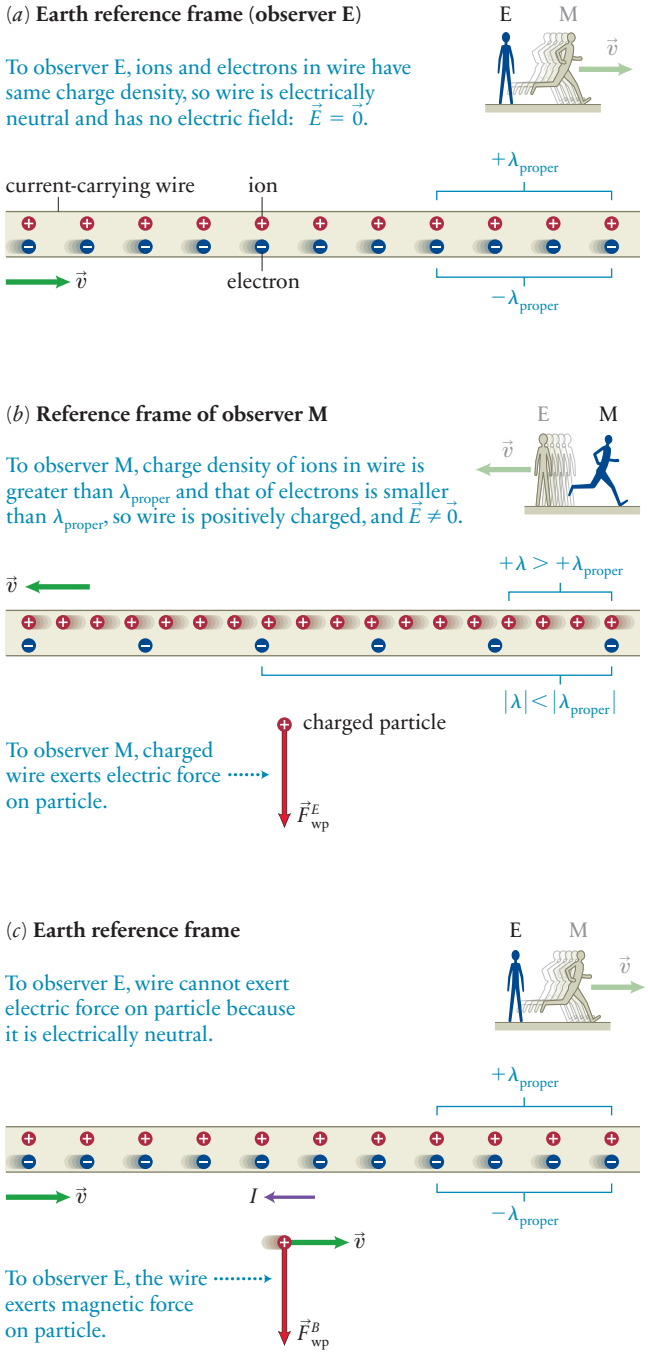
Let us now try to understand qualitatively how special relativity requires a magnetic interaction between charge carriers in motion. The treatment that follows

CONCEPTS

Figure 27.26 Because a rod appears shorter when it is moving relative to the observer, its charge density appears larger than when the rod is at rest.

relies on very little knowledge of special relativity—only the concept of length contraction is needed (see Section 14.6): When an object moves relative to an observer, the observer measures the length of the object in the direction of its motion to be shorter than the proper length of the object.

A direct result of length contraction is that the charge density of an object depends on its motion relative to the observer. Consider, for example, a rod carrying a positive charge q. At rest in the Earth reference frame, the rod has length ℓ_{proper} and its "proper" charge density is $\lambda_{\text{proper}} = q/\ell_{\text{proper}}$. If the rod is set in motion along its lengthwise axis, its length measured by an observer at rest is smaller than ℓ_{proper} (**Figure 27.26**). Because the charge on the rod is still q, the observer at rest sees a greater charge density on the moving rod.*



27.13 Consider the two identical rods in Figure 27.26, one moving and the other at rest relative to observer E, at rest in the Earth reference frame. Suppose a second observer M moves along with the moving rod. (*a*) Which rod has the greater charge density according to observer M? (*b*) Suppose the charge on the rod moving in the Earth reference frame is adjusted so that its charge *density* as seen by observer E is the same as the charge density of the rod at rest in the Earth reference frame. Is the charge density on each rod as seen by observer M greater than, equal to, or smaller than $\lambda_{\text{proper}} = q/\ell_{\text{proper}}$?

Understanding the changes in charge density that occur when charge carriers move relative to the observer is the key point for the remainder of this section. Thus

*It is not immediately obvious that the charge of a system is not affected by the motion of the charge carriers. Experiments, however, show that charge is, indeed, an invariant (that is, its value does not depend on the choice of reference frame).

Figure 27.27 Observers E (at rest in the Earth reference frame) and M (moving in the Earth reference frame) observe a current-carrying wire.

if you did not complete the preceding checkpoint, please go back and do it now before reading on.

Let us now apply these ideas to the interaction between a current-carrying wire and a charged particle. **Figure 27.27***a* schematically shows a current-carrying wire consisting of fixed positively charged ions (red) and negatively charged electrons (blue) traveling to the right at velocity $\vec{v}$. (For clarity, the ions and electrons are drawn side by side rather than intermingled as they are in a real conductor.)

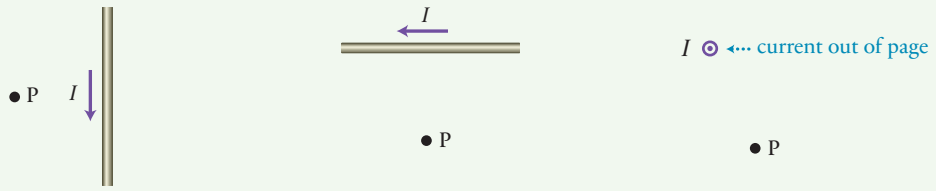
CONCEPTS

To an observer E at rest relative to the ions, the wire does not carry a surplus charge, and so any length of wire contains the same number of ions and electrons. That is, to E the linear charge density of the ions, λ_{proper}, is equal in magnitude to that of the electrons, $-\lambda_{\text{proper}}$. Consequently, there is no electric field outside the wire, and the wire cannot exert an electric force on a charged particle placed near the wire.

Suppose, however, that a positively charged particle moves alongside the wire—for simplicity, we let it move at the same velocity $\vec{v}$ relative to the wire as the electrons in the wire. First we consider the particle and the wire from the point of view of an observer M moving along with the particle. Because the particle is at rest relative to M, it experiences no magnetic force according to this observer. From M's point of view, the electrons in the wire are at rest and the ions move at velocity $\vec{v}$ to the left (Figure 27.27*b*). In addition, as you saw in Checkpoint 27.13, the charge densities seen by M are different from those seen by E. To M, the positive ions are closer together because they are moving, which means their charge density is greater than λ_{proper}. The oppositely charged electrons, on the other hand, are at rest relative to M and so farther apart. According to observer M the magnitude of their linear charge density therefore must be smaller than that observed by E relative to whom they are moving.

The different charge densities mean that although the wire appears electrically neutral to E, it cannot also appear neutral to M. According to M, the magnitude of the electron density is smaller than λ_{proper}, and the magnitude of the ion density is greater than λ_{proper}. Thus, the wire appears positively charged to observer M. Observer M therefore sees a downward electric field due to the wire at the location of the charged particle, with the wire and the particle repelling each other.

In the reference frame of the fixed ions, a very different picture emerges. Observer E, seeing no electric field (Figure 27.27*a*), cannot attribute the repulsion between the wire and the particle to an electric interaction. Instead, E attributes this repulsion to a magnetic interaction between two currents, one in the wire and the other caused by the moving charged particle (Figure 27.27*c*). As we shall see in Section 27.8, this magnetic interaction can be completely accounted for by the Coulomb interaction and special relativity, and in principle any other magnetic interaction can also be explained this way. However, because transforming back and forth from one moving reference frame to another is cumbersome, it is easier to develop a separate treatment for magnetism that does not require reference-frame transformations and that ignores any relativistic effects. It is important to keep in mind, however, that magnetic and electric interactions are two aspects of one *electromagnetic* interaction, with magnetism being a relativistic correction to the electric interaction.



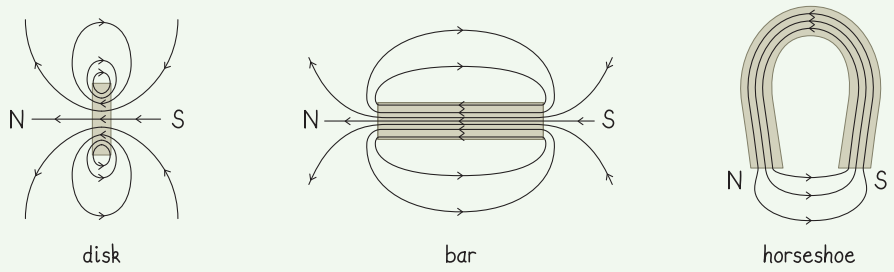
CONCEPTS

27.14 What is the direction of current through the rod in (*a*) Figure 27.27*b* and (*b*) Figure 27.27*c*? (*c*) Is the direction of the force in Figure 27.27*c* in agreement with what we learned about the interaction of two parallel current-carrying wires in Section 27.3? (*d*) If the particle moving alongside the wire in Figure 27.27 carries a negative charge, is the force exerted by the wire on the particle attractive or repulsive? (*e*) Is this direction consistent with the direction of the forces exerted on each other by two parallel current-carrying wires?

Self-quiz

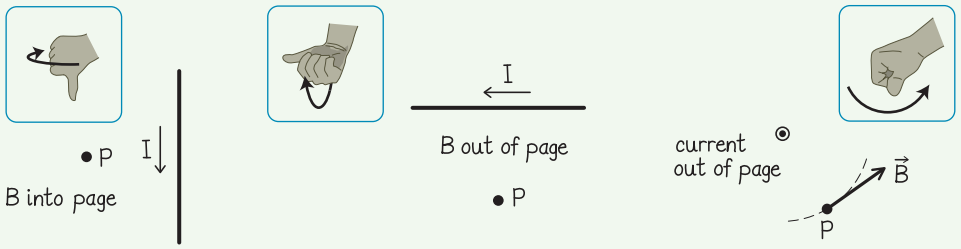
1. A compass sits on a table with its needle pointing to Earth's North Pole. A bar magnet with its long axis oriented along an east-west line is brought toward the compass from the east. If the needle turns clockwise, which pole of the bar magnet is nearer the compass?
2. Draw the magnetic field lines associated with the magnets in Figures 27.1*b–d* (both outside and inside the magnets). Assume that the pole on the left of each magnet is the north pole.
3. For each situation shown in **Figure 27.28**, apply the appropriate right-hand rule to determine the direction at position P of the magnetic field generated by the current-carrying wire.

Figure 27.28



4. For each situation in Figures 27.20*a*, 27.20*b*, and 27.21*a*, reverse the polarity of the magnet and then apply the appropriate right-hand rule to determine the direction of the force exerted by the bar magnet on the current-carrying wire.

Answers



1. South pole. The clockwise rotation means the needle tip (which is a north pole by definition) moves toward the bar magnet. Because opposite poles attract, the bar magnet's south pole must be the closer one. (Remember that Earth's geographic North Pole is a magnetic south pole and so attracts the north pole of any compass needle.)
2. See **Figure 27.29**.

Figure 27.29

3. See **Figure 27.30**. (See Checkpoint 27.7 if you do not understand this answer.)

Figure 27.30

4. Reversing the magnet polarity reverses the direction of the force exerted on the wire, unless the force is zero, in which case it remains zero.

27.5 Current and magnetism

As we saw in the first part of this chapter, currents exert magnetic forces on one another. That is, a current creates a magnetic field, and magnetic fields exert forces on currents. Let us therefore begin this part of the chapter by introducing a quantitative definition of current. As mentioned in Section 27.3, **current** I is the rate at which charged particles cross a section of a conductor in a given direction. For a constant current, we have

$$I \equiv \frac{q}{\Delta t} \quad \text{(constant current)}, \tag{27.1}$$

where q is the quantity of charge passing a given position in a time interval Δt. If the current is not constant, we evaluate the flow of charged particles over infinitesimally small time intervals, yielding

$$I \equiv \frac{dq}{dt}, \tag{27.2}$$

where dq is the infinitesimal quantity of charge crossing a given section of a conductor in an infinitesimally small time interval dt. Note that I can be positive or negative; by definition it is positive in the direction from high to low potential because that is the direction in which positive charge carriers flow (which we defined earlier as the direction of current).

The SI unit of current is the **ampere** (A). This base unit is now defined in terms of the precise value of the charge of the electron—that is, the elementary electric charge. The elementary charge is equal to exactly $1.602176634 \cdot 10^{-19}$ ampere-seconds (A · s). As we saw in Chapter 22, the coulomb is derived from the ampere: 1 C corresponds to the quantity of charge transported by a current of 1 A through a chosen section in a time interval of 1 s, or

$$1\ \text{C} \equiv 1\ \text{A} \cdot \text{s}. \tag{27.3}$$

Even though a charge of 1 C is extremely large by ordinary standards, currents of several amperes are quite common. Simple devices, which we shall discuss in Chapter 31, allow us to measure the current through a conductor quite readily. In the remainder of this chapter, we shall discuss constant currents—that is, currents whose magnitude does not change with time.

Experiments show that when a straight wire carrying a current I is placed in a uniform external magnetic field,* the magnetic force $\vec{F}_{\text{w}}^{B}$ exerted by the magnetic field on the wire is proportional to the length ℓ of wire in the magnetic field and to the magnitude of the current I. The force also depends on the angle θ between the direction of the current through the wire and the magnetic field (**Figure 27.31**). When the wire is parallel to the magnetic field ($\theta = 0$), the magnetic force exerted on the wire is zero. When the wire and the magnetic field are perpendicular to each other ($\theta = 90°$), the force is maximum:

$$F_{\text{w, max}}^{B} = |I|\ell B \quad \begin{matrix}\text{(straight wire perpendicular} \\ \text{to uniform magnetic field).}\end{matrix} \tag{27.4}$$

Because I is a signed quantity, we need to put absolute-value symbols around it to indicate its magnitude.

Equation 27.4 defines the magnitude B of the magnetic field. If we measure the magnetic force exerted by a magnetic field on a wire of known length carrying a known current, we can determine B from Eq. 27.4:

$$B \equiv \frac{F_{\text{w, max}}^{B}}{|I|\ell} \quad \begin{matrix}\text{(straight wire perpendicular} \\ \text{to uniform magnetic field).}\end{matrix} \tag{27.5}$$

*This magnetic field does not include the magnetic field of the current-carrying wire.

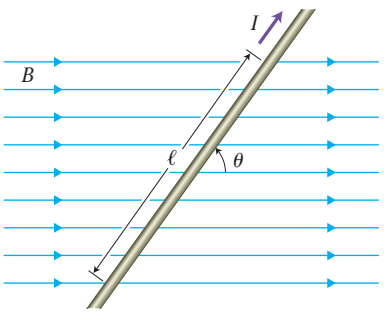


Figure 27.31 A current-carrying wire in an external magnetic field (that is, a magnetic field created by an object other than the wire).

QUANTITATIVE TOOLS

It follows from this expression that the magnetic field has SI units of $N/(A \cdot m)$, a derived unit called the **tesla** (in honor of engineer and inventor Nikola Tesla):

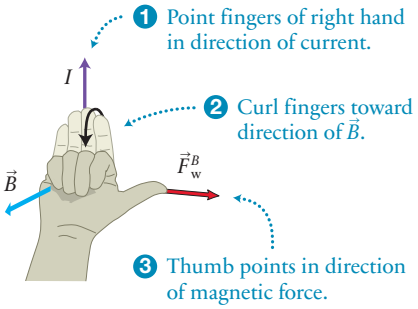
$$1\ T \equiv 1\ N/(A \cdot m) = 1\ kg/(s^2 \cdot A). \quad (27.6)$$

A magnetic field of 1 T is relatively large. Earth's magnetic field at Earth's surface varies between 3×10^{-5} T and 6×10^{-5} T. Table 27.2 provides some examples of the magnitudes of various magnetic fields.

At intermediate angles θ, the magnitude of the magnetic force exerted on the wire is proportional to $\sin\theta$, and so for an arbitrary angle θ between 0 and 180°, the magnitude of the magnetic force exerted on the wire is

$$F_w^B = |I|\ell B \sin\theta \quad (0 < \theta < 180°). \quad (27.7)$$

As we saw in Figure 27.22, the direction of the magnetic force exerted by a magnet on a current-carrying wire is always perpendicular to both the direction of the current I and the magnetic field $\vec{B}$, and is given by the right-hand force rule. In Figure 27.31, for example, the force is directed into the plane of the page. (If you line up the fingers of your right hand with the direction of current and then curl them, over the smallest angle, toward the direction of the magnetic field, your thumb points into the page.) If we define a vector $I\vec{\ell}$, whose magnitude is given by the product of the magnitude of the current and the length ℓ of the wire, and whose direction is given by the direction of current through the wire, we can write the **magnetic force** in Eq. 27.7 as the vector product of two vectors (see Section 12.8):



$$\vec{F}_w^B = I\vec{\ell} \times \vec{B} \quad (\text{straight wire in uniform magnetic field}). \quad (27.8)$$

This vector product represents a force that has the magnitude given in Eq. 27.7. The direction of $\vec{F}_w^B$ is always perpendicular to both $I\vec{\ell}$ (the direction of current) and $\vec{B}$ and is obtained by curling the fingers of the right hand from the direction of current to $\vec{B}$ (Figure 27.32).

Table 27.2 Magnetic fields

Object	B (T)
Earth's surface	5×10^{-5}
small bar magnet	0.01
neodymium magnet	0.2
laboratory magnet	10
neutron star surface	10^8

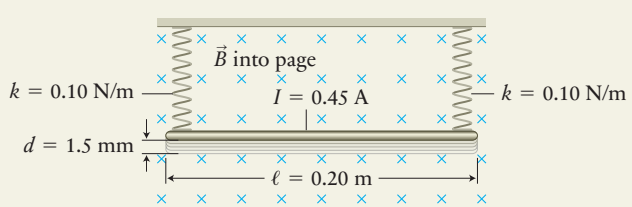


Figure 27.32 The right-hand rule for the direction of the vector product $I\vec{\ell} \times \vec{B}$.

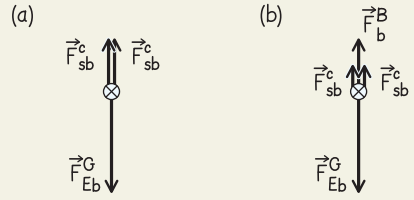
EXAMPLE 27.2 Magnetic field meter



A metal bar 0.20 m long is suspended from two springs, each with spring constant $k = 0.10$ N/m, and the bar is in an external magnetic field directed perpendicular to the bar length (Figure 27.33). With a current of 0.45 A in the bar, the bar rises a distance $d = 1.5$ mm. (*a*) In what direction is the current? (*b*) What is the magnitude B of the external magnetic field?

Figure 27.33 Example 27.2.

❶ **GETTING STARTED** I begin by making a free-body diagram for the bar with and without the current through the bar. Without the current, the bar is subject to two upward forces exerted by the springs and a downward force of gravity (Figure 27.34*a*). With the current turned on, an upward magnetic force lifts the bar, and so, according to Hooke's law (see Section 8.9), the springs exert a smaller force on the bar (Figure 27.34*b*). The amount by which the bar rises determines by how much the force exerted by the springs is reduced, which in turn gives me the magnitude of the upward magnetic force exerted on the bar.

Figure 27.34

(Continued)

2 DEVISE PLAN I know the directions of the external magnetic field (into the page) and of the force (upward) exerted by that field, so I can determine the direction of the current from the right-hand force rule. Because the bar is straight and perpendicular to the external magnetic field, I can use Eq. 27.5 to relate the magnitude of the magnetic field to the magnitude of the magnetic force. I know both the current and the length of the bar but not the magnitude of the force exerted on the bar. I know, however, that this force magnitude is equal to the change in the magnitude of the force exerted by the springs, which I can calculate using Hooke's law (Eq. 8.20).

3 EXECUTE PLAN (*a*) The external magnetic field is into the plane of the page (Figure 27.33) and the magnetic force is directed upward. I therefore lay my right hand on top of Figure 27.33 with my thumb pointing up to represent the upward force. I can lay my hand on the page palm up or palm down. In the palm-up position, curling my fingers draws the tips away from the direction of $\vec{B}$. In the palm-down position, curling them draws the tips toward the direction of $\vec{B}$. Therefore that's the position I want, telling me the current is to the right, in the direction my fingers point before I curl them. ✔

(*b*) From Eq. 8.20, I know that raising the bar a distance d reduces the spring force by an amount kd, and so the magnitude of the magnetic force is $F_b^B = 2kd$. Substituting this result into Eq. 27.5 gives

$$B = \frac{2kd}{|I|\ell} = \frac{2(0.10\ \text{N/m})(1.5\times10^{-3}\ \text{m})}{(0.45\ \text{A})(0.20\ \text{m})} = 3.3\times10^{-3}\ \text{T}. \checkmark$$

4 EVALUATE RESULT The magnitude of the magnetic field I obtain is about 100 times greater than Earth's magnetic field and of the same order of magnitude as that of a bar magnet and therefore not unreasonable.

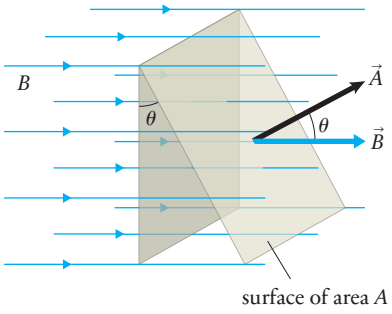
27.15 Suppose the charge carriers flowing through the horizontal bar in Example 27.2 are negatively charged. In which direction must they flow so that the magnetic force exerted on the wire is still directed upward?

27.6 Magnetic flux

From the field line picture for electrostatics, we obtained Gauss's law, which states that the electric flux Φ_E through any closed surface is proportional to the enclosed charge. Gauss's law allows us to determine the electric field of certain symmetrical charge distributions with great ease.

Because magnetic fields can also be described by field lines, we can follow a similar treatment for magnetism. Consider a surface of area A in a uniform magnetic field $\vec{B}$ (**Figure 27.35**). If a line normal to the surface makes an angle θ with the field, we can define a **magnetic flux** in analogy to the electric flux defined in Eq. 24.2:

$$\Phi_B \equiv BA\cos\theta = \vec{B}\cdot\vec{A} \quad \text{(uniform magnetic field)}, \tag{27.9}$$



where $\vec{A}$ is an area vector (see Section 24.6) whose magnitude is equal to the area A of the surface and whose direction is normal to the surface. In the case of a closed surface, the direction of $\vec{A}$ is always chosen to be outward. Magnetic flux is a scalar, and as you can see from Eq. 27.9, magnetic flux has SI units of $\text{T}\cdot\text{m}^2$. This derived unit is given the name **weber** (Wb), in honor of the German physicist Wilhelm Weber:

$$1\ \text{Wb} \equiv 1\ \text{T}\cdot\text{m}^2 = 1\ \text{m}^2\cdot\text{kg}/(\text{s}^2\cdot\text{A}).$$

If the field is nonuniform or the surface is not flat, we follow the same procedure as for the electric flux and divide the surface into small surface elements, apply Eq. 27.9 to each surface element, and then sum the magnetic flux through all the elements. In the limit that the area of each element approaches zero, the sum is replaced by a surface integral (Eq. 24.4):

$$\Phi_B \equiv \int \vec{B}\cdot d\vec{A}, \tag{27.10}$$

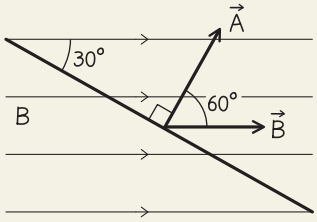
Figure 27.35 The magnetic flux through a surface of area A is given by the scalar product of the area vector $\vec{A}$ and the magnetic field $\vec{B}$.

QUANTITATIVE TOOLS

where $d\vec{A}$ is the area vector of an infinitesimally small segment of the surface. The meaning of magnetic flux Φ_B is similar to that of electric flux. It is a quantitative measure of the number of magnetic field lines crossing the surface specified in the integration.

As we saw in Section 27.2, magnetic field lines always form loops. Thus, the magnetic flux through any closed surface must always be zero because every field line that exits the surface must enter it somewhere else:

$$\Phi_B = \oint \vec{B} \cdot d\vec{A} = 0. \tag{27.11}$$



The zero reflects the fact that magnetic field lines always form loops or, equivalently, that there is no magnetic equivalent of an isolated charged particle. Equation 27.11 is called **Gauss's law for magnetism.** However, because of the zero result and because magnetic fields generally do not exhibit the same type of symmetry as electric fields, this expression does not allow us to determine magnetic fields in the same way that Gauss's law allows us to determine electric fields. As we shall see in Chapter 29, however, the magnetic flux is an important quantity when we consider changing magnetic fields.

EXAMPLE 27.3 Magnetic flux through a loop

A square loop 0.20 m on each side is placed in a uniform magnetic field of magnitude 0.50 T. The plane of the loop makes a 30° angle with the magnetic field. What is the magnetic flux through the loop?

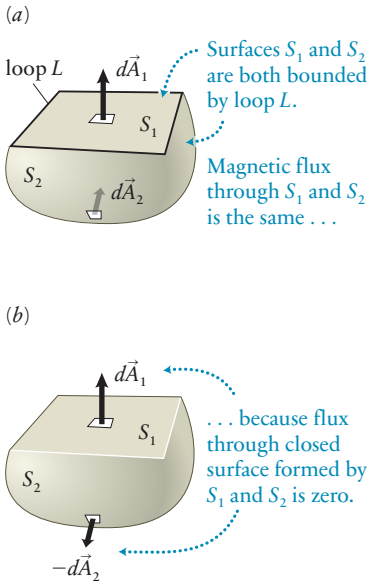
❶ **GETTING STARTED** I begin by drawing a side view to visualize the situation (Figure 27.36). I have to calculate the magnetic flux through the flat surface defined by the loop.

Figure 27.36

❷ **DEVISE PLAN** Because the magnetic field is uniform, I can use Eq. 27.9 to calculate the magnetic flux through the loop.

❸ **EXECUTE PLAN** The area of the loop is $A = (0.20\ \text{m})^2 = 0.040\ \text{m}^2$. Because the loop makes a 30° angle with the magnetic field, the angle between the magnetic field and a normal to the plane of the loop is 60°. Therefore

$$\Phi_B = AB\cos\theta = (0.040\ \text{m}^2)(0.50\ \text{T})\cos(60°)$$
$$= 1.0 \times 10^{-2}\ \text{Wb}. \checkmark$$



❹ **EVALUATE RESULT** I arbitrarily chose the area vector $\vec{A}$ to point upward and to the right. Had I chosen to point it downward and to the left, the angle between $\vec{A}$ and $\vec{B}$ would have been 120° and, given that $\cos 120° = -\frac{1}{2}$, I would have obtained $\Phi_B = -0.010$ Wb. The flat surface defined by the loop doesn't constitute a closed surface, however, and so there is no unique direction for $\vec{A}$. The sign of the magnetic flux is therefore not determined by the information given in the question. I have no means of evaluating the magnitude of the flux, so I carefully check my calculations one more time.

Because we can draw an infinite number of surfaces that are bounded by a loop, the expression "flux through the loop" in Example 27.3 appears open to interpretation. Figure 27.37*a* on the next page, for example, shows two surfaces S_1 and S_2 bounded by the same loop L. Which surface should we use when computing the magnetic flux? The answer is: *any* surface bounded by L yields the same magnetic flux. To see why, let us examine the magnetic fluxes through S_1 and S_2. In both cases we use a surface normal that points up through loop L.

The magnetic flux through S_2 is

$$\Phi_B = \int_{S_2} \vec{B} \cdot d\vec{A}_2. \tag{27.12}$$

Figure 27.37 Any surface bounded by loop L yields the same magnetic flux.

To see how this flux relates to that through S_1, consider the magnetic flux through the closed surface made up of S_1 and S_2 (Figure 27.37*b*). Because this surface is closed, we know the magnetic flux through it is zero (Eq. 27.11):

$$\oint_{S_1+S_2} \vec{B}\cdot d\vec{A} = \int_{S_1} \vec{B}\cdot d\vec{A} + \int_{S_2} \vec{B}\cdot d\vec{A} = 0, \tag{27.13}$$

where the area vector $d\vec{A}$ points *outward* from the closed surface. In terms of the surface normals $d\vec{A}_1$ and $d\vec{A}_2$ shown in Figure 27.37*a*, Eq. 27.13 becomes

$$\oint_{S_1+S_2} \vec{B}\cdot d\vec{A} = \int_{S_1} \vec{B}\cdot d\vec{A}_1 + \int_{S_2} \vec{B}\cdot(-d\vec{A}_2)$$

$$= \int_{S_1} \vec{B}\cdot d\vec{A}_1 - \int_{S_2} \vec{B}\cdot d\vec{A}_2. \tag{27.14}$$

The term $\int_{S_1} \vec{B}\cdot d\vec{A}_1$ represents the magnetic flux through the flat surface S_1; the term $\int_{S_2} \vec{B}\cdot d\vec{A}_2$ represents the magnetic flux through the curved surface S_2. Because the magnetic flux through the closed surface is zero (Eq. 27.11), the right side of Eq. 27.14 must also be zero, and so

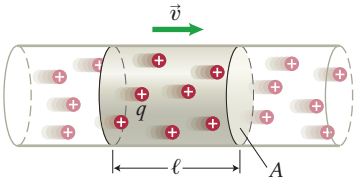
$$\int_{S_1} \vec{B}\cdot d\vec{A}_1 = \int_{S_2} \vec{B}\cdot d\vec{A}_2. \tag{27.15}$$

27.16 A cube 1.0 m on each side is placed in a 1.0-T magnetic field with the field perpendicular to one surface of the cube. What are (*a*) the magnetic flux through the side through which the field enters the cube and (*b*) the magnetic flux through the entire surface of the cube?

27.7 Moving particles in electric and magnetic fields

The magnetic force exerted by a magnetic field on a straight current-carrying wire is really the sum of the magnetic forces exerted on many individual charge carriers moving through the wire. By examining how a current I through a conductor is related to the properties of the charge carriers causing that current, we can therefore deduce the magnetic force acting on a single charge carrier.

Consider a constant current caused by a flow of charge carriers, each carrying a quantity of charge q through a wire of cross-sectional area A (**Figure 27.38**). If the charge carriers flow at speed v, then in a time interval Δt each advances a distance $\ell = v\Delta t$. Thus all the charge carriers in the shaded volume $V = A\ell$ pass through a cross section of the wire in a time interval Δt. If the wire contains n charge carriers per unit volume, the shaded volume contains nV charge carriers and the charge flowing through the cross section is $Q = nVq = nA\ell q = nA(v\Delta t)q$. The current through the wire is thus



$$I \equiv \frac{Q}{\Delta t} = \frac{nA(v\Delta t)q}{\Delta t} = nAqv. \tag{27.16}$$

Substituting this result into Eq. 27.7, we can write for the magnitude of the magnetic force exerted on the current-carrying wire

$$F_w^B = |nA\ell qv|B\sin\theta = nA\ell|q|vB\sin\theta, \tag{27.17}$$

where θ is the angle between the velocity of the charge carriers and the magnetic field. Because n is the number of charge carriers per unit volume and $A\ell$ is the volume of a length ℓ of the wire, the quantity $N = nA\ell$ represents the number of charge carriers in a length ℓ of the wire. The magnetic force exerted on that length of the wire can thus be written

Figure 27.38 If the charge carriers in a straight current-carrying wire move at speed v, they advance a distance $\ell = v\Delta t$ in a time interval Δt. All the charge carriers in the shaded volume pass through the cross-sectional area A in that time interval.

QUANTITATIVE TOOLS

$F_w^B = N|q|vB \sin\theta$. Because there are N charge carriers in the length ℓ, the magnitude of the **magnetic force** exerted on a single particle carrying a charge q moving at velocity $\vec{v}$ is

$$F_p^B = |q|vB \sin\theta \tag{27.18}$$

or, in vector form,

$$\vec{F}_p^B = q\vec{v} \times \vec{B}. \tag{27.19}$$

Note that the vector $q\vec{v}$ always points in the direction of current—that is, from high potential to low potential—regardless of the sign of q. As we saw in Section 25.3, a negatively charged particle moves from low to high potential, so $\vec{v}$ points opposite the direction of current, but because $q < 0$, the vector $q\vec{v}$ points in the direction of current.

This is the fundamental expression for the magnetic force acting on a moving charge carrier. Even though we derived Eq. 27.19 for a positively charged particle, it holds for any kind of charge. Because of its velocity dependence, this force is very different from any of the other forces we have encountered so far. In particular, if the charge carrier is at rest *relative to the reference frame in which the magnetic field is measured*, the magnetic force is equal to zero. (In contrast, the electric force exerted on a charged particle is independent of the motion of the charged particle relative to the reference frame in which the electric field is measured.)

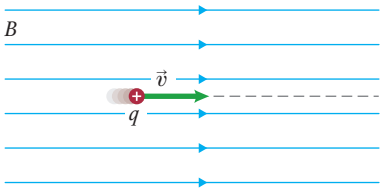
In the presence of both electric and magnetic fields, the **electromagnetic force** exerted on each charge carrier is

$$\vec{F}_p^{EB} = q\vec{E} + q\vec{v} \times \vec{B} = q(\vec{E} + \vec{v} \times \vec{B}). \tag{27.20}$$

Let us now examine what kind of trajectory a charged particle follows when it travels through a region of uniform magnetic and electric fields. We begin by examining the two special cases of a positive charge carrier traveling into a region of uniform magnetic field. When the carrier travels parallel to the direction of $\vec{B}$, as in **Figure 27.39a**, the magnetic force is zero because the vector product in Eq. 27.19 is zero when $\vec{v}$ is parallel to $\vec{B}$. (Alternatively, you can visualize the moving charge carrier as a current. As we have seen in Section 27.3, the magnetic force is zero when the current is parallel to the magnetic field.)

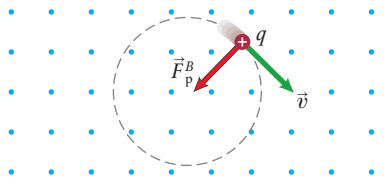
When the charge carrier moves perpendicular to a uniform magnetic field, as in Figure 27.39*b*, the magnetic force is nonzero. Because the magnetic force is always perpendicular to both $\vec{B}$ and $\vec{v}$, it lies in the plane of the drawing and is perpendicular to $\vec{v}$. Because the force acting on the change carrier always remains perpendicular to the direction of motion, the speed of the charge carrier does not change and we have the condition for circular motion at constant speed. The magnetic force, always directed toward the center of the circular path in which the charge carrier moves, provides the centripetal acceleration.

The equation of motion for the charge carrier is



$$\Sigma\vec{F} = m\vec{a}. \tag{27.21}$$

If we ignore the force of gravity exerted on the charge carrier, the only force exerted on it is the magnetic force. Because $\vec{B}$ and $\vec{v}$ are perpendicular, the magnitude of this force is $F_p^B = |q|vB$ (Eq. 27.18). The magnitude of the charge carrier's centripetal acceleration is given by Eq. 11.15, $a_c = v^2/R$, where R is the radius of its circular trajectory. Therefore



$$|q|vB = \frac{mv^2}{R}. \tag{27.22}$$

Figure 27.39 A charged particle moving in a uniform magnetic field travels (*a*) in a straight line when its velocity is parallel to the field and (*b*) in a circle when the two are perpendicular.

(*a*) Particle's velocity is parallel to field

(*b*) Particle's velocity is perpendicular to field

$\vec{B}$ out of page

Solving for R, we obtain for the radius of the trajectory

$$R = \frac{mv}{|q|B}. \tag{27.23}$$

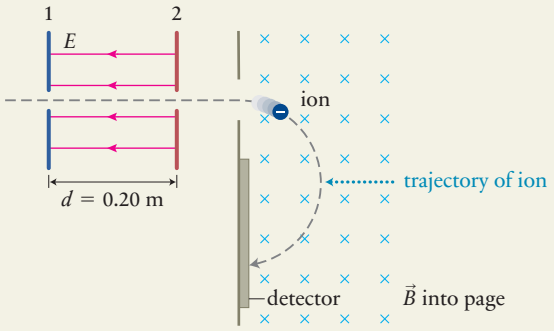
Because the ratio $m/|q|$ is fixed for a given charge carrier, we see that the radius of its trajectory depends on the charge carrier's speed. In a given magnetic field, fast charge carriers move in larger circles than slow ones of the same type. Interestingly, the time interval needed for one full revolution is independent of the carrier's speed. This time interval is equal to the circumference of the trajectory divided by the carrier's speed:

$$T = \frac{2\pi R}{v} = \frac{2\pi}{v}\frac{mv}{|q|B} = \frac{2\pi m}{|q|B}. \tag{27.24}$$

The corresponding angular frequency is

$$\omega = 2\pi f = \frac{2\pi}{T} = \frac{|q|B}{m}. \tag{27.25}$$

This angular frequency is sometimes called the *cyclotron frequency* after a type of particle accelerator, called a *cyclotron*, in which particles are accelerated between successive semicircular trajectories.



27.17 A proton and an electron travel through a region of uniform magnetic field $\vec{B}$. If their speeds are the same, what is the ratio R_p/R_e of the radii of their circular paths through the field?

EXAMPLE 27.4 Mass spectrometer

Figure 27.40 shows a schematic of a device, called a *mass spectrometer*, for determining the mass of ions or other charged particles. The ions that enter the mass spectrometer are first accelerated by an electric field and then deflected by a magnetic field. The mass of the ions is obtained from the position at which they hit a detector after being deflected by the magnetic field.

Figure 27.40 Example 27.4.

In a certain mass spectrometer, the electric field is caused by a potential difference of 10 kV across a distance $d = 0.20$ m between plates 1 and 2, and the magnitude of the magnetic field is $B = 0.20$ T. An oxygen ion with a charge q of $-2e$ ($1e = 1.6022 \times 10^{-19}$ C) and a mass m of 16 atomic mass units (1 atomic mass unit = 1 u = 1.6605×10^{-27} kg) enters the electric field with negligible initial velocity. At what distance from the point of entry into the magnetic field does the ion hit the detector?

❶ **GETTING STARTED** From the schematic I see that the ion's motion consists of two parts: a linear motion at constant acceleration in the uniform electric field, followed by circular motion at constant speed in the uniform magnetic field. Because the drawing shows the ion entering the magnetic field perpendicular to the plane of the detector, the ion traces out a half circle before hitting the detector. The distance we must determine is therefore equal to the diameter of the circular trajectory of the ion.

❷ **DEVISE PLAN** Equation 27.23 gives the radius of the circular trajectory. I am given B, m, and q, but I don't know the speed v at which the ion enters the magnetic field. This speed is equal to the final speed the ion acquires after accelerating in the electric field. I know from Eq. 25.17 how much electrostatic work is done on the ion as it traverses the potential difference between plates 1 and 2 that set up the electric field. According to Eq. 25.17, I have $W_{ion}(1 \to 2) = -qV_{12}$. This work increases the kinetic energy of the ion. Because the initial kinetic energy is zero, I have $W_{ion}(1 \to 2) = \Delta K = K_f$. I know q, V_{12}, and m, so I can now calculate v from $K_f = \frac{1}{2}mv^2$ and then use that value in Eq. 27.23 to obtain the answer to this question.

❸ **EXECUTE PLAN** The electrostatic work done on the ion is

$$W_{ion}(1 \to 2) = -qV_{12} = 2eV_{12}.$$

From the expression for kinetic energy, I obtain for the ion's speed as it enters the magnetic field

$$v = \sqrt{\frac{K_f}{\frac{1}{2}m}} = \sqrt{\frac{4eV_{12}}{m}}.$$

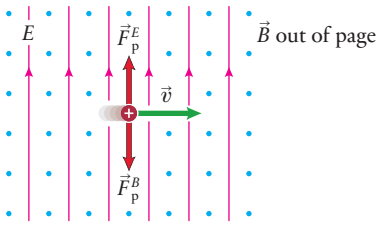
QUANTITATIVE TOOLS

Substituting this speed and the magnitude of the charge q on the oxygen ion into Eq. 27.23, I obtain for the diameter of the ion's circular trajectory

$$2R = \frac{2mv}{|q|B} = \frac{2m}{2eB}\sqrt{\frac{4eV_{12}}{m}} = \frac{2}{B}\sqrt{\frac{mV_{12}}{e}}$$

$$= \frac{2}{0.20\ \text{T}}\sqrt{\frac{16(1.66\times10^{-27}\ \text{kg})(1.0\times10^{4}\ \text{V})}{1.60\times10^{-19}\ \text{C}}}$$

$$= 0.41\ \text{m}.\ \checkmark$$



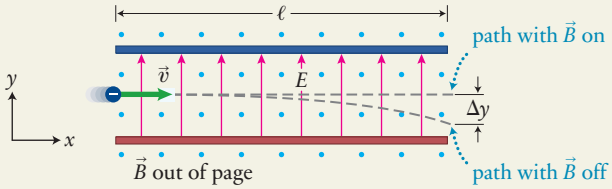
❹ **EVALUATE RESULT** To be measurable in a laboratory, the distance from the point of entry at which the ions hit the detector must be neither too small nor too great. Given these constraints, the distance I obtained appears reasonable.

Let us next consider the trajectory of a charged particle in combined uniform electric and magnetic fields. If the charged particle has a velocity component perpendicular to the magnetic field, it is subject to a magnetic force in addition to an electric force. With an appropriate choice of fields, it is possible for the two forces to add up to zero, leaving the charged particle undisturbed. This arrangement is illustrated in **Figure 27.41**: A positive charged particle moves at right angles to both $\vec{E}$ and $\vec{B}$, which are perpendicular to each other. If the two forces are of equal magnitude, we have $F_{\text{p}}^{B} = F_{\text{p}}^{E}$, and so from Eqs. 27.18 and 23.6 $|q|vB = |q|E$ or

$$v = \frac{E}{B} \quad \text{(electric and magnetic force cancel)}. \tag{27.26}$$

Thus, if we adjust the magnitudes of the electric and magnetic fields so that one charged particle goes through undeflected, then any other charged particle moving at the same velocity also passes through the fields undeflected, *regardless of its mass or charge*. Consequently, the setup shown in Figure 27.41 serves as a *velocity selector*: If charge carriers traveling at different speeds are injected from the left into a region where an electric field and a magnetic field are perpendicular to each other, only those whose speed satisfies Eq. 27.26 make it through without being deviated. Another important application of the cancellation of electric and magnetic forces is discussed in the box "The Hall effect" on page 962.

Figure 27.41 Charged particles whose speed satisfies Eq. 27.26 move in a straight line through magnetic and electric fields that are oriented perpendicular to each other.



27.18 In Figure 27.41, do $\vec{F}_{\text{p}}^{B}$ and $\vec{F}_{\text{p}}^{E}$ still cancel if the charged particle (*a*) carries a negative charge, (*b*) travels in the opposite direction, (*c*) travels at a slight angle to the two fields?

EXAMPLE 27.5 The mass of the electron

Figure 27.42 shows schematically part of the apparatus used in 1897 by J. J. Thomson to determine the charge-to-mass ratio of the electron. A beam of electrons, all moving at the same speed v, enters a region of electric and/or magnetic fields. When an electric field of magnitude 1.0 kV/m and a magnetic field of magnitude 1.2×10^{-4} T are turned on, the electrons go through the device undeflected. When the magnetic field is turned off, the electrons are deflected by 3.2 mm in the negative y direction after traveling the length $\ell = 0.050$ m of the apparatus. Given that the charge of the electron is $-e = -1.60\times10^{-19}$ C, what is the mass of each electron?

Figure 27.42 Example 27.5.

❶ **GETTING STARTED** When the magnetic field is turned on, the electrons travel in a straight line, which means that

(Continued)

QUANTITATIVE TOOLS

the forces exerted by the electric and magnetic fields on the electron cancel and the electrons travel at constant speed in the $+x$ direction. When the magnetic field is turned off, the electrons undergo a constant acceleration in the $-y$ direction due to the electric field while continuing to travel at constant speed in the $+x$ direction. I know from the expression $\vec{a} = (q/m)\vec{E}$ we derived in Section 23.4 that the acceleration of the electrons in the electric field depends on their charge-to-mass ratio. If I can determine this ratio from the electrons' trajectory, I can obtain their mass.

❷ **DEVISE PLAN** Because I know the magnitudes of the electric and magnetic fields that yield a straight trajectory, I can obtain the speed v of the electrons as they enter the apparatus from Eq. 27.26. Because the electrons move in the $+x$ direction, I know that the x component of their velocity is given by $v_x = +v$ (regardless of whether the magnetic field is on or off). When the magnetic field is off, their acceleration in the y direction is given by $a_y = F_y^E/m_e = -eE/m_e$. I can solve this expression for m_e, but I don't know a_y. I do know, however, that I can use kinematics to determine a_y.

❸ **EXECUTE PLAN** Because the electron's initial velocity in the y direction is zero, the amount of deflection is given by $\Delta y = \frac{1}{2}a_y\Delta t^2$, where Δt is the time interval during which the electrons travel in the electric field. This time interval is equal to $\Delta t = \ell/v_x = \ell/v$, so that

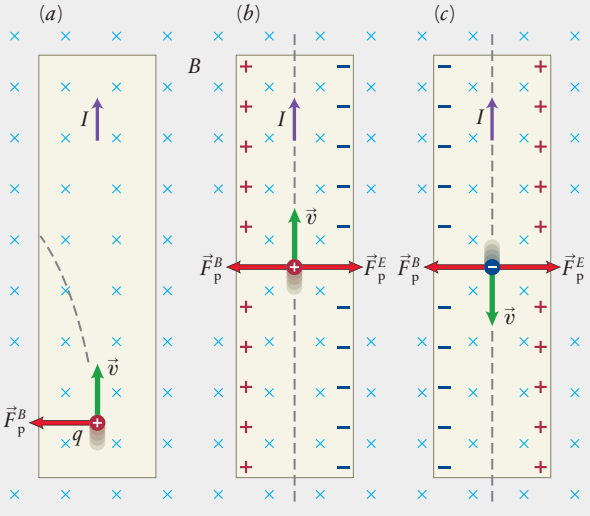
$$a_y = \frac{2\Delta y}{(\Delta t)^2} = \frac{2\Delta y}{(\ell/v)^2} = \frac{2\Delta y\, v^2}{\ell^2} = \frac{2\Delta y(E/B)^2}{\ell^2}, \qquad (1)$$

where I have substituted Eq. 27.26 for the speed v of the electrons. Substituting $a_y = -eE/m_e$ into Eq. 1 and solving for m_e, I get

$$m_e = \frac{-eE}{a_y} = \frac{-e\ell^2B^2}{2\Delta yE}$$

$$= \frac{(-1.60\times10^{-19}\text{ C})(0.050\text{ m})^2(1.2\times10^{-4}\text{ T})^2}{2(-3.2\times10^{-3}\text{ m})(1.0\times10^{3}\text{ V/m})}$$

$$= 9.0\times10^{-31}\text{ kg.}\ \checkmark$$



❹ **EVALUATE RESULT** The value I obtain is close to the published value of the electron mass ($m_e = 9.10938370\times10^{-31}$ kg), giving me confidence in my calculation.

The Hall effect

The canceling of electric and magnetic forces exerted on a charge carrier makes it possible to determine whether the mobile charge carriers in a conductor are positively or negatively charged. This determination is done using a phenomenon called the *Hall effect*.

Consider the rectangular conducting strip carrying an upward current illustrated in **Figure 27.43** (that is, the bottom of the strip is at a higher potential than the top). The strip is placed in a magnetic field directed into the page. If the current is caused by positive charge carriers (Figure 27.43*a*), the carriers move upward and so, according to the right-hand rule, the magnetic force acting on them is to the left. This force deflects the carriers toward the left side of the strip, where they pile up. This accumulation of positive charge carriers on the left causes an electric field to the right across the strip that exerts on the carriers an electric force that pulls them to the right. As more carriers accumulate on the left, the magnitude of this electric force increases until it becomes equal in magnitude to the magnetic force. Once the two forces are equal in magnitude, the carriers are no longer deflected and so no more carriers accumulate on the left. Any subsequent charge carriers travel in a straight line.

Figure 27.43

The accumulation of charge carriers can be determined by measuring the potential difference between the left (L) and right (R) sides of the strip. If, as illustrated in Figure 27.43*b*, positive carriers accumulate on the left, this potential difference is positive:

$$V_{RL} = V_L - V_R > 0.$$

As illustrated in Figure 27.43*c*, however, if the mobile charge carriers causing the current are negatively charged, V_{RL} is *negative*. This is so because an upward current means that negative charge carriers move downward and, as you can verify using the right-hand rule, the magnetic force exerted on these carriers is also to the left. Thus, regardless of

QUANTITATIVE TOOLS

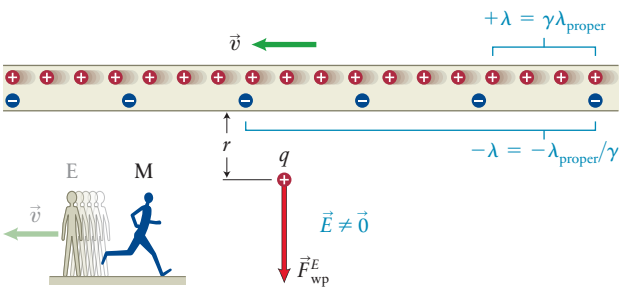
the sign of their charge, the mobile charge carriers pile up on the left. If they are positively charged, V_{RL} is positive; if they are negatively charged, V_{RL} is negative. Experiments on strips of common metals always yield a negative V_{RL}, showing that the mobile charge carriers in these metals are negatively charged, as we stated earlier (see Section 22.3 and Checkpoint 22.15).

27.19 (*a*) Express the magnitude of the electric field inside the strip in Figure 27.43 in terms of the width w of the strip and the potential difference V_{RL}. (*b*) Given the magnitude B of the magnetic field, what is the speed at which the charge carriers travel? (*c*) Show how this information, together with Eq. 27.16, can be used to determine the number density n of the charge carriers.

27.8 Magnetism and electricity unified

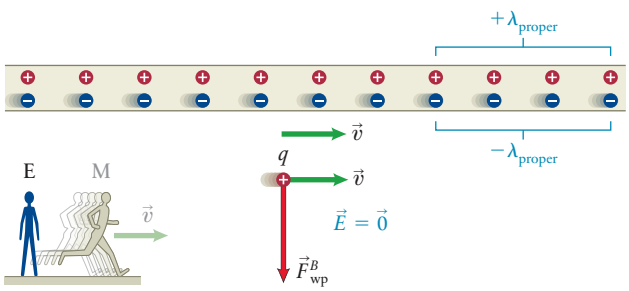
In this section we quantitatively examine the situation discussed in the latter part of Section 27.4—the interaction between a current-carrying wire and a positively charged particle moving parallel to the wire. For simplicity, we again let the charged particle move at the same speed v as the electrons in the wire.* In the Earth reference frame in Figure 27.27 the wire is electrically neutral: The linear charge density of the fixed positively charged ions $\lambda_{proper} > 0$ is equal in magnitude to that of the electrons, $-\lambda_{proper}$. The interaction between the wire and the charged particle is thus purely magnetic.

As we saw in Section 27.4, the wire appears to be positively charged to observer M, who moves along with the electrons. According to M, the average distance between the positively charged ions has decreased by the factor



$$\gamma = \frac{1}{\sqrt{1 - v^2/c_0^2}} \tag{27.27}$$

due to length contraction (Eqs. 14.28 and 14.6; $\gamma > 1$). Thus the charge density of the ions is increased and has a magnitude $\lambda_{M\ ions} = \gamma\lambda_{proper}$ (**Figure 27.44*a***). The electrons, on the other hand, are at rest relative to M and moving relative to E. Therefore the average distance between the electrons according to E must be decreased by the factor γ in Eq. 27.27 relative to the distance observed by M. Because to observer E in the Earth reference frame the wire is electrically neutral, the charge density of the



*In the more general case where the charged particle does not move at the same speed as the electrons in the wire, the algebra becomes more complicated but the conclusions remain the same.

Figure 27.44 A positively charged particle moving parallel to a current-carrying wire, as seen by two observers in motion relative to each other.

(*a*) **Reference frame of electrons in wire (observer M)**

(*b*) **Earth reference frame (observer E)**

electrons in that reference frame must be the negative of that of the ions: $-\lambda_{\text{proper}}$. According to M, therefore, the charge density must be $\lambda_{\text{M electrons}} = -\lambda_{\text{proper}}/\gamma$. Consequently, the combined charge density of the ions and the electrons in the moving reference frame of observer M is

$$\lambda_{\text{M}} = \lambda_{\text{M ions}} + \lambda_{\text{M electrons}} = \gamma\lambda_{\text{proper}} - \frac{\lambda_{\text{proper}}}{\gamma} = \lambda_{\text{proper}}\left(\gamma - \frac{1}{\gamma}\right). \quad (27.28)$$

Because $\gamma > 1$, the term in parentheses is positive, making the combined charge density positive. Using Eq. 14.9 we can rewrite the term in parentheses as

$$\gamma - \frac{1}{\gamma} = \gamma\left(1 - \frac{1}{\gamma^2}\right) = \gamma\,\frac{v^2}{c_0^2}. \quad (27.29)$$

Substituting Eq. 27.29 into Eq. 27.28, we see that according to M the wire has a (nonzero) charge density equal to

$$\lambda_{\text{M}} = \lambda_{\text{proper}}\gamma\,\frac{v^2}{c_0^2}. \quad (27.30)$$

Using the expression $E = 2k\lambda/r$ for the magnitude of the electric field of a charged wire (see Exercise 24.7), we obtain for the magnitude of the electric field at a distance r from the wire according to M

$$E_{\text{M}} = \frac{2k\lambda_{\text{M}}}{r} = \frac{2k\lambda_{\text{proper}}\gamma v^2}{rc_0^2}. \quad (27.31)$$

(Because the distance to the wire is perpendicular to the direction of motion, both observers measure the same distance r and so we need no subscript on r.)

According to observer M, the electric force exerted by the wire on the charged particle therefore has a magnitude

$$F^E_{\text{Mwp}} = |q|E_{\text{M}} = |q|\,\frac{2k\lambda_{\text{proper}}\gamma v^2}{rc_0^2} \quad (27.32)$$

and points perpendicular to and away from the wire.

Now we return to the Earth reference frame, as illustrated in Figure 27.44*b*. In this reference frame, the combined charge density of the ions and electrons is

$$\lambda_{\text{ions}} + \lambda_{\text{electrons}} = \lambda_{\text{proper}} - \lambda_{\text{proper}} = 0, \quad (27.33)$$

and so the electric field outside the wire is zero. Consequently, the force between the wire and the charged particle cannot be due to an electric interaction. We know experimentally, however, that according to observer E the current-carrying wire exerts a *magnetic* force on the particle. The direction of this force is also perpendicular to and away from the wire. Is this magnetic force the same as the electric force seen by M?

To answer this question we first need to determine the relationship between the forces measured by two observers in motion relative to each other. To determine this relationship, we shall use the definition of force given in Eq. 8.4, $\Sigma\vec{F} \equiv d\vec{p}/dt$, where $\Sigma\vec{F} = \vec{F}_{\text{wp}}$. The vector $d\vec{p}$ points in the same direction as the force—perpendicular to the relative velocity of the two frames—and so must be the same for both observers: $d\vec{p} = d\vec{p}_{\text{M}}$. Because of time dilation, however, we have from Eq. 14.13, $dt = \gamma dt_{\text{M}}$,

where dt is the infinitesimal time interval measured by observer E and dt_M is the corresponding time interval measured by observer M (because M moves along with the particle, this is a proper time interval). The magnitude of the force exerted by the wire on the particle measured by observer E is thus

$$F_{wp} = \frac{dp}{dt} = \frac{dp_M}{\gamma dt_M} = \frac{F_{Mwp}}{\gamma}, \tag{27.34}$$

where F_{Mwp} is the magnitude of the force exerted by the wire on the particle measured by observer M. To observer M this force is electric in nature and its magnitude is given by Eq. 27.32. Substituting Eq. 27.32 on the right in Eq. 27.34 thus yields

$$F_{wp} = |q| \frac{2k\lambda_{proper} v^2}{rc_0^2}. \tag{27.35}$$

The quantity $\lambda_{proper} v$ is just the current I because if the electrons advance by a distance d in a time interval Δt, a quantity of charge $|q| = \lambda_{proper} d$ flows through the wire in that time interval. So the rate at which the charge carriers flow is

$$I \equiv \left| \frac{q}{\Delta t} \right| = \lambda_{proper} \frac{d}{\Delta t} = \lambda_{proper} v. \tag{27.36}$$

This result means that we can write Eq. 27.35 as

$$F_{wp} = |q| v \frac{2kI}{rc_0^2}. \tag{27.37}$$

Equation 27.37 gives the magnitude of the force exerted by the current-carrying wire on the particle measured by observer E. The magnitude depends on the current I through the wire, on the speed v and charge q of the particle, and on the distance r between the wire and the particle. Observer E interprets this force as a magnetic force due to the magnetic field caused by the current through the wire. From Eq. 27.18 we see that the magnitude of the magnetic force exerted by the wire on the moving particle is $F^B_{wp} = |q|vB$ (because $\vec{v}$ and $\vec{B}$ are at right angles, $\sin\theta = 1$). Substituting this expression into Eq. 27.37 and dividing both sides by qv, we see that the magnitude of the magnetic field according to observer E is

$$B = \frac{2kI}{rc_0^2} = \frac{2k}{c_0^2} \frac{I}{r}. \tag{27.38}$$

In words, the magnitude B of the magnetic field is proportional to the current I and inversely proportional to the distance r to the wire, with the proportionality constant being $2k/c_0^2$. As we shall see in the next chapter, experiments confirm this dependence. Here we see that Coulomb's law, together with special relativity, *requires* a magnetic field of this form. In other words, electricity and magnetism are two aspects of the same interaction, not two different interactions.

27.20 Explain why the $1/r$ dependence expressed in Eq. 27.38 is consistent with the symmetry of the wire causing the magnetic field.

Chapter Summary

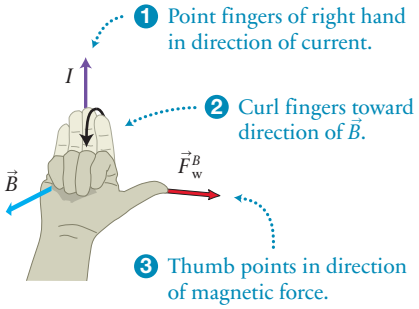
Magnetic field (Sections 27.1, 27.2)

Concepts Every **magnet** has two *magnetic poles*. The pole attracted to Earth's North Pole is called a *north pole;* the magnet's opposite pole is called a *south pole*.

Like magnetic poles repel each other, and opposite magnetic poles attract each other. Earth's North Pole is a magnetic south pole because it attracts the north pole of a compass needle.

Magnetic materials are attracted to both types of magnetic poles. The presence of a magnet induces **magnetic polarization** in magnetic materials.

A magnet is surrounded by a **magnetic field.** This field exerts a force on the poles of other magnets and is represented by **magnetic field lines.** At any position, the direction of the magnetic field is tangent to the magnetic field line passing through that position. Magnetic field lines form loops that exit a magnet at its north pole and reenter the magnet at its south pole. Near (but outside of) a magnet, magnetic field lines point away from north poles and toward south poles. At any location, the magnitude of the magnetic field is proportional to the field line density at that location.



Currents and magnetic fields (Sections 27.3, 27.5)

Concepts A flow of charged particles, called a **current,** causes a magnetic field.

The *direction of current* through a conductor is the direction in which positive charge carriers would flow, which is from high potential to low potential.

Right-hand current rule: If you point the thumb of your right hand in the direction of the current, the fingers curl in the direction of the magnetic field produced by that current.

Right-hand rule for vector product $I\vec{\ell} \times \vec{B}$

Quantitative Tools If a particle carrying charge dq passes a given section of a conductor in a time interval dt, the current I through that section is

$$I \equiv \frac{dq}{dt}. \tag{27.2}$$

We measure current in **amperes** (A), where

$$1\ \text{C} \equiv 1\ \text{A}\cdot\text{s}. \tag{27.3}$$

If a straight wire of length ℓ carrying a current I perpendicular to a uniform magnetic field $\vec{B}$ experiences a force $\vec{F}^B_{w,\,max}$, the magnitude of the magnetic field is

$$B \equiv \frac{F^B_{w,\,max}}{|I|\,\ell}. \tag{27.5}$$

The SI unit of the magnetic field is the **tesla** (T), where

$$1\ \text{T} \equiv 1\ \text{N}/(\text{A}\cdot\text{m}) = 1\ \text{kg}/(\text{s}^2\cdot\text{A}). \tag{27.6}$$

The **magnetic force** $\vec{F}^B_w$ exerted on a straight wire in a uniform magnetic field is

$$\vec{F}^B_w = I\vec{\ell} \times \vec{B}, \tag{27.8}$$

where the direction of $\vec{\ell}$ is the direction of the current through the wire. The direction of $\vec{F}^B_w$ is obtained by curling the fingers of the right hand from the direction of the current to $\vec{B}$.

Table 27.1 Right-hand rules in magnetism

	Thumb points in direction of	Fingers curl
Current rule	Current	Along magnetic field
Force rule	Magnetic force	From current to magnetic field

It is sometimes helpful to write out Eq. 27.8 component by component:

$$F^B_{wx} = I\ell_y B_z - I\ell_z B_y$$
$$F^B_{wy} = I\ell_z B_x - I\ell_x B_z$$
$$F^B_{wz} = I\ell_x B_y - I\ell_y B_x.$$

Magnetic flux (Section 27.6)

Concepts The **magnetic flux** through a surface is a measure of the number of magnetic field lines crossing the surface. The magnetic flux through any closed surface is zero because magnetic field lines always form closed loops.

Quantitative Tools The **magnetic flux** Φ_B through a surface is

$$\Phi_B \equiv \int \vec{B} \cdot d\vec{A}, \tag{27.10}$$

where the integral is taken over the surface.

Magnetic flux is measured in **webers** (Wb), where

$$1\ \text{Wb} \equiv 1\ \text{T} \cdot \text{m}^2 = 1\ \text{m}^2 \cdot \text{kg}/(\text{s}^2 \cdot \text{A}).$$

For any closed surface, **Gauss's law for magnetism** is

$$\Phi_B = \oint \vec{B} \cdot d\vec{A} = 0. \tag{27.11}$$

Forces exerted on moving particles (Section 27.7)

Quantitative Tools If a charged particle of charge q moves with velocity $\vec{v}$ in the presence of an electric field and a magnetic field, the **electromagnetic force** $\vec{F}^{EB}_p$ exerted on the particle by the fields is

$$\vec{F}^{EB}_p = q(\vec{E} + \vec{v} \times \vec{B}). \tag{27.20}$$

It is sometimes helpful to write out Eq. 27.20 component by component:

$$F^{EB}_{px} = q(E_x + v_y B_z - v_z B_y), \quad F^{EB}_{py} = q(E_y + v_z B_x - v_x B_z),$$
$$F^{EB}_{pz} = q(E_z + v_x B_y - v_y B_x).$$

A charged particle of charge q and mass m moving at speed v perpendicular to a uniform magnetic field $\vec{B}$ follows a circular path of radius R given by

$$R = \frac{mv}{|q|B}. \tag{27.23}$$

The time interval T for one revolution is

$$T = \frac{2\pi m}{|q|B}, \tag{27.24}$$

and the angular frequency ω is

$$\omega = \frac{|q|B}{m}. \tag{27.25}$$

Magnetism and electricity unified (Sections 27.4, 27.8)

Concepts The interaction observed between charge carriers depends on their motion relative to the observer: The interaction can be purely electric, purely magnetic, or a combination of the two. Magnetic and electric interactions are two aspects of one *electromagnetic* interaction, with magnetism being a relativistic correction to the electric interaction.

Questions and Problems

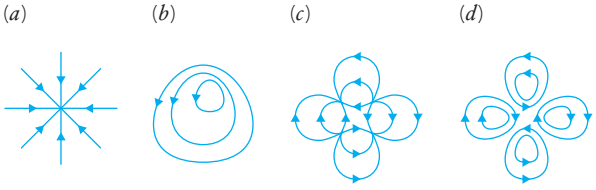
For instructor-assigned homework, go to Mastering Physics

Dots indicate difficulty level of problems: • = *easy*, •• = *intermediate*, ••• = *hard*; CR = *context-rich problem.*

27.1 Magnetism

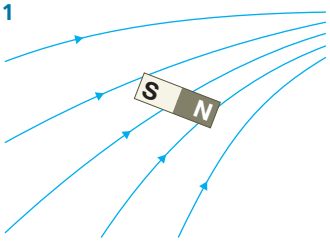
1. Which way does the north pole of a compass needle point in the Southern Hemisphere? •
2. You place two magnets side by side but, instead of attracting, the magnets repel each other. Provide a possible explanation of your observation. •
3. How are the elementary magnets aligned in the magnet in Figure P27.3? •

Figure P27.3



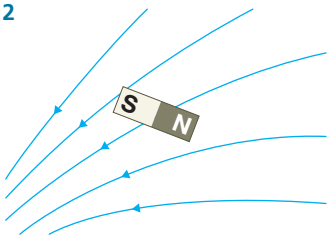
4. Is it possible to separate the north pole from the south pole of a bar magnet by cutting it in half? Explain your reasoning. •
5. You are given three bars of metal. Two of them are magnets, and the third is made of a magnetic material but is not magnetized. Describe how, using only the three bars, you could determine which of them is not a magnet. ••
6. You are given two metal rods. One is a magnet, and the other is made of magnetic material but does not have the elementary magnets aligned. Using no other objects, how can you determine which is the magnet? ••
7. Sketch and describe the magnetic poles of a spherical piece of uniformly magnetized material. •••

27.2 Magnetic fields



8. Which field line patterns in Figure P27.8 can represent a magnetic field? •

Figure P27.8



9. A bar magnet is enclosed by a spherical surface. (*a*) What is the magnetic flux through the entire surface? (*b*) If the magnetic flux through the hemisphere closest to the magnet's north pole is positive, is the flux through the hemisphere closest to the magnet's south pole positive, negative, or zero? (*c*) The magnet is now moved so that its north half is outside the surface. What is the flux through the entire surface now? (*d*) The portion of the magnet outside the surface is sawed off. What is the flux through the surface now? •
10. Is the field line pattern created by a magnetic dipole the same as the field line pattern created by an electric dipole? Draw both field line patterns. ••
11. Describe what happens to a bar magnet placed in the nonuniform external magnetic field shown in Figure P27.11. ••

Figure P27.11

12. Describe what happens to a bar magnet placed in the nonuniform external magnetic field shown in Figure P27.12. ••

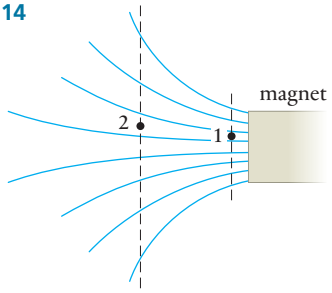


Figure P27.12

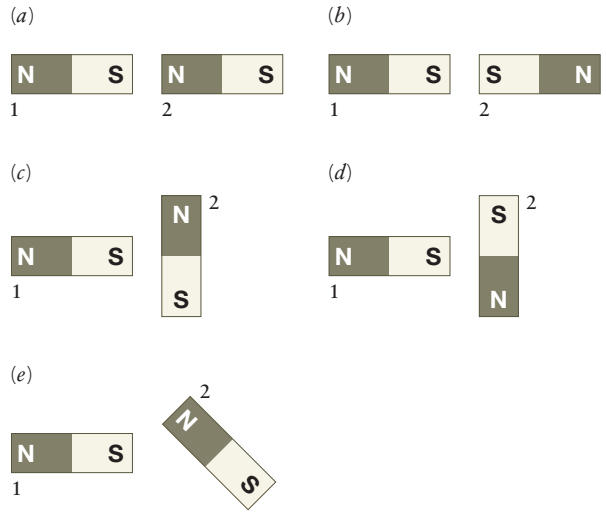
13. How can the direction of the magnetic field at a certain point along a curved field be determined? •



14. Estimate the magnitude of the magnetic field at location 2 in Figure P27.14 if the magnetic field magnitude at location 1 is 0.27 T. Note that real magnetic field lines spread out in three dimensions. The spreading is shown in only two dimensions here, but you must imagine that the spreading also occurs into and out of the page. ●●

Figure P27.14

15. Rank the magnet pairs in Figure P27.15 in order of the magnitude of torque on magnet 2, smallest torque first. Assume all the magnets are equal in strength and the spacing between magnets is comparable in all pairs. ●●●

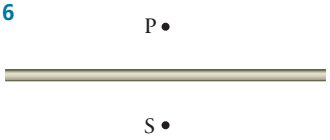


Figure P27.15

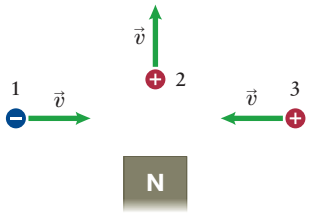
27.3 Charge flow and magnetism

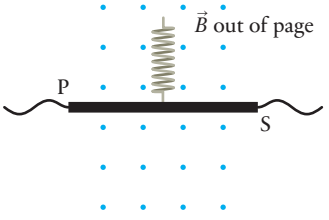
16. The long, straight current-carrying wire of Figure P27.16 lies in the plane of the page, and the magnetic field it produces at position P points out of the page. (*a*) In what direction does the magnetic field point at position S? (*b*) What is the current direction in the wire? ●

Figure P27.16



17. Figure P27.17 shows a long, straight current-carrying wire running perpendicular to the plane of the page. The current produces a magnetic field that points to the right at position P. (*a*) In what direction does the magnetic field point at position S? (*b*) What is the current direction in the wire? ●

Figure P27.17



18. Figure P27.18 shows three particles passing near the north end of a bar magnet. Particle 1 is an electron, and particles 2 and 3 are protons. All three particles move at the same speed. (*a*) Determine the direction of the magnetic force exerted on each particle as it passes over the magnet. (*b*) What is the direction of the force (if any) exerted by each particle on the magnet? ●

Figure P27.18

19. Figure P27.19 shows a conducting rod suspended from a spring in a region where a uniform magnetic field points horizontally out of the page. The rod can be supplied with current by two thin wires connecting its ends to the terminals of a battery (not shown). (*a*) Does the tension in the spring depend on whether or not the wires are connected to the battery? (*b*) Does the tension depend on which wire is connected to which battery terminal? If so, which wire should be connected to the positive terminal in order to increase the tension in the spring? ●●

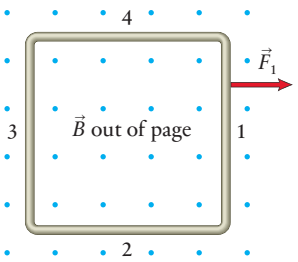


Figure P27.19

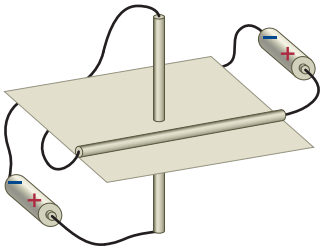
20. A wire is coiled in the shape of a helical spring with closely spaced turns. (*a*) When current is passed through it, does the coil tend to lengthen, shorten, or stay the same length? (*b*) Does your answer depend on the current direction? ●●



21. The square loop of wire in Figure P27.21 carries a current, and an external magnetic field is directed out of the page everywhere. If the magnetic force exerted on side 1 is to the right, determine (*a*) the direction of the current in the loop and (*b*) the directions of the magnetic forces exerted on sides 2, 3, and 4. ●●

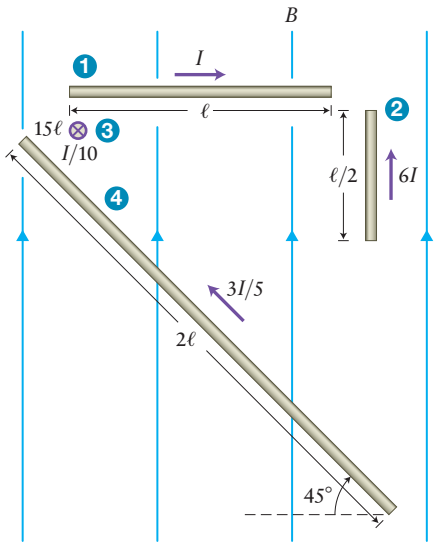
Figure P27.22

27.4 Magnetism and relativity

23. If two charged particles M and S are at rest relative to each other, there is no magnetic force between them. Suppose instead that particle M is moving relative to particle S while S is at rest in the Earth reference frame. Is a magnetic force exerted on S? ●

24. A positively charged particle is at rest on the positive z axis in reference frame S. Reference frame S′ is moving along the positive x axis of S, reference frame S″ is moving along the negative x axis, and reference frame S‴ is moving along the y axis, all with speed v relative to S. The axes of all the reference frames are oriented the same way, and their origins coincide at instant $t = 0$, when observers in each reference frame make measurements. In which reference frames do observers measure an electric field? ●

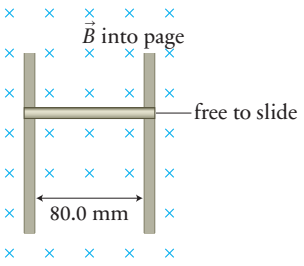
25. Write expressions for the magnitudes and directions of the electric fields measured in Problem 24. ●●



26. Compare the magnitudes and directions of the magnetic fields measured in Problem 24. ●●

27.5 Current and magnetism

27. A 0.40-m wire carries a current of 1.7 A and is at an angle to a 0.20-T uniform external magnetic field. What must be the angle between the wire and the magnetic field so that the field exerts a force of 0.068 N on the wire? ●●

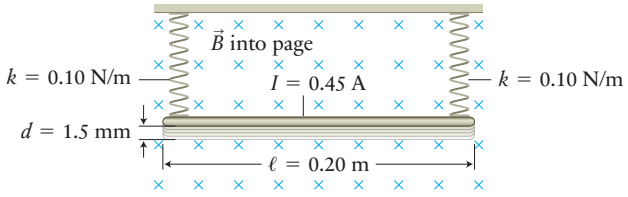


28. In Figure P27.28, an external magnetic field is directed upward throughout a region that contains four current-carrying wires having the lengths and currents shown. Rank the wires according to the magnitude of the magnetic force exerted on them by the external field, smallest force first. Ignore any interactions between the wires. ●

Figure P27.28

29. Two vertical parallel rails made of material that is an electrical conductor are 80.0 mm apart (Figure P27.29). A wire 80.0 mm long is free to slide along the rails, which allow a current to be maintained through the wire as it slides. An external magnetic field of magnitude 0.250 T is directed into the page in Figure P27.29. If the mass of the wire is 4.00 g, what are the current and current direction in the wire if the wire doesn't fall under gravity? ●●

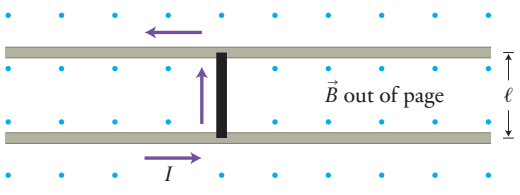
Figure P27.29



30. A current-carrying wire is bent into a circular loop of radius R and lies in an xy plane. A uniform external magnetic field in the $+z$ direction exists throughout the plane of the loop. What is the magnetic force exerted by the external field on the loop? ●●

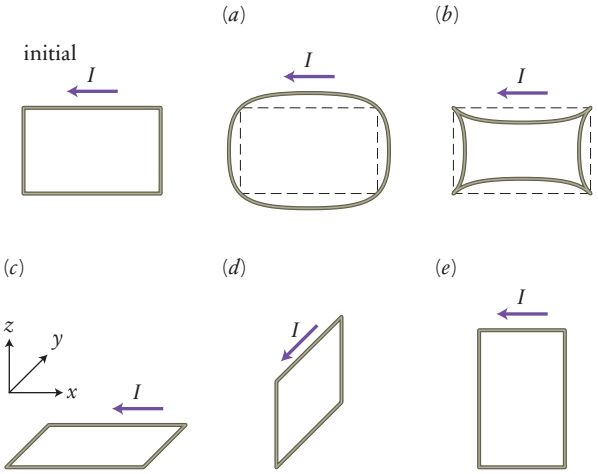
31. Draw an xyz coordinate system with the x axis pointing horizontally to the right, the y axis pointing up the page, and the z axis pointing out of the page. Show a current-carrying wire lying on the x axis, and a 2.5-A current through the wire directed in the positive x direction. (*a*) If the charge carriers are only electrons, how many of them pass through a cross-sectional area of the wire each second? (*b*) In which direction are the electrons moving? (*c*) If this wire is in a 0.20-T external magnetic field directed into the page, what is the force magnitude per unit length exerted by the external field on the wire? (*d*) On your diagram, show the direction of the magnetic field and the direction of the force exerted by the external field on the wire. ●●

32. A square loop of side $a = 50$ cm is suspended from the left arm of a scale, which is kept at equilibrium by adding weights to the right side. The lower half of the loop is in a uniform magnetic field of magnitude 0.4 T, orthogonal to the surface of the loop, but the upper half is outside the magnetic field. (*a*) It is observed that when a current I flows in the loop, one needs to add 25 g to the right arm to bring the scale back to equilibrium. Find the current flowing in the loop. (*b*) If the direction of current were now to be reversed, what would need to be done to bring the scale back to equilibrium? ●●



33. Figure P27.33 shows the arrangement we looked at in Example 27.2: a metal bar 0.20 m long suspended from two springs, each having a spring constant $k = 0.10$ N/m. Initially there is no current through the bar, and it is suspended at rest below the ceiling. With a current of 0.45 A, the bar rises a distance $d = 1.5$ mm. Suppose that the current is turned off, the bar drops down to its original position, and we attach a 5.0-mg piece of plastic to the center of the bar. Now how much current must there be through the bar to make it rise a distance $d = 1.5$ mm? ●●

Figure P27.33



34. Two horizontal parallel conducting rods are connected such that a conducting crossbar free to slide along them has a constant current I running through it (Figure P27.34). The rods are separated by a distance ℓ and are in an external uniform magnetic field of magnitude B directed out of the page. The crossbar has a length ℓ and mass m. (*a*) In which direction does the crossbar move? (*b*) If there is a coefficient of static friction μ_s between rods and crossbar, what is the minimum current I_0 necessary for the crossbar to move? ●●

Figure P27.34

35. The top left portion of Figure P27.35 shows a current-carrying wire shaped into a rectangular loop that is very flexible. The loop is mounted on a base (not shown) that allows it to spin in any direction, and in this way any forces that cause the loop to move, spin, or distort can be detected. If the current direction through the loop is counterclockwise as indicated, what magnetic field direction(s) could cause the shape and orientation changes shown in parts (*a*)–(*e*) of Figure P27.35? If no magnetic field is necessary to make a shown change, write "none." If there is no way a magnetic field could cause a shown change, write "not possible." ●●

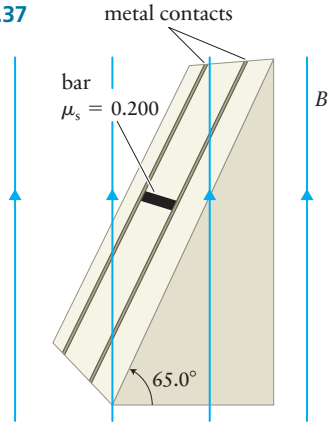


Figure P27.35

36. An arbitrary-shaped tangle of wire is connected such that it carries a current I_0 from position $\vec{r}_1$ to position $\vec{r}_2$ in a region where there is an external uniform magnetic field $\vec{B}_0$. Show that the magnetic force exerted by the external field on the wire is given by $\vec{F}_w^B = I_0(\vec{r}_2 - \vec{r}_1) \times \vec{B}_0$. ●●●

37. A 1.00-m metal bar that has a mass of 0.900 kg is initially pinned in place on an incline 65.0° above the horizontal (Figure P27.37). There is a 0.850-T magnetic field directed upward in the region around the bar, and metal contacts along the incline allow a current through the bar. If the coefficient of static friction between bar and contacts is 0.200, (*a*) what are the minimum magnitude and the direction of the current that must pass through the bar to keep it from moving once it is released? (*b*) Is there a maximum current that can be used in that same direction that will also hold the bar in place? ●●●

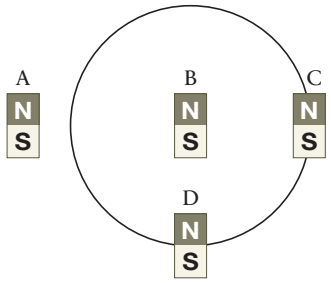

Figure P27.37

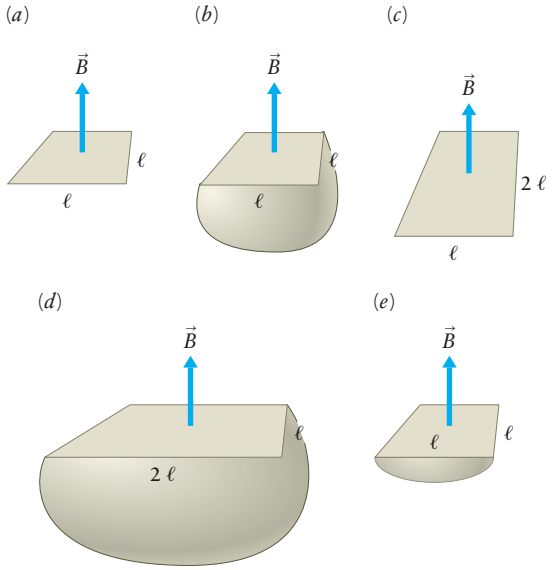
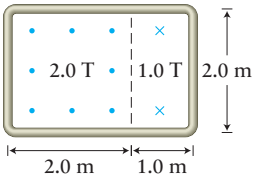
27.6 Magnetic flux



38. Figure P27.38 shows a bar magnet placed at four positions on and near a spherical shell. Rank the positions according to the amount of magnetic flux through the shell, smallest flux first. •

Figure P27.38

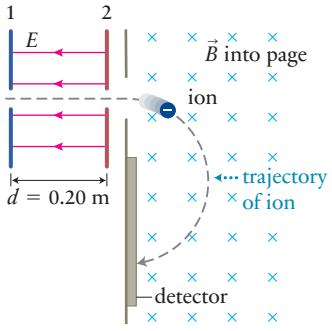


39. Figure P27.39 shows five objects, all placed in the same uniform, upward-directed external magnetic field. Rank the objects according to the amount of magnetic flux through them, smallest flux first. •

Figure P27.39

40. A square loop of side length 1 m is placed on a wooden table in a uniform magnetic field of magnitude 0.5 T. The greatest magnetic flux through the loop is measured when the loop is flat on the table. (*a*) What is the direction of the magnetic field? (*b*) What is the flux through the loop when it is tilted such that the plane of the loop makes an angle of 30° with the table? ••
41. A circular loop of diameter 150 mm is placed on a wooden table that makes angle of 24.5° with a uniform magnetic field. What must be the magnitude of the magnetic field if the magnetic flux through the loop is $4.20 \times 10^{-4}\ \text{T} \cdot \text{m}^2$? ••
42. A square loop of wire has a perimeter of 60 cm and is oriented such that two of its parallel sides form a 30° angle with the horizontal. A uniform horizontal magnetic field of magnitude 0.2 T passes through the loop. (*a*) Calculate the magnetic flux through the loop. (*b*) Another loop lies in the same plane but has an irregular shape resembling that of a starfish. Its area equals that of the square loop. Calculate the flux through this loop. ••
43. The loop of Figure P27.43 is partially in a region where there is a 2.0-T magnetic field pointing out of the page and partially in a region where there is a 1.0-T magnetic field pointing into the page. Calculate the magnetic flux through the loop. ••

Figure P27.43



44. A hemispherical bowl of radius R is placed in a uniform magnetic field that has magnitude B_0 and is in the positive z direction. The open top of the bowl is in the xy plane. Obtain an expression for the magnetic flux through the hemispherical surface of the bowl. ••

27.7 Moving particles in electric and magnetic fields

45. Can a charged particle move in a region of uniform magnetic field without experiencing an external force? If yes, how? If no, why not? •
46. Figure P27.46 shows the semicircular path through which charged particles travel in the magnetic field of a

Figure P27.46

mass spectrometer. If the particles are oxygen ions carrying a charge of $-2e$ and the magnetic field magnitude is 0.20 T, how long does it take each ion to travel the semicircular path through the magnetic field? The mass of an O^{2-} ion is 2.6×10^{-26} kg. •

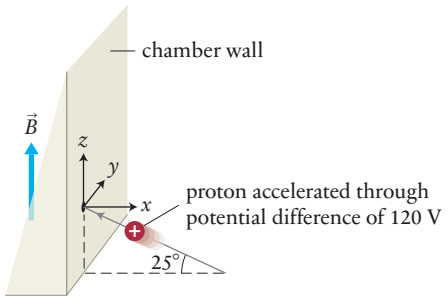
47. An electron is moving at speed 7.0×10^{10} m/s perpendicular to a uniform magnetic field of magnitude 0.80 T. (*a*) What is the diameter of the circular path that the electron follows? Calculate the electron's (*b*) angular frequency and (*c*) period of motion. •••

48. An alpha particle ($m = 6.64 \times 10^{-27}$ kg), which has twice the charge and approximately four times the mass of a proton, moves in a circular orbit 100 mm in diameter that is perpendicular to a uniform 0.75-T magnetic field. Calculate the alpha particle's (*a*) angular frequency and period of motion, (*b*) speed, and (*c*) kinetic energy. •••

49. An electron that has been accelerated through a 100-V potential difference moves in a circular orbit perpendicular to a uniform magnetic field of magnitude 0.4 T. For this electron, determine (*a*) its speed, (*b*) its angular frequency and period of motion, and (*c*) the radius of its orbit. ••

50. A deuteron is a charged particle that has the same charge as a proton but approximately twice the mass. An alpha particle has twice the charge and approximately four times the mass of a proton. For this problem, assume the mass ratios are exactly 2 and 4. If a proton, a deuteron, and an alpha particle move in a uniform magnetic field in circles having the same radii, compare their (*a*) speeds, (*b*) kinetic energies, and (*c*) angular momentum magnitudes. ••

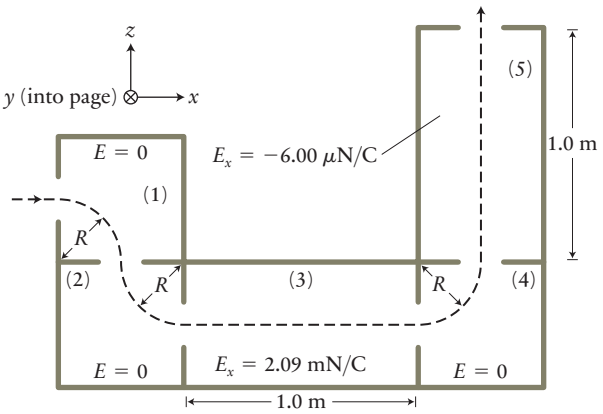
51. The isotopes magnesium-24 (mass 3.983×10^{-26} kg) and magnesium-26 (mass 4.315×10^{-26} kg) are to be separated using a mass spectrometer in which the magnetic field magnitude is 0.4 T. The ions used are the ones that have lost one electron each, $^{24}Mg^{+}$ and $^{26}Mg^{+}$. The resolution of your detector screen is 3 mm. What is the minimum value of the potential difference through which these ions must be accelerated to see them distinctly on the detector screen? ••



52. A particle that has mass m and charge q enters a uniform magnetic field of magnitude B. The initial velocity v of the particle forms an angle of 30° with the magnetic field. After some time t, the velocity of the particle has the same magnitude and direction that it had initially. What is the distance d traveled by the particle over this time period? ••

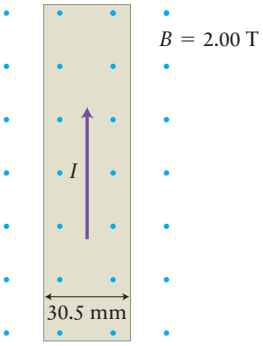
53. A horizontal metal strip 1.0 mm thick and 10 mm wide carries a 12-A current along its length, and both the length and the width are perpendicular to a uniform magnetic field of magnitude 1.0 T that is directed vertically up. The potential difference across the strip width is 3 μV. (*a*) If the side of the strip width that is to your left as you look in the direction of the current is at the higher potential, what is the sign of the mobile charge carriers? What is (*b*) the speed and (*c*) the number density of the charge carriers? ••

54. The cross section of a copper strip is 1.0 mm thick and 20 mm wide. There is a 10-A current through this cross section, with the charge carriers traveling down the length of the strip. The strip is placed in a uniform magnetic field that has a magnitude of 2.0 T and is directed perpendicular to both the length and the width of the strip. If the number density of free electrons in copper is 8.47×10^{19} mm^{-3}, calculate (*a*) the speed of the electrons in the strip and (*b*) the potential difference across the strip width. ••



55. A proton is accelerated through a potential difference of 120 V, as shown in Figure P27.55, and fired into a chamber. There is no electric field in the chamber, but there is a 0.15-T magnetic field in the positive z direction. The proton enters the chamber at a 25° angle above the horizontal, and this entry location is the origin of the xyz coordinate system. Determine the coordinates of the location at which the proton will later strike this same wall from the inside. ••

Figure P27.55



56. A beam of protons enters the network of five chambers shown in Figure P27.56 with an initial speed of 300 m/s and moves through the network along the path indicated by the dashed black line. In each chamber, the electric field is as specified, and the radius of curvature R is 0.40 m wherever it is shown. For each chamber, calculate the component of the magnetic field perpendicular to the path of the protons. •••

Figure P27.56

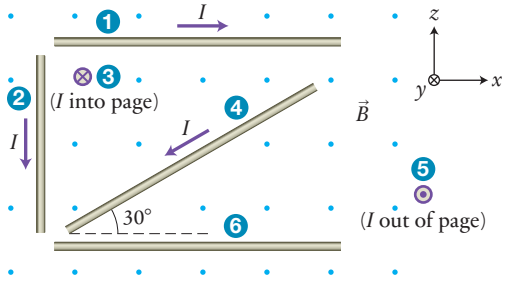
57. Electrons are made to flow through the copper strip of Figure P27.57. The strip's cross section is 1.00 mm high and 30.5 mm wide, and the strip is placed in a 2.00-T magnetic field that is directed out of the page. If the number of mobile electrons per unit volume in the copper is 8.46×10^{28} m^{-3} and the current in the strip is 12 A, calculate the potential difference across the width of the strip when conditions have been allowed to equilibrate. •••

Figure P27.57

27.8 Magnetism and electricity unified

58. On average, the number density of free electrons in copper is 8.46×10^{19} mm^{-3}. (*a*) Calculate what the linear charge density λ for a copper wire 1.00 mm in radius would be if this quantity of electrons were missing. (*b*) Assume this copper wire is electrically neutral in the Earth reference frame, in which it is at rest and carrying a current. Calculate the linear charge density λ' of the copper wire in a reference frame moving along with the electrons if the electrons are moving at 4.70×10^{-4} m/s. ••

59. A square loop of wire 1.00 m on a side is at rest and has a linear charge density of zero in the Earth reference frame. The loop lies in the *xy* plane of an *xyz* coordinate system, and there is a clockwise electric current through the loop as seen by a person looking down the positive *z* axis to the *xy* plane. The electrons move at speed *v*, and an observer M, moving at this same speed *v*, approaches the loop along the *y* axis (moving in the positive *y* direction). In which side(s) of the loop ($+x$, $+y$, $-x$, $-y$) does M see the linear charge density as being due (*a*) to surplus positive charge carriers and (*b*) to surplus negative charge carriers? ••



60. Suppose electrons move through a copper wire at speed *v*. Call the linear charge densities in the Earth reference frame λ_{Ep} for the fixed positive ions in the wire and λ_{En} for the (negative) electrons. Observer E in the Earth reference frame (which is also the reference frame of the positive ions) measures the wire to be electrically neutral. Observer M is moving along with the electrons (in the same direction as the electrons and at speed *v*). Calculate the linear charge density of the wire as measured by M in terms of λ_{En} if the speed is (*a*) 3.0×10^5 m/s and (*b*) 3.0 mm/s (an achievable speed for electrons in copper wire). ••

61. A long wire that is at rest in the Earth reference frame initially carries no current. Observer E in this reference frame measures linear charge densities of $\lambda_{En} = 45.00\ \mu$C/m for the (negative) electrons in the wire and $\lambda_{Ep} = 60.00\ \mu$C/m for the positive ions. A current is created as electrons are made to move through the wire at speed *v*, and observer M moves along with the electrons at their speed *v*. What value must *v* have in order for M to measure an electric field of magnitude $E = 3.00 \times 10^7$ N/C at a distance 0.0100 m above the wire? •••

Additional Problems

62. In Figure P27.62, an external magnetic field is directed out of the page, and six wires are placed, one at a time, in this field. Each wire carries a current in the direction indicated; if there is no indicated direction, the current is zero. Determine the direction of the magnetic force exerted by the magnetic field on each wire. •

Figure P27.62

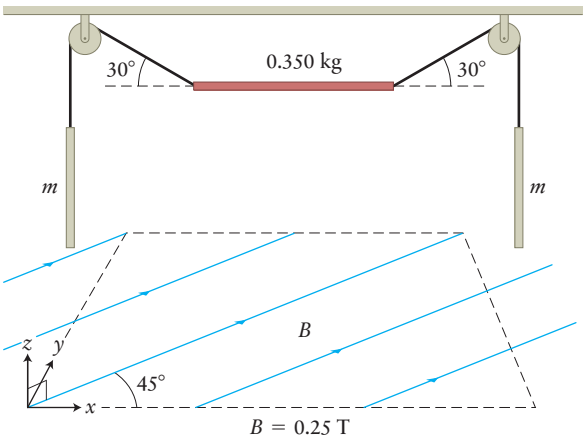
63. Three charged particles initially have identical masses, charges, and speeds and are traveling perpendicular to the same magnetic field. Because they are all in the same magnetic field and have identical masses and charges, all particles have the same initial cyclotron frequency and revolve with the same period *T*. The speed of particle 1 is doubled; particle 2 enters a region in which the magnetic field has been reduced by a factor of 2; and particle 3 collides with and sticks to a neutral particle of the same mass, causing a change in speed. Determine the new period of each particle in terms of the initial period *T*. •

64. At the equator, the direction of Earth's magnetic field is horizontal and to the north, and the magnitude is 3.5×10^{-5} T. (*a*) What is the magnetic flux through a circular loop of radius 0.10 m, lying flat on the ground at the equator? The loop is now balanced on its edge and the axis that runs perpendicular to the plane of the loop is pointed in different directions. What is the magnetic flux through the loop when this axis is pointed (*b*) northwest, (*c*) due north, and (*d*) west? •

65. When a wire 2.0 m long carries a 10-A current in the $+x$ direction in a uniform external magnetic field, the magnetic force exerted by the field on the wire is 3 N

in the $+y$ direction. When the wire is rotated until the charge carriers travel in the $+y$ direction, the magnitude of the magnetic force exerted by the field on the wire is 5 N. What are the magnitude and direction of the magnetic field? ••

66. Blood contains both positive and negative ions. In a certain patient being tested, the speed of these ions in a large artery is measured at 0.60 m/s. The patient is placed in a uniform magnetic field of magnitude 0.20 T. If a potential difference of 1.0×10^{-3} V is measured across the diameter of the artery, what is that diameter? ••



67. Electrons enter a region of perpendicular electric and magnetic fields (similar to Example 27.5). The region occupied by the fields is 40.0 mm long in the x direction, where x is taken to be the original direction of motion. After passing through this region, the electrons then travel an additional 300 mm in the x direction before hitting a phosphorescent screen that lights up where the electrons strike it. The electrons pass undeflected through the region of perpendicular fields when $E = 2.0 \times 10^3$ N/C and $B = 1.2 \times 10^{-5}$ T. (*a*) Determine the speed of the undeflected electrons. (*b*) If the magnetic field is turned off but the electric field is left on, by what distance have the electrons been deflected when they reach the phosphorescent screen? ••

68. A positively charged particle of mass m and charge $+q$ moves in a circle of radius r in a uniform magnetic field of magnitude B. How does the radius of the particle's motion change when (*a*) the magnitude of the magnetic field is reduced into half, (*b*) the mass of the charge is doubled, and (*c*) the sign of the charge is changed to negative? ••

69. You are designing magnetic motors. A colleague insists that like magnetic poles attract—north poles attract north poles and south poles attract south poles. You feel the need to remove this idea from his head. You possess three unlabeled bar magnets. How can you use them to convince him? ••• CR

70. Figure P27.70 shows a 1.0-m, 0.350-kg horizontal metal rod attached to two ropes, each of which makes an angle of 30° with the horizontal. Each rope then drapes over a pulley and is attached to a vertical rod of mass m. Assume the pulleys have negligible mass. There is a 0.25-T magnetic field in the region of the rod, parallel to the xy plane, oriented 45° from the long axis of the horizontal rod. When the horizontal rod is made to carry a current I, suddenly the rod moves upward until the ropes holding it make an angle of 5.0° with the horizontal. What was the value of I? •••

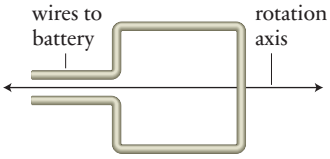


Figure P27.70

71. A wire bent into a semicircle of radius R lies in a plane that is perpendicular to a uniform external magnetic field $\vec{B}$. If the wire carries a current I, what are the magnitude and direction of the magnetic force exerted by the external field on the wire? •••

72. You are working with the square wire loop shown in Figure P27.72. The loop lies in a magnetic field, is connected to a battery, and is attached to an axis that runs through its center and is parallel to the plane of the loop. Initially the loop is held in place, but once it is released, it immediately rotates 180° about this axis. You know that magnetic fields can induce a torque on a current-carrying wire, but you are surprised by the rotation of exactly 180°. In an attempt to explain why this happened, you determine the direction of the current in the loop and the direction of the magnetic field in the region of the loop. Are multiple answers possible? Is there any way to keep the loop rotating in the same direction? ••• CR

28.7 Magnetic fields due to currents
28.8 Magnetic field of a moving charged particle

In this chapter we investigate further the relationship between the motion of charged particles and the occurrence of magnetic fields. As we shall see, *all* magnetism is due to charged particles in motion—whether moving along a straight line or spinning about an axis. It takes a moving or spinning charged particle to create a magnetic field, and it a takes another moving or spinning charged particle to "feel" that magnetic field. We shall also discuss various methods for creating magnetic fields, which have wide-ranging applications in electromechanical machines and instruments.

28.1 Source of the magnetic field

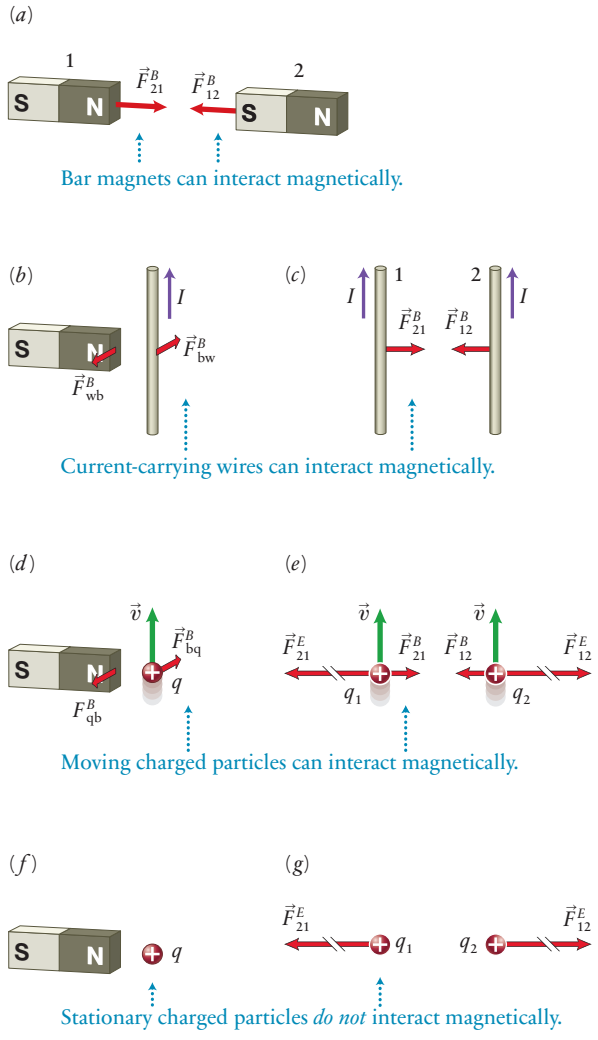
As we saw in Chapter 27, magnetic interactions take place between magnets, current-carrying wires, and moving charged particles. **Figure 28.1** summarizes the interactions we have encountered so far. Figures 28.1*a–c* show the interactions between magnets and current-carrying wires. The sideways interaction between a magnet and a current-carrying wire (Figure 28.1*b*) is unlike any other interaction we have encountered. The forces between the wire and the magnet are not central; they do not point directly from one object to the other. As we saw in Section 27.7, the magnetic force exerted on a current-carrying wire is the sum of the magnetic forces exerted on many individual moving charge carriers. Similarly the magnetic field due to a current-carrying wire is the sum of the magnetic fields of many individual moving charge carriers. Figures 28.1*d* and *e* illustrate the magnetic interactions of moving charged particles. Note that for two charged particles moving parallel to each other (Figure 28.1*e*), there is, in addition to an attractive magnetic force, a (much greater) repulsive electric force.

It is important to note that the magnetic interaction depends on the state of motion of the charged particles. No magnetic interaction occurs between a bar magnet and a stationary charged particle (Figure 28.1*f*) or between two stationary charged particles (Figure 28.1*g*). These observations suggest that the motion of charged particles might be the origin of *all* magnetism. There are two problems with this assumption, however. First, the magnetic field of a wire carrying a constant current looks very different from that of a bar magnet. (Compare Figures 27.13 and 27.19.) Second, there is no obvious motion of charged particles in a piece of magnetic material.

Figure 28.2*a* shows the magnetic field line pattern of a straight wire carrying a constant current. The lines form circles centered on the wire, circles that reflect the cylindrical symmetry of the wire (the symmetry of an infinite cylinder, see Section 24.4). The horizontal distance between adjacent circles is smaller near the wire, where the magnitude of the field is greater.

A single moving charged particle does not have cylindrical symmetry because, unlike for an infinitely long straight wire, moving the particle up or down along its line of motion changes the physical situation. Because of the *circular* symmetry of the situation, the field still forms

Figure 28.1 Summary of magnetic interactions. Notice that stationary charged particles do not engage in magnetic interactions.



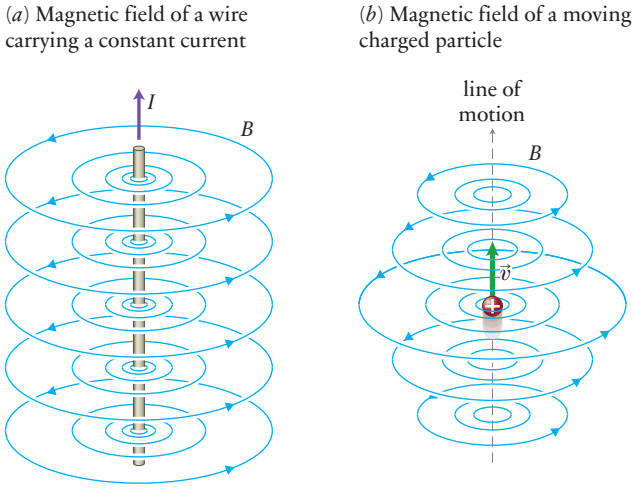


Figure 28.2 Comparing the magnetic fields of a current-carrying wire and a moving charged particle.

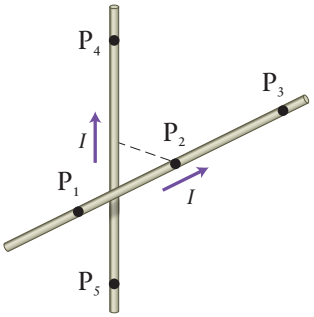


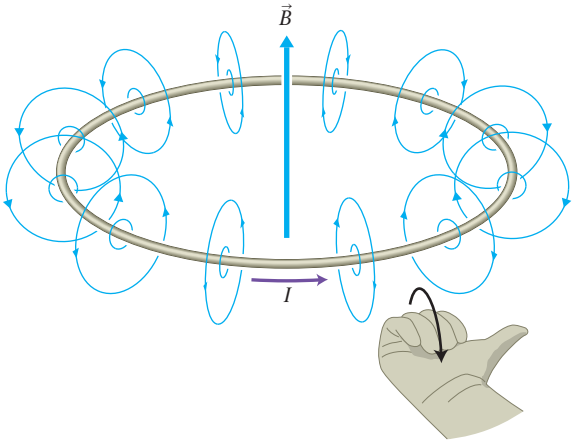
CONCEPTS

circles around the line of motion, but the magnitude of the field at a fixed distance from the particle's line of motion decreases if one moves away from the particle (Figure 28.2*b*). It is not at all obvious how the field pattern shown in Figure 28.2*b* could give rise to the magnetic field of a bar magnet; there are certainly no poles in the magnetic field of the moving charged particle.

28.1 Make a sketch showing the directions of the magnetic forces exerted on each other by (*a*) an electron moving in the same direction as the current through a wire, (*b*) a moving charged particle and a stationary charged particle, and (*c*) two current-carrying wires at a right angle to each other as illustrated in **Figure 28.3**. (Hint: Determine the forces exerted at points P_1 through P_5.)

Figure 28.3 Checkpoint 28.1*c*.

28.2 Current loops and spin magnetism



The circular pattern of magnetic field lines around a wire carrying a constant current suggests a method for generating a strong magnetic field: If a wire carrying a constant current is bent into a loop as shown in **Figure 28.4**, all the magnetic field lines inside the loop point in the same direction, reinforcing one another.*

What does the magnetic field of such a current-carrying loop, called a **current loop** for short, look like? To answer this question, we treat the current loop as a collection of small segments of a current-carrying wire and determine the direction of the magnetic field at various points around the loop. As we did in Chapter 27, we shall assume all currents to be constant in the remainder of this chapter.

We begin by considering the magnetic field due to a small segment of the current loop at a point on the central axis that passes perpendicularly through the face of the loop (point A in **Figure 28.5**). Segment 1 carries a current that points into the page. The magnetic field lines of this segment are concentric circles centered on the segment. Using the right-hand current rule, we see that the magnetic field curls clockwise in the plane of the drawing, and

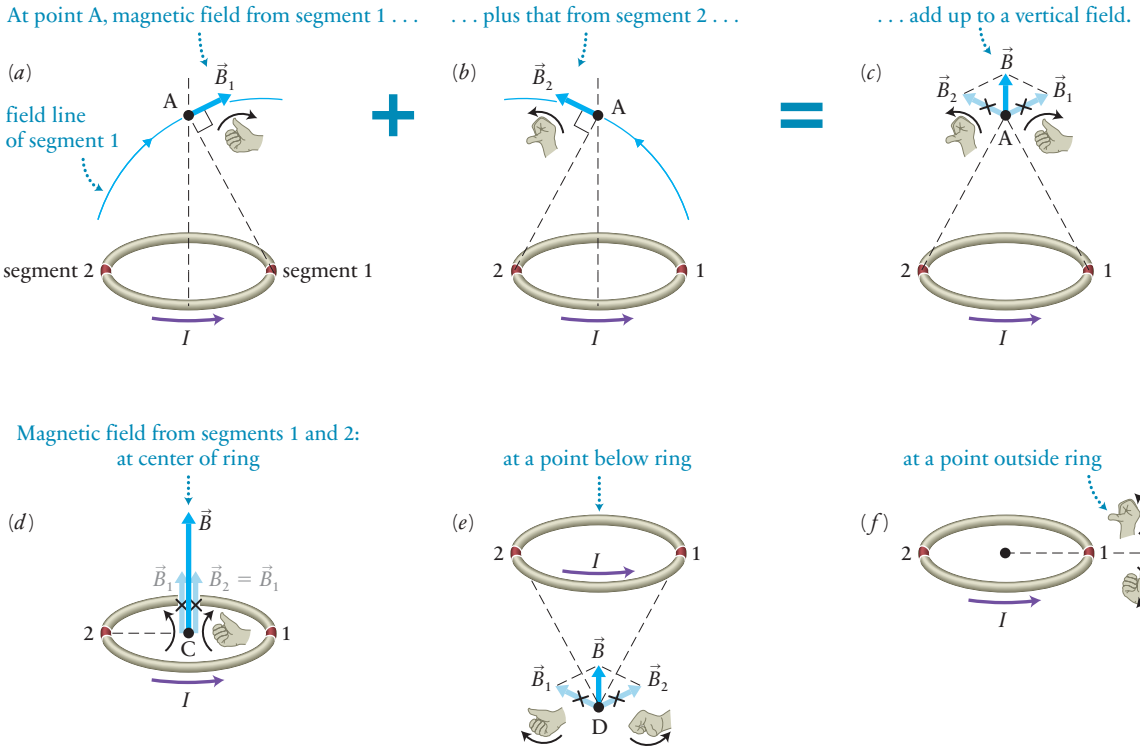
*For now, we'll ignore how to make charge carriers flow through such a loop. In Section 28.6 we'll discuss physical arrangements that accomplish the situation illustrated in Figure 28.4.

Figure 28.4 The magnetic field of a wire loop carrying a constant current. The magnetic fields from all parts of the loop reinforce one another in the center of the loop.

so the magnetic field due to segment 1 at A points up and to the right. Figure 28.5*b* shows a magnetic field line through A due to segment 2. Because the current through segment 2 points out of the page, this field line curls counterclockwise, and so the magnetic field due to segment 2 at A points up and to the left.

Figure 28.5*c* shows the contributions from segments 1 and 2 together; because their horizontal components cancel, the vector sum of $\vec{B}_1$ and $\vec{B}_2$ points vertically up. The same arguments can be applied to any other pair of segments lying on opposite sides of the current loop. Therefore the magnetic field due to the entire current loop points vertically up at A.

Now consider point C at the center of the current loop. As illustrated in Figure 28.5*d*, the magnetic fields due to segments 1 and 2 point straight up there, too. The same is true for all other segments, and so the field at point C also points straight up. We can repeat the procedure for point D below the current loop, and as shown in Figure 28.5*e*, the magnetic field there also points up.



To determine the direction of the magnetic field at a point outside the current loop, consider point G in Figure 28.5*f*. Using the right-hand current rule, you can verify that the field due to segment 1 points vertically down and the field due to segment 2 points vertically up. Because G is closer to 1 than it is to 2, the magnetic field due to 1 is stronger, and so the sum of the two fields points down.

28.2 What is the direction of the magnetic field at a point vertically (*a*) above and (*b*) below segment 1 in Figure 28.5?

The complete magnetic field pattern of the current loop, obtained by determining the magnetic fields for many more points, is shown in **Figure 28.6***a*. Close to the wire, the field lines are circular, but as you move farther away from the wire, the circles get squashed inside the loop and stretched outside due to the

CONCEPTS

Figure 28.5 Mapping the magnetic field of a current loop. The magnetic field contributions from (*a*) segment 1 and (*b*) segment 2 at A (*c*) add up to a vertical field. Magnetic fields are shown at (*d*) point C at the center of the ring, (*e*) point D below the ring, and (*f*) point G to the right of the ring. Note that in all cases the magnetic field of each segment is perpendicular to the line connecting that segment to the point at which we are determining the field.

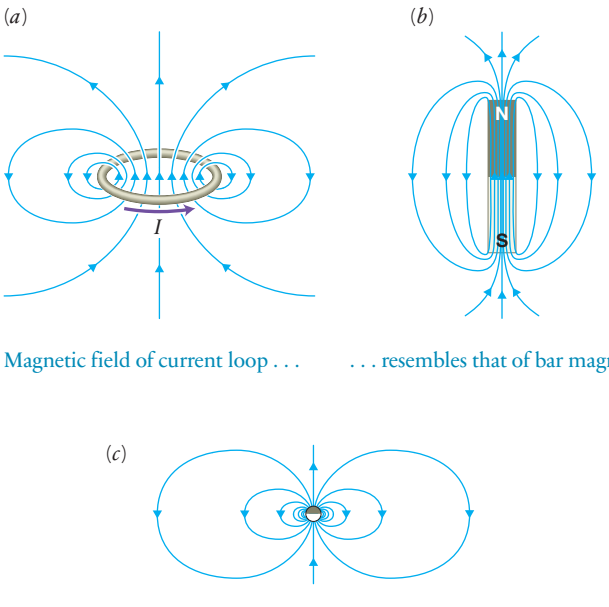
contributions of other parts of the loop to the magnetic field.

As you may have noticed, the field line pattern of a current loop resembles that of a bar magnet (Figure 28.6*b*). Indeed, if you shrink the size of both the current loop and the bar magnet, their magnetic field line patterns become identical (Figure 28.6*c*). The magnetic field line pattern in Figure 28.6*c* is that of an infinitesimally small magnetic dipole.

Given that a current loop produces a magnetic field similar to that of a bar magnet, is the magnetic field of a bar magnet then perhaps due to tiny current loops inside the magnet? More precisely, are elementary magnets (see Section 27.1) simply tiny current loops?

The connection between current loops and elementary magnets becomes clearer once we realize that a current loop is nothing but an amount of charge that revolves around an axis. Consider, for example, a positively charged ring spinning around a vertical axis through its center (**Figure 28.7**). The spinning charged

Figure 28.6 The magnetic field lines of a current loop (*a*) resemble that of a dipole (*b*, *c*).



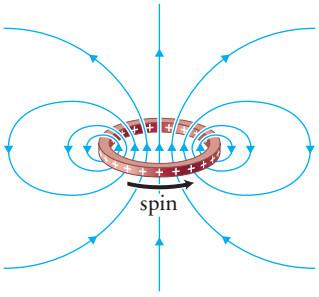


Figure 28.7 The magnetic field of a charged spinning ring is identical to that of a current loop.

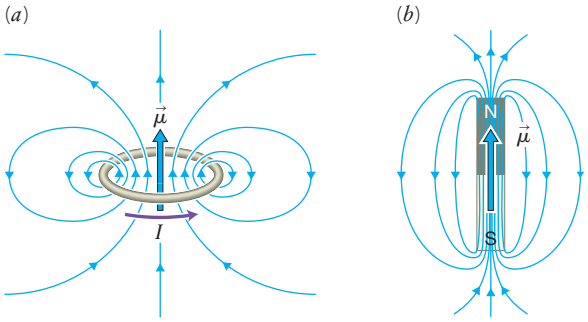
CONCEPTS

particles cause a current moving in a circle exactly like the current through the circular loop in Figure 28.5. If we let the radius of the ring approach zero, the ring becomes a spinning charged particle, and its magnetic field pattern approaches that of the magnetic dipole illustrated in Figure 28.6*c*. This surprising result tells us:

A spinning charged particle produces a magnetic field identical to that produced by an infinitesimally small magnetic dipole.

Experiments show that most elementary particles, such as electrons and protons, possess an intrinsic angular momentum—as if they permanently spin around—and such spinning motion indeed would produce a magnetic field of the form shown in Figure 28.6*c*. Because of the combined intrinsic angular momentum of these elementary particles inside atoms, certain atoms have a magnetic field, causing them to be the elementary magnets we discussed earlier. The reason we cannot separate north and south magnetic poles is therefore a direct consequence of the fact that the magnetic field of a particle with intrinsic angular momentum is that of an infinitesimally small magnetic dipole.



28.3 Suppose a negatively charged ring is placed directly above the positively charged ring in Figure 28.7. If both rings spin in the same direction, is the magnetic interaction between them attractive or repulsive?

28.3 Magnetic dipole moment and torque

To specify the orientation of a magnetic dipole we introduce the **magnetic dipole moment.** This vector, represented by the Greek letter $\vec{\mu}$ (mu), is defined to point, like a compass needle, along the direction of the magnetic field through the center of the dipole (**Figure 28.8**). For a bar magnet the magnetic dipole moment points from the south pole to the north pole. To determine the direction of $\vec{\mu}$ for a current loop, you can use a right-hand rule: When you curl the fingers of your right hand along the direction of the current, your thumb points in the direction of $\vec{\mu}$.

Figure 28.8 The magnetic dipole moment points in the direction of the magnetic field through the center of the dipole.

We now have three right-hand rules in magnetism, illustrated in **Figure 28.9** and summarized in **Table 28.1** together with the right-hand vector product rule. What helps distinguish these right-hand rules from one another is looking at which quantity curls: For a current-carrying wire, it is the magnetic field that curls, whereas for a current loop, it is the current that curls. The only additional thing you need to remember is that in the case of the magnetic force exerted on a current-carrying wire, the fingers are associated with the curl from the direction of the current to the direction of the magnetic field.

Table 28.1 Right-hand rules

Right-hand rule	thumb points along	fingers curl
vector product	$\vec{C} = \vec{A} \times \vec{B}$	from $\vec{A}$ to $\vec{B}$
current rule	current	along B-field
force rule	magnetic force	from current to B-field
dipole rule	$\vec{\mu}$ (parallel to $\vec{B}$)	along current loop

CONCEPTS

Figure 28.9 Right-hand rules in magnetism.

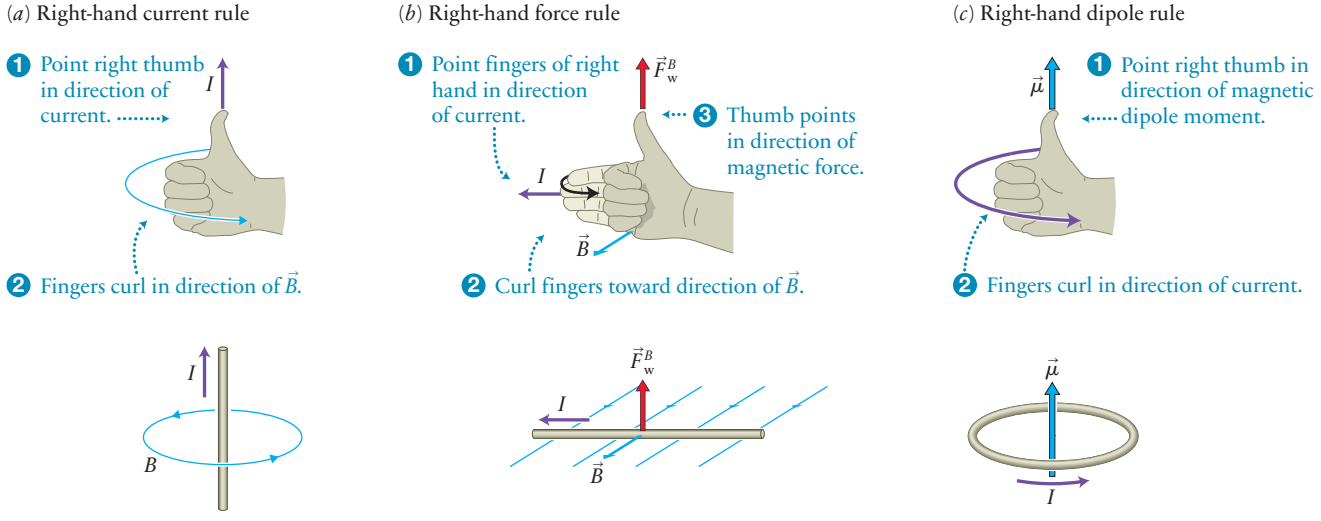


Figure 28.10 Magnetic forces exerted on a square current loop that is oriented so that its magnetic dipole moment is perpendicular to an external magnetic field.

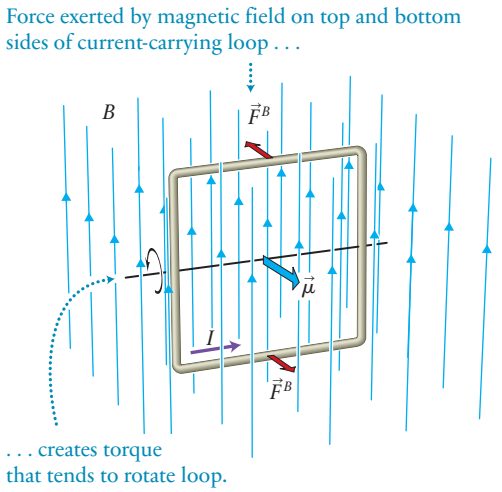

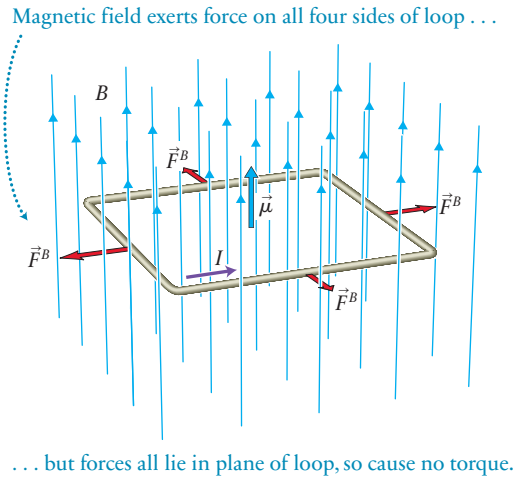

Figure 28.11 Magnetic forces exerted on a square current loop that is oriented so that its magnetic dipole moment is parallel to an external magnetic field.

Note, also, that the order of application of each rule in Figure 28.9 can be reversed to solve for a different variable. If you know the direction in which the magnetic field lines curl, for example, you can use the right-hand current rule to determine the current direction.

28.4 Does the direction of the electric field along the axis inside an electric dipole coincide with the direction of the electric dipole moment?

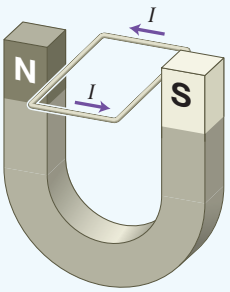
What happens when a current loop is placed in a magnetic field? To find out, consider a square current loop of wire placed in a uniform magnetic field with its magnetic dipole moment perpendicular to the magnetic field (**Figure 28.10**). The current loop experiences magnetic forces on the top and bottom sides but not on the vertical sides because they are parallel to the direction of the magnetic field (see Section 27.3). Using the right-hand force rule of Figure 28.9*b*, we see that the magnetic forces exerted on the top and bottom sides cause a torque that tends to rotate the loop as indicated in Figure 28.10.

When the current loop is oriented with its magnetic dipole moment parallel to the magnetic field, all four sides experience a magnetic force (**Figure 28.11**). However, because all four forces lie in the plane of the loop, none of them causes any torque. Because the magnitudes of the four forces are the same, their vector sum is zero and the loop is not accelerated sideways.

28.5 As the current loop in Figure 28.10 rotates over the first 90°, do the magnitudes of (*a*) the magnetic force exerted on the horizontal sides and (*b*) the torque caused by these forces increase, decrease, or stay the same? (*c*) As the loop rotates, do the two vertical sides experience any force, and, if so, do these forces cause any torque? (*d*) What happens to the torque as the loop rotates beyond 90°?

Summarizing the results of Checkpoint 28.5:

A current loop placed in a magnetic field tends to rotate such that the magnetic dipole moment of the loop becomes aligned with the magnetic field.



This alignment is completely analogous to the alignment of the electric dipole moment in the direction of an external electric field, which we studied in Section 23.8 (see Figure 23.32).

28.6 Suppose the square current loop in Figure 28.10 is replaced by a circular loop with a diameter equal to the width of the square loop and with the same current. Does the circular loop experience a torque? If not, why not? If so, how does this torque compare with that on the square loop?

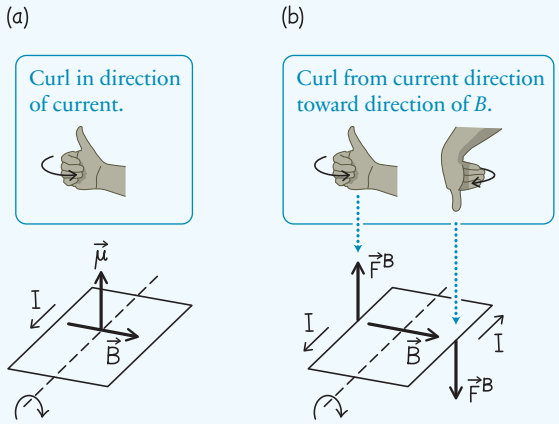
EXAMPLE 28.1 Current loop torque

When placed between the poles of a horseshoe magnet as shown in **Figure 28.12**, does a rectangular current loop experience a torque? If so, in which direction does the loop rotate?

Figure 28.12 Example 28.1.

1 GETTING STARTED I know that a current loop placed in a magnetic field tends to rotate such that the magnetic dipole moment of the loop becomes aligned with the magnetic field. If the loop tends to rotate, it experiences a torque.

2 DEVISE PLAN The simplest way to answer this question is to look at the directions of the magnetic field $\vec{B}$ and the magnetic dipole moment $\vec{\mu}$. By definition, the magnetic field between the poles of the magnet points from the north pole to the south pole. To determine the direction of $\vec{\mu}$, I can use the right-hand dipole rule.



(Continued)

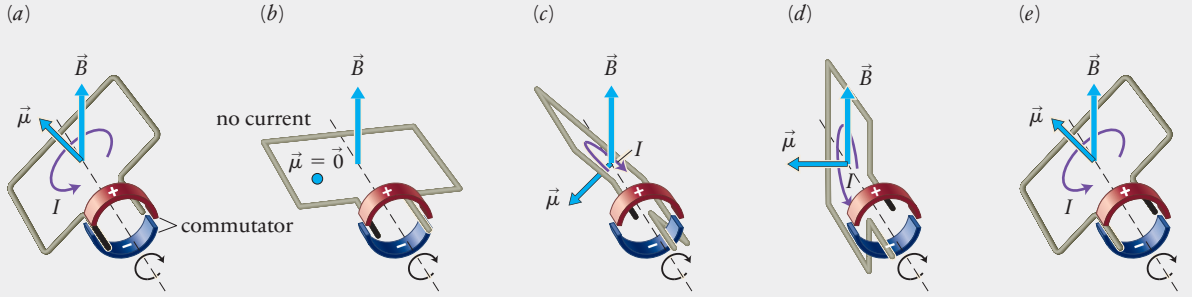
CONCEPTS

3 EXECUTE PLAN I begin by sketching the loop and indicating the direction of the magnetic field (**Figure 28.13*a***). To determine the direction of $\vec{\mu}$, I curl the fingers of my right hand along the direction of the current through the loop. My thumb shows that $\vec{\mu}$ points straight up. To align $\vec{\mu}$ with $\vec{B}$, therefore, the loop rotates in the direction shown by the curved arrow in Figure 28.13*a*. The loop must experience a torque in order for this rotation to occur. ✔

4 EVALUATE RESULT I can verify my answer by determining the force exerted by the magnetic field on each side of the loop and seeing if these forces cause a torque (Figure 28.13*b*). The front and rear sides experience no force because the current through them is either parallel or antiparallel to $\vec{B}$. To determine the direction of the force exerted on the left side of the loop, I point my right-hand fingers along the direction of the current through that side and curl them toward the direction of the magnetic field. My upward-pointing thumb indicates that the force exerted on the left side is upward. Applying the right-hand force rule to the right side of the loop tells me that the magnetic force exerted on that side is directed downward. The magnetic forces exerted on the left and right sides thus cause a torque that makes the loop rotate in the same direction I determined earlier.

Figure 28.13

The alignment of the magnetic dipole moment of current loops in magnetic fields is responsible for the operation of any device involving an electric motor (see the box below titled "Electric motors").



Electric motors

The torque caused by the forces exerted on a current loop in a magnetic field is the basic operating mechanism of an electric motor. A problem with the arrangement shown in Figure 28.12, however, is that once the magnetic dipole moment is aligned with the magnetic field, the torque disappears. Also if the current loop overshoots this equilibrium position, the torque reverses direction (see Checkpoint 28.5*d*). The most common way to overcome this problem is with a *commutator*—an arrangement of two curved plates that reverses the current through the current loop each half turn. The result is that the current loop keeps rotating.

The basic operation is illustrated in **Figure 28.14**. Each half of the commutator is connected to one terminal of a battery and is in contact with one end of the current loop. In the position illustrated in Figure 28.14*a*, the black end is in contact with the negative commutator (that is, the half of the commutator connected to the negative battery terminal). Consequently, the current direction is counterclockwise as seen from above through the current loop, and the magnetic dipole moment $\vec{\mu}$ points up and to the left. The vertical magnetic field therefore causes a torque that turns the loop clockwise to align $\vec{\mu}$ with $\vec{B}$.

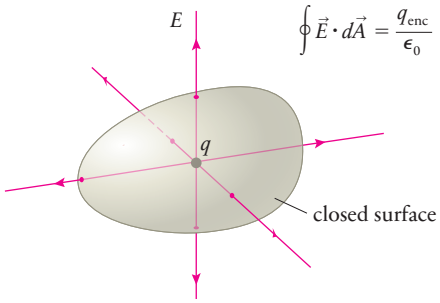
Once the loop has rotated to the position shown in Figure 28.14*b*, $\vec{\mu}$ is aligned with $\vec{B}$ but the contact between the ends of the current loop and the commutator is broken, which means there is no current in the loop. The loop overshoots this equilibrium position, but as soon as it does so, the current direction reverses because now the black end of the loop is in contact with the positive commutator (Figure 28.14*c*). The current direction is now clockwise as seen from above, and so $\vec{\mu}$ is reversed. Consequently, the current loop continues to rotate clockwise, as illustrated in Figures 28.14*c–e*. After half a revolution, we reach the initial situation again and the sequence repeats.

Figure 28.14 Operating principle of an electric motor. At instant (*b*), the current direction through the current loop is reversed.

CONCEPTS

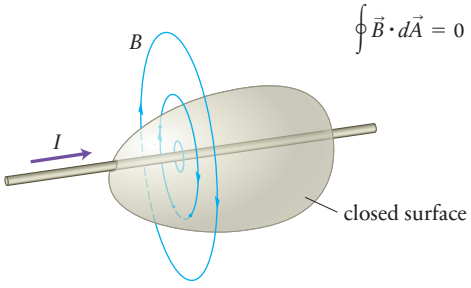
28.7 Describe the motion of the current loop in Figure 28.12 if the magnitude of the magnetic field between the poles of the magnet is greater on the left than it is on the right.

28.4 Ampèrian paths



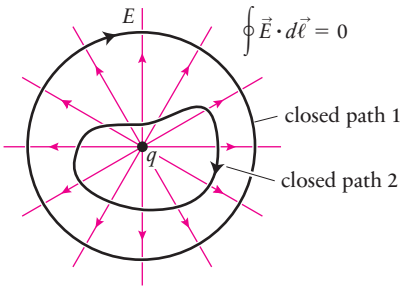
In electrostatics, Gauss's law provides a powerful tool for determining the electric field of a charge distribution: The electric flux through a closed surface is determined by the amount of charge enclosed by that surface (see Section 24.3). The basic reason for Gauss's law is illustrated in **Figure 28.15a**: Electric field lines originate or terminate on charged particles, and the number of "field line piercings" through a closed surface is proportional to the amount of charge enclosed by that surface. As you saw in Checkpoint 27.6, however, Gauss's law for magnetism is not as helpful for determining magnetic fields. The reason is illustrated in Figure 28.15*b*: Magnetic field lines form loops, so if they exit a closed surface, they must reenter it at some other point. Consequently, the magnetic flux through a closed surface is always zero, regardless of whether or not the surface encloses any magnets or current-carrying wires. In mathematical language, the surface integral of the magnetic field over a closed surface is always zero.

Let us next consider line integrals of electric and magnetic fields. As we saw in Section 25.5, the line integral of the electrostatic field around a closed path is always zero. Consider, for example, the line integral of the electrostatic field around closed path 1 in Figure 28.15*c*. Because the electrostatic field generated by the charged particle at the center of path 1 is always perpendicular to the path, $\vec{E}$ is perpendicular to $d\vec{\ell}$. Therefore $\vec{E} \cdot d\vec{\ell} = 0$ and so the line integral is always zero. Any other path, such as closed path 2 in Figure 28.15*c*, can be broken down into small radial and circular segments. As we saw in Section 25.5, going once around a closed path, all the nonzero contributions along the radial segments add up to zero. Physically this means that as you move a charged particle around a closed path through an electrostatic field, the work done by the electrostatic field on the particle is zero.

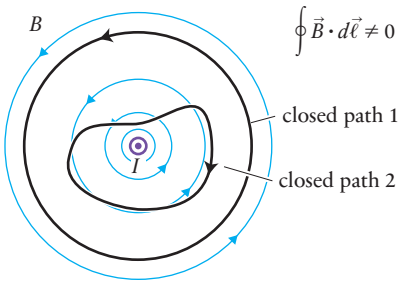


Consider now, however, the line integral around closed path 1 in Figure 28.15*d*, which is concentric with a wire carrying a current out of the page. The magnetic field generated by the current through the wire always points in the same direction as the direction of this path. Therefore $\vec{B} \cdot d\vec{\ell}$ is always positive, making the line integral nonzero and positive. Along closed path 2, the component of the magnetic field tangent to the path is always opposite the direction of the path. Therefore $\vec{B} \cdot d\vec{\ell}$ is always negative and the line integral is negative.

Figure 28.15 Surface and line integrals of electric and magnetic fields.



(*a*) Surface integral of electric field (Gauss's law)



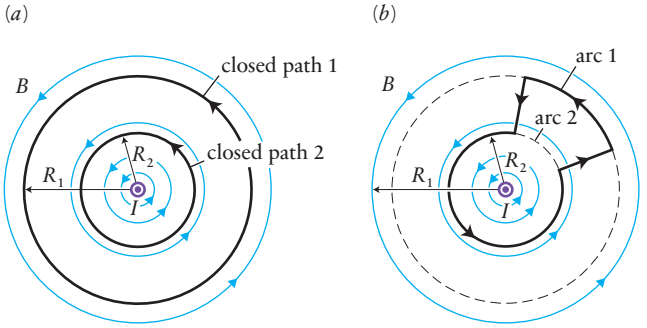
(*b*) Surface integral of magnetic field (Gauss's law for magnetism)

(*c*) Line integral of electric field

(*d*) Line integral of magnetic field

CONCEPTS

Figure 28.16 (*a*) Two closed circular paths concentric with a wire that carries a current directed out of the page. (*b*) A noncircular path encircling the current-carrying wire. The two arcs each represent one-eighth of a circle.



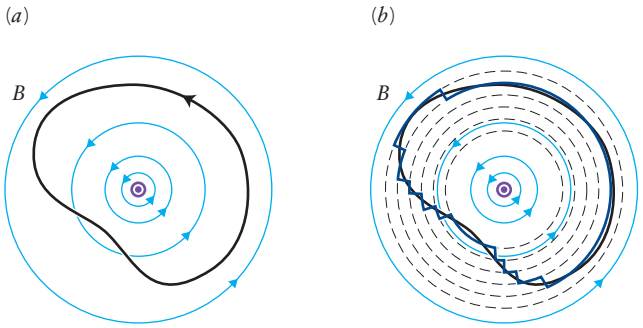


Figure 28.17 (*a*) A noncircular closed path encircling a current-carrying wire. (*b*) We can approximate the path by using small arcs and radial segments.

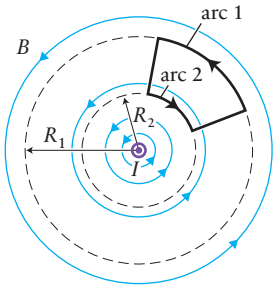
Let us next compare the line integrals along two closed circular paths of different radius (**Figure 28.16*a***). The arrowheads in the paths indicate the direction along which we carry out the integration. Let the magnitude of the magnetic field a distance R_1 from the wire at the center of the paths be B_1. Because this magnitude is constant along the entire circular path, the line integral along this path is the product of the field magnitude and the length of the path: $B_1(2\pi R_1) = 2\pi B_1 R_1$. Along closed path 2 we obtain $2\pi B_2 R_2$, where B_2 is the magnetic field magnitude a distance R_2 from the wire. As you may suspect from the cylindrical symmetry of the wire, the magnitude of the magnetic field decreases as $1/r$ with distance r from the wire (we'll confirm this dependence in Example 28.6). This means that as we go from R_2 to R_1, the field decreases by a factor R_2/R_1. In other words, $B_1 = B_2(R_2/R_1)$ or $B_1 R_1 = B_2 R_2$. Thus we see that the line integrals along the two paths are equal: $2\pi B_1 R_1 = 2\pi B_2 R_2$. The same argument can be applied to any other closed circular path centered on the wire, from which we conclude that the line integral of the magnetic field of a straight current-carrying wire over any circular path centered on the wire has the same value.

CONCEPTS

28.8 If the magnitude of the current I through a wire is increased, do you expect the line integral of the magnetic field around a closed path around the wire to increase, decrease, or stay the same?

Now consider the noncircular path illustrated in Figure 28.16*b*. Most of the path lies along a circle of radius R_2, with the exception of one-eighth of a revolution, which is along two radial segments and an arc of radius R_1. Because the radial segments are perpendicular to the magnetic field, they do not contribute to the line integral. How do the line integrals along arcs 1 and 2 compare? As we just saw, the line integrals along the two closed circular paths in Figure 28.16*a* are equal, so the line integrals along one-eighth of each closed path in Figure 28.16*a* must also be equal. The same must be true in Figure 28.16*b*, which means the line integrals along arcs 1 and 2 are identical, and so the line integral along the noncircular path in Figure 28.16*b* is equal to that along any circular path centered on the wire.



We can make the deviations from a circular path progressively more complicated, but as illustrated in **Figure 28.17**, any path can always be broken down into small segments that are either radial or circular and concentric with the wire. The radial segments never contribute to the line integral because the magnetic field is always perpendicular to them, while the circular segments always add up to a single complete revolution. So, in conclusion:

The value of the line integral of the magnetic field along a closed path encircling a current-carrying wire is independent of the shape of the path.

28.9 What happens to the value of the line integral along the closed path in Figure 28.17*a* when (*a*) the direction of the current through the wire is reversed; (*b*) a second wire carrying an identical current is added parallel to and to the right of the first one (but still inside the path); and (*c*) the direction of the current through the second wire is reversed?

Next let's examine the line integral along a closed path near a current-carrying wire lying outside the path. One such path is shown in **Figure 28.18** as two arcs joined by two radial segments. As before, the radial segments do not contribute to the line integral. The magnitudes of the line integrals along arcs 1 and 2 are equal, but because the direction of arc 2 is opposite the direction of the magnetic field, the line integral along that arc is negative. Consequently, the line integral along the entire path adds up to zero. We can again extend this statement to a path of a different

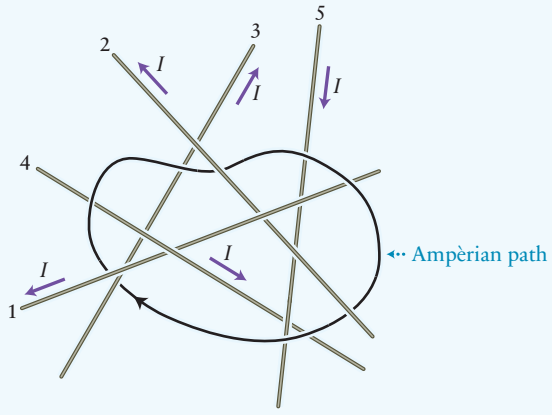
Figure 28.18 A noncircular closed path not encircling a current-carrying wire.

form, but as long as the path does not encircle the current-carrying wire, the line integral is zero:

> **The line integral of the magnetic field along a closed path that does not encircle any current-carrying wire is zero.**

Putting the above results together, we see that the line integral of the magnetic field along a closed path tells us something about the amount of current encircled by the path:

> **The line integral of the magnetic field along a closed path is proportional to the current encircled by the path.**



We shall put this statement in a more quantitative form in Section 28.5. As we shall see there, this law, called **Ampère's law,** plays a role analogous to Gauss's law: Given the amount of current encircled by a closed path, called an **Ampèrian path,** we can readily determine the magnetic field due to the current, provided the current distribution exhibits certain simple symmetries. Because the line integral along a closed path depends on the direction of integration, we must always choose a direction along the path when specifying an Ampèrian path. Exercise 28.2 illustrates the importance of the direction of the Ampèrian path.

28.10 Suppose the path in Figure 28.17 were tilted instead of being in a plane perpendicular to the current-carrying wire. Would this tilt change the value of the line integral of the magnetic field around the path?

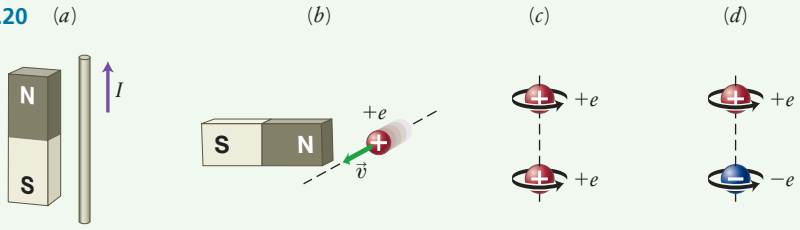
EXERCISE 28.2 Crossed wires

Consider the Ampèrian path going through the collection of current-carrying wires in **Figure 28.19**. If the magnitude of the current is the same in all the wires, is the line integral of the magnetic field along the Ampèrian path positive, negative, or zero?

Figure 28.19 Exercise 28.2.

SOLUTION For each wire, I must determine whether or not the path encircles the wire and, if it does, whether the component of that wire's magnetic field tangent to the path points in the same direction as the path. I see that wires 1 and 3 go through the path but the other three wires lie either on top of the path or beneath it.

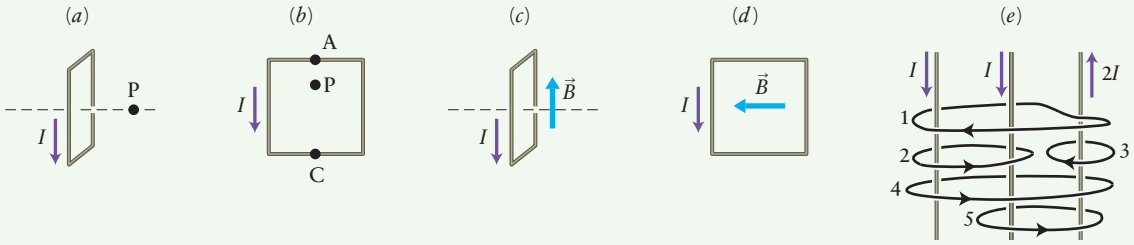
The direction of current through wire 1 is forward out of the plane of the page, so the magnetic field lines around this wire curl counterclockwise—opposite the direction of the Ampèrian path—giving a negative contribution to the line integral. The direction of current through wire 3 is down into the plane of the page, so it yields a positive contribution to the line integral. Because the two currents are equal in magnitude, the contributions to the line integral add up to zero. ✔



28.11 How do the following changes affect the answer to Exercise 28.2: (*a*) reversing the current through wire 1, (*b*) reversing the current through wire 2, (*c*) reversing the direction of the Ampèrian path?

CONCEPTS

Self-quiz

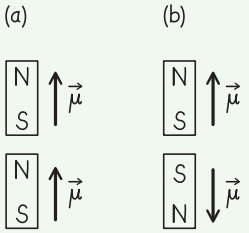


1. Determine the direction of the magnetic force exerted at the center of the wire or on the particles in **Figure 28.20**.

Figure 28.20

2. Determine the direction of the magnetic field at P due to (*a*) the current loop in **Figure 28.21a** and (*b*) segments A and C of the current loop in Figure 28.21*b*.

Figure 28.21



3. Determine in which direction the current loop rotates (*a*) in Figure 28.21*c* and (*b*) in Figure 28.21*d*.
4. (*a*) Determine the currents encircled by the five Ampèrian paths in Figure 28.21*e*. (*b*) Rank the paths according to the magnitudes of the line integral of the magnetic field along each path, greatest first.

Answers

1. (*a*) No magnetic force is exerted by the magnet on the wire because the magnetic field at the location of the wire and the current are antiparallel. (*b*) The magnetic force acting on the particle is upward. To see this, consider the moving positively charged particle to be current in the direction of the velocity of the particle and then use the right-hand force rule, which makes your thumb point upward. (*c*) The magnetic dipole moments of the two spinning particles both point up and so the particles attract each other, just like two bar magnets oriented the way the spinning particles are (**Figure 28.22a**). (*d*) The magnetic dipole moment of the negative particle points down, that of the positive particle points up, and so the two particles repel each other. The comparable bar magnet orientation is shown in Figure 28.22*b*.

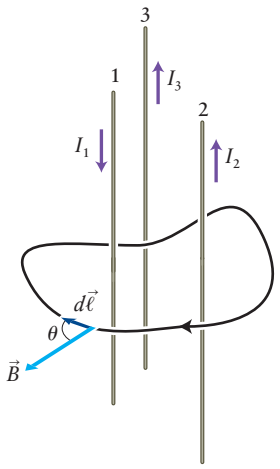
Figure 28.22

2. (*a*) The right-hand dipole rule tells you that the magnetic dipole of the loop and the magnetic field produced by the loop point to the right at P. (*b*) Segments A and C both contribute a magnetic field that points out of the page at P, so the magnetic field due to both segments also points out of the page at P.
3. (*a*) $\vec{\mu}$ for the current loop points to the right, so the current loop rotates counterclockwise about an axis perpendicular to the page and through the center of the loop. (*b*) $\vec{\mu}$ for the current loop points out of the page, so the loop rotates about an axis aligned with the vertical sides of the loop. The right side of the loop moves up out of the page, and the left side moves down into the page.
4. (*a*) Path 1 encircles two currents I in the same direction as the magnetic field: $+2I$. Path 2 encircles the same two currents in the opposite direction: $-2I$. Path 3 encircles $2I$ in the direction opposite the magnetic field direction: $-2I$. Path 4 encircles all three currents, which add up to zero. Path 5 encircles I in the direction opposite the magnetic field direction and $2I$ in the same direction as the magnetic field: $+I$. (*b*) Each line integral is proportional to the current encircled, making the ranking line integral 1 = line integral 2 = line integral 3 > line integral 5 > line integral 4.

28.5 Ampère's law

In the preceding section, we saw that the line integral of the magnetic field around a closed path, called an Ampèrian path, is proportional to the current encircled by the path, I_{enc}. This can be expressed mathematically as

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I_{enc} \quad \text{(constant currents)}, \tag{28.1}$$



where $d\vec{\ell}$ is an infinitesimal segment of the path and the proportionality constant μ_0 is called the **magnetic constant** (sometimes called *permeability constant*). Using the base unit for current, the ampere (see Section 27.5), the value of the magnetic constant is

$$\mu_0 = 4\pi \times 10^{-7}\ \text{T} \cdot \text{m/A}.$$

Equation 28.1 is called **Ampère's law,** after the French physicist André-Marie Ampère (1775–1836).

Let us illustrate how Eq. 28.1 is used by applying it to the closed path in Figure 28.23. From the figure we see that the path encircles wires 1 and 2 but not 3, which lies behind the path. To calculate the right side of Eq. 28.1, we must assign an algebraic sign to the contributions of currents I_1 and I_2 to I_{enc}. As we saw in Section 28.3, we can do so using the right-hand current rule. Putting the thumb of our right hand in the direction of I_1, we see that the magnetic field of I_1 curls in the same direction as the direction of the integration path (the Ampèrian path) indicated in the diagram. Applying the same rule to I_2 tells us that the magnetic field of this current curls in the opposite direction. Thus I_1 yields a positive contribution and I_2 yields a negative contribution to the line integral. The right side of Eq. 28.1 thus becomes $\mu_0(I_1 - I_2)$.

Figure 28.23 A closed path encircling two of three straight current-carrying wires.

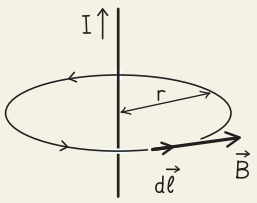
PROCEDURE: Calculating the magnetic field using Ampère's law

For magnetic fields with straight or circular field lines, Ampère's law allows you to calculate the magnitude of the magnetic field without having to carry out any integrations.

1. Sketch the current distribution and the magnetic field by drawing one or more field lines using the right-hand current rule. A two-dimensional drawing should suffice.
2. If the field lines form circles, the Ampèrian path should be a circle. If the field lines are straight, the path should be rectangular.
3. Position the Ampèrian path in your drawing such that the magnetic field is either perpendicular or tangent to the path and constant in magnitude. Choose the direction of the Ampèrian path so that, where it runs parallel to the magnetic field lines, it points in the same direction as the field. If the current distribution divides space into distinct regions, draw an Ampèrian path in each region where you wish to calculate the magnetic field.
4. Use the right-hand current rule to determine the direction of the magnetic field of each current encircled by the path. If this magnetic field and the Ampèrian path have the same direction, the contribution of the current to I_{enc} is positive. If they have opposite directions, the contribution is negative.
5. For each Ampèrian path, calculate the line integral of the magnetic field along the path. Express your result in terms of the unknown magnitude of the magnetic field B along the Ampèrian path.
6. Use Ampère's law (Eq. 28.1) to relate I_{enc} and the line integral of the magnetic field and solve for B. (If your calculation yields a negative value for B, then the magnetic field points in the direction opposite the direction you assumed in step 1.)

You can use the same general approach to determine the current given the magnetic field of a current distribution. Follow the same procedure, but in steps 4–6, express I_{enc} in terms of the unknown current I and solve for I.

QUANTITATIVE TOOLS



To calculate the line integral on the left side of Eq. 28.1, we first divide the closed path into infinitesimally small segments $d\vec{\ell}$, one of which is shown in Figure 28.23. The segments are directed tangentially along the path in the direction of integration. For each segment $d\vec{\ell}$, we take the scalar product of $d\vec{\ell}$ with the magnetic field $\vec{B}$ at the location of that segment, $\vec{B} \cdot d\vec{\ell}$, and then we add up the scalar products for all segments of the closed path. In the limit that the segment lengths approach zero, this summation becomes the line integral on the left in Eq. 28.1. In the situation illustrated in Figure 28.23, we cannot easily carry out this integration because of the irregular shape of the path. Just like Gauss's law in electrostatics, however, Ampère's law allows us to easily determine the magnetic field for highly symmetrical current configurations. The general procedure is outlined in the Procedure box on the previous page. The next two examples illustrate how this procedure can be applied to simplify calculating the line integral in Ampère's law.

EXAMPLE 28.3 Magnetic field generated by a long straight current-carrying wire

A long straight wire carries a current of magnitude I, and this current creates a magnetic field $\vec{B}$. Derive an expression for the magnitude of the magnetic field a radial distance r from the wire.

❶ **GETTING STARTED** I begin by making a sketch of the wire, arbitrarily orienting it vertically (**Figure 28.24**). I know that the magnetic field is circular, so I draw one circular field line, centering it on the wire and giving it a radius r. Using the right-hand current rule, I determine the direction in which the magnetic field points along the circle and indicate that with an arrowhead in my drawing.

Figure 28.24

❷ **DEVISE PLAN** To begin my derivation I can use Ampère's law (Eq. 28.1). If I let the field line in my sketch be the Ampèrian path, the magnetic field is constant in magnitude and tangential all along the circular path, simplifying the integral on the left in Eq. 28.1. I let the direction of the Ampèrian path be the same as that of the magnetic field. That is to say, the infinitesimal path segment $d\vec{\ell}$ points in the same direction as $\vec{B}$ all along the Ampèrian path.

❸ **EXECUTE PLAN** With my choice of Ampèrian path, $d\vec{\ell}$ and $\vec{B}$ are always pointing in the same direction, and so $\vec{B} \cdot d\vec{\ell} = B\, dl$. Because the magnitude B is the same all around the path, I can write for the left side of Eq. 28.1

$$\oint \vec{B} \cdot d\vec{\ell} = \oint B\, d\ell = B \oint d\ell.$$

The line integral on the right here is the sum of the lengths of all the segments $d\vec{\ell}$ around the Ampèrian path; that is to say, it is equal to the circumference of the circle. Therefore I have

$$\oint \vec{B} \cdot d\vec{\ell} = B \oint d\ell = B(2\pi r). \qquad (1)$$

Because the direction in which the Ampèrian path encircles the current I is the same as the direction of the magnetic field generated by the current, the right side of Eq. 28.1 yields

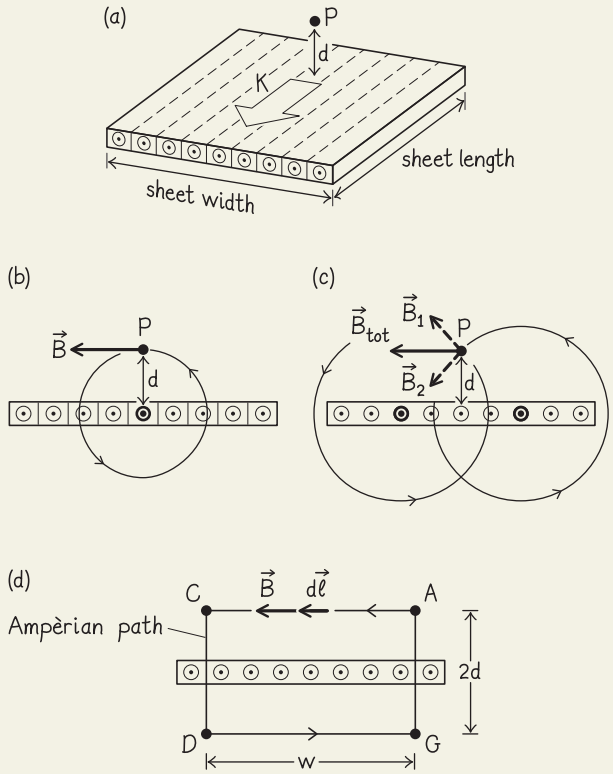
$$\mu_0 I_{\text{enc}} = +\mu_0 I. \qquad (2)$$

Substituting the right side of Eq. 2 and Eq. 1 into Eq. 28.1, I get $B(2\pi r) = \mu_0 I$ or

$$B = \frac{\mu_0 I}{2\pi r}. \checkmark$$

❹ **EVALUATE RESULT** My result shows that the magnitude of the magnetic field is proportional to I, as I expect (doubling the current should double the magnetic field), and inversely proportional to the radial distance r from the wire. I know from Chapter 24 that the electric field is also inversely proportional to r in cases that exhibit cylindrical symmetry, another indication that my result here makes sense.

QUANTITATIVE TOOLS



28.12 Suppose the wire in Example 28.3 has a radius R and the current is uniformly distributed throughout the volume of the wire. Follow the procedure of Example 28.3 to calculate the magnitude of the magnetic field inside ($r < R$) and outside ($r > R$) the wire.

EXAMPLE 28.4 Magnetic field generated by a large current-carrying sheet

A large flat metal sheet carries a current. The magnitude of the current per unit of sheet width is K. What is the magnitude of the magnetic field a distance d above the sheet?

❶ **GETTING STARTED** I begin by drawing the sheet and indicating a point P a distance d above it where I am to determine the magnetic field magnitude (**Figure 28.25*a***). I draw a lengthwise arrow to show the current through the sheet.

Figure 28.25

❷ **DEVISE PLAN** I'll solve this problem using Ampère's law (Eq. 28.1). I first need to determine the direction of the magnetic field on either side of the sheet. To this end, I divide the sheet into thin parallel strips, as indicated by the dashed lines in Figure 28.25*a*. I can then treat each strip as a current-carrying wire.

Figure 28.25*b* is a cross-sectional view of the sheet after I have divided it into strips. The perspective here is looking into the sheet in the direction opposite the direction of the current. Using the right-hand current rule, I determine that the strip right underneath point P contributes a magnetic field at P that points parallel to the sheet and to the left. Next I look at the contributions from the two strips labeled 1 and 2 in Figure 28.25*c*, equidistant on either side of P. The two large circles show the magnetic field lines from these two strips that go through P. Because the magnitudes of the contributions from the two strips are equal, the vector sum of their contributions to the magnetic field also points parallel to the sheet and to the left. The same argument can be applied to any other pair of strips that are equidistant on either side of P. Thus, at P the magnetic field due to the entire sheet must be parallel to the sheet and to the left. Similar reasoning shows that the magnetic field below the sheet is also parallel to the sheet and points to the right.

To exploit what I know about the magnetic field, I choose the rectangular path ACDG in Figure 28.25*d* as my Ampèrian path, making the direction of the path the same as that of the magnetic field. The width of this path is w, and its height is $2d$.

❸ **EXECUTE PLAN** I can write the line integral around the Ampèrian path as the sum of four line integrals, one over each side of the path:

$$\oint \vec{B}\cdot d\vec{\ell} = \int_A^C \vec{B}\cdot d\vec{\ell} + \int_C^D \vec{B}\cdot d\vec{\ell} + \int_D^G \vec{B}\cdot d\vec{\ell} + \int_G^A \vec{B}\cdot d\vec{\ell}.$$

Along sides CD and GA the magnetic field is perpendicular to the Ampèrian path and so $\vec{B}\cdot d\vec{\ell}$ is zero. Along each of the two horizontal sides, $d\vec{\ell}$ and $\vec{B}$ point in the same direction, and so $\vec{B}\cdot d\vec{\ell} = B\,d\ell$.

Symmetry requires that the magnitude of the magnetic field a distance d below the sheet be the same as the magnitude a distance d above it (because flipping the sheet upside down does not alter the physical situation). Therefore I can take the magnitude B out of the integral:

$$\oint \vec{B}\cdot d\vec{\ell} = \int_A^C B\,d\ell + \int_D^G B\,d\ell = B\int_A^C d\ell + B\int_D^G d\ell.$$

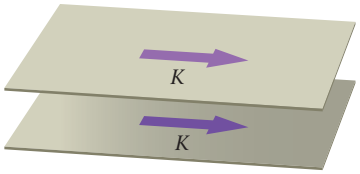
These two line integrals $\int d\ell$ yield the length of the two horizontal sides, which is the Ampèrian path width w, and so the left side of Eq. 28.1 becomes

$$\oint \vec{B}\cdot d\vec{\ell} = B(w+w) = 2Bw. \qquad (1)$$

To get an expression for the right side of Eq. 28.1, I must first determine the amount of current encircled by the Ampèrian path. Because the magnitude of the current per unit of width through the sheet is K, the magnitude of the current through the Ampèrian path of width w is Kw. The right side of Eq. 28.1 thus becomes

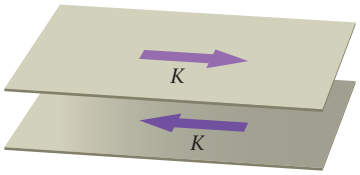
$$\mu_0 I_{\text{enc}} = \mu_0 K w. \qquad (2)$$

Substituting the right sides of Eqs. 1 and 2 into Ampère's law, I get $2Bw = \mu_0 K w$, or



$$B = \tfrac{1}{2}\mu_0 K. \checkmark$$

❹ **EVALUATE RESULT** Because the sheet has planar symmetry (see Section 24.4), I expect that, by analogy with the electric field around a flat charged sheet, the magnetic field on either side of my sheet here is uniform. That is, the field magnitude does not depend on the distance from the sheet, and this is just what my result shows. It also makes sense that my result shows that the magnitude of the magnetic field is proportional to the current per unit width K through the sheet.



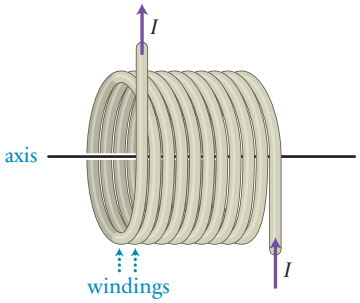
QUANTITATIVE TOOLS

Figure 28.26 Checkpoint 28.13.

(*a*)

(*b*)

28.13 (*a*) What are the direction and magnitude of the magnetic field between the parallel current-carrying sheets of **Figure 28.26a**? What is the direction of $\vec{B}$ outside these sheets? (*b*) Repeat for the sheets of Figure 28.26*b*.



28.6 Solenoids and toroids

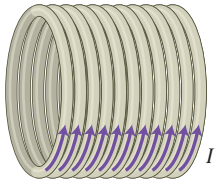
A **solenoid** is a long, tightly wound helical coil of wire (**Figure 28.27a**). In general, the diameter of the coil is much smaller than the length of the coil. When a current enters a solenoid at one end and exits at the other end, the solenoid generates a strong magnetic field. If a magnetic core is placed in the solenoid, the solenoid exerts a strong magnetic force on the core, turning electrical energy into motion. Solenoids are therefore often used in electrical valves and actuators. Because solenoids are generally very tightly wound, we can treat the windings of a solenoid as a stack of closely spaced current loops (Figure 28.27*b*).

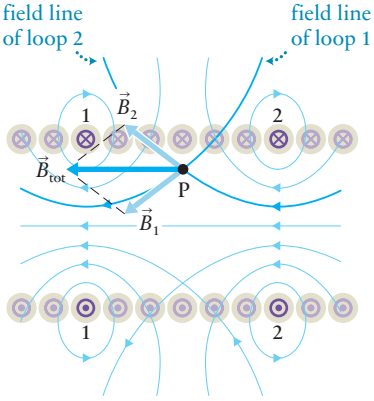
Figure 28.28a shows that the magnetic field inside a long solenoid must be directed along the axis of the solenoid. Consider, for example, point P inside the solenoid. The figure shows the field lines of two of the loops, one on either side of P and equidistant from that point. The magnetic field contributions of the two loops give rise to a magnetic field that points along the axis of the solenoid. The same argument can be applied to any other pair of loops and to any other point inside the solenoid. Therefore the magnetic field everywhere inside a long solenoid must be directed parallel to the solenoid axis.

Figure 28.27 A solenoid is a tightly wound helical coil of wire.

(*a*) A solenoid

(*b*) A solenoid approximated as a stack of parallel current loops





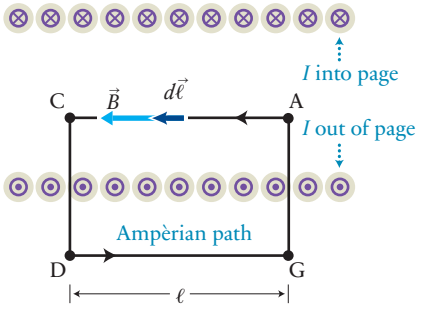


Figure 28.28 The magnetic field of a solenoid that carries a current *I*.

(*a*) Cross section of a solenoid showing the contribution of two loops to the magnetic field at a point inside the solenoid

(*b*) Ampèrian path for calculating the magnetic field inside the solenoid

QUANTITATIVE TOOLS

Because magnetic field lines form loops, all the lines that go through the solenoid must loop back from one end of the solenoid to the other. Because there is much more space available outside the solenoid, the density of the field lines as they loop back is much smaller than the field line density inside the solenoid. The longer the solenoid, the smaller the field line density in the immediate vicinity outside the solenoid. In the limit of an infinitely long solenoid, we can expect the magnetic field outside the solenoid to approach zero.

We can now use Ampère's law to determine the magnitude of the magnetic field when there is a current of magnitude I through the solenoid. Exploiting what we know about the direction of the magnetic field, we choose the rectangular path ACDG in Figure 28.28*b* as the Ampèrian path. Along AC, the magnetic field is parallel to the path, and so $\vec{B} \cdot d\vec{\ell} = B\, d\ell$. Along CD and GA, the magnetic field is perpendicular to the path, so these segments do not contribute: $\vec{B} \cdot d\vec{\ell} = 0$. Because the magnetic field approaches zero outside the solenoid, the segment DG also does not contribute. The line integral on the left side of Ampère's law (Eq. 28.1) thus becomes

$$\oint \vec{B} \cdot d\vec{\ell} = \int_A^C B\, d\ell. \tag{28.2}$$

The cylindrical symmetry of the solenoid requires the magnitude of the magnetic field to be constant along AC, so we can pull B out of the integral:

$$\oint \vec{B} \cdot d\vec{\ell} = \int_A^C B\, d\ell = B \int_A^C d\ell = B\ell, \tag{28.3}$$

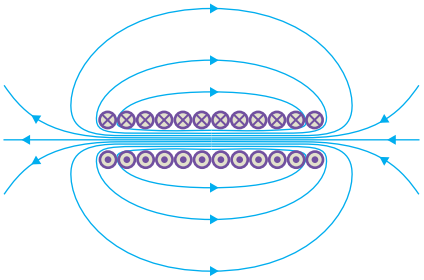
where ℓ is the length of side AC.

What is the current encircled by the Ampèrian path? Each winding carries a current of magnitude I, but the path encircles more than one winding. If there are n windings per unit length, then $n\ell$ windings are encircled by the Ampèrian path, and the encircled current is I times the number of windings:

$$I_{\text{enc}} = n\ell I. \tag{28.4}$$

Substituting Eqs. 28.3 and 28.4 into Ampère's law (Eq. 28.1), we obtain

$$B\ell = \mu_0 n\ell I \tag{28.5}$$



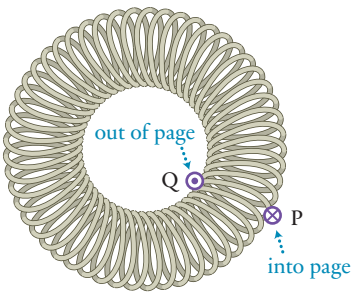
$$B = \mu_0 n I \quad \text{(infinitely long solenoid)}. \tag{28.6}$$

This result shows that the magnetic field inside the solenoid depends on the current through the windings and on the number of windings per unit length. The field within the solenoid is uniform—it does not depend on position inside the solenoid. Although Eq. 28.6 holds for an infinitely long solenoid, the result is pretty accurate even for a solenoid of finite length. For a solenoid that is at least four times as long as it is wide, the magnetic field is very weak outside the solenoid and approximately uniform and equal to the value given in Eq. 28.6 inside. An example of the magnetic field of a finite solenoid is shown in **Figure 28.29**. Note how the magnetic field pattern resembles that of the magnetic field around a bar magnet.

If a solenoid is bent into a circle so that its two ends are connected (**Figure 28.30*a***), we obtain a **toroid**. The magnetic field lines in the interior of a toroid (that is, the donut-shaped cavity enclosed by the coiled wire) close on themselves; thus they do not need to reconnect outside the toroid, as in the case of a solenoid. The entire magnetic field is contained inside

Figure 28.29 Magnetic field line pattern in a solenoid of finite length.

(*a*) Magnetic field of a solenoid, shown in cross section



(*b*) The magnetic field of a solenoid

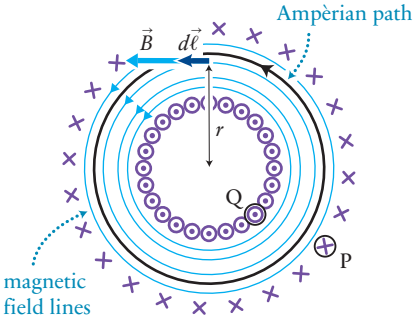


Figure 28.30 A toroid is a solenoid bent into a ring.

(*a*) Toroid

(*b*) Cross section showing magnetic field and a choice of Ampèrian path

QUANTITATIVE TOOLS

the cavity. Symmetry requires the field lines to form circles inside the cavity; the field lines run in the direction of your right thumb when you curl the fingers of your right hand along the direction of the current through the windings. Figure 28.30*b* shows a few representative magnetic field lines in a cross section of the toroid where the current goes into the page on the outside rim of the toroid (as at point P, for example) and out of the page on the inside rim (as at point Q).

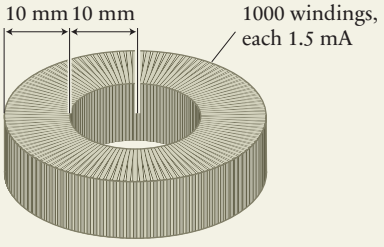
To determine the magnitude of the magnetic field, we apply Ampère's law (Eq. 28.1) to a circular path of radius r that coincides with a magnetic field line (Figure 28.30*b*). Because the field is tangential to the integration path, we have $\vec{B} \cdot d\vec{\ell} = B\, d\ell$. Furthermore, symmetry requires the magnitude of the magnetic field to be the same all along the field line, and so we can pull B out of the integration:

$$\oint \vec{B} \cdot d\vec{\ell} = \oint B\, d\ell = B \oint dl = B(2\pi r). \tag{28.7}$$

The Ampèrian path encircles one side of all of the windings, so if there are N windings, the encircled current is

$$I_{\text{enc}} = NI. \tag{28.8}$$

Substituting these last two equations into Ampère's law (Eq. 28.1), we obtain



$$B = \mu_0 \frac{NI}{2\pi r} \quad \text{(toroid)}. \tag{28.9}$$

This result tells us that in contrast to a solenoid, the magnitude of the magnetic field in a toroid is not constant—it depends on the distance r to the axis through the center of the toroid.

EXAMPLE 28.5 Square toroid

The toroid in **Figure 28.31** has 1000 windings carrying a current of 1.5 mA. Each winding is a square of side length 10 mm, and the toroid's inner radius is 10 mm. What is the magnitude of the magnetic field at the center of the winding squares?

Figure 28.31 Example 28.5.

❶ **GETTING STARTED** The fact that the windings are square does not change the magnetic field pattern. The magnetic field is still circular as in Figure 28.30*b*, and the arguments given in the derivation of Eq. 28.9 still apply.

❷ **DEVISE PLAN** I can use Eq. 28.9 to determine the magnitude of the magnetic field.

❸ **EXECUTE PLAN** The distance from the center of the toroid to the center of each winding is 10 mm + 5 mm = 15 mm, so

$$B = (4\pi \times 10^{-7}\ \text{T} \cdot \text{m/A}) \frac{(1000)(1.5 \times 10^{-3}\ \text{A})}{2\pi(0.015\ \text{m})}$$

$$= 2.0 \times 10^{-5}\ \text{T}. \checkmark$$

❹ **EVALUATE RESULT** The magnetic field magnitude I obtain is small—comparable to the magnitude of Earth's magnetic field at ground level—but the current through the toroid is very small, so my answer is not unreasonable.

28.14 Use Ampère's law to determine the magnetic field outside a toroid at a distance r from the center of the toroid (*a*) when r is greater than the toroid's outer radius and (*b*) when r is smaller than the toroid's inner radius.

QUANTITATIVE TOOLS

28.7 Magnetic fields due to currents

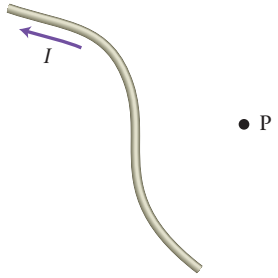
Ampère's law allows us to determine the magnetic field in only a few symmetrical situations involving current-carrying conductors. For any other situation, such as the one illustrated in **Figure 28.32*a***, Ampère's law is of little help. Suppose, for example, that we are interested in determining the magnetic field at point P due to the current of magnitude I through this conductor. To calculate this field, we develop a procedure that parallels the procedure we developed in Section 23.7 to calculate the electric field of continuous charge distributions.

We begin by treating the wire as a current path and dividing it into small segments, each of length $d\ell$. For each segment we can define a vector $d\vec{\ell}$ that has length $d\ell$ and points in the direction of the current. One such vector segment is shown in Figure 28.32*b*. Let the magnetic field at P due to this segment be $d\vec{B}_s$. If we obtain an expression for the magnetic field due to the segment $d\vec{\ell}$ at an arbitrary position, we can determine the contributions of all the segments that make up the wire to the magnetic field at P and sum these to obtain $\vec{B}$. In the limit of infinitesimally small segments, this summation becomes an integral:

$$\vec{B} = \int_{\substack{\text{current}\\ \text{path}}} d\vec{B}_s, \tag{28.10}$$

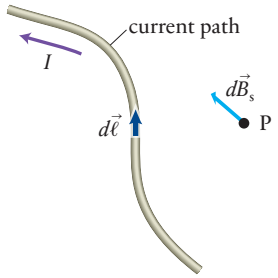
where the integration is to be taken along the path followed by the current—that is, a path in the shape of the wire and in the direction of the current.

Before we can carry out the integration, we need to obtain an expression for the magnetic field $d\vec{B}_s$ of a current-carrying segment $d\vec{\ell}$. Because the magnetic field caused by one small segment is too feeble to measure, we cannot determine this field experimentally. From the expression for the magnetic field of a long straight current-carrying wire, however, it is possible to deduce what the field of a segment such as $d\vec{\ell}$ should be.



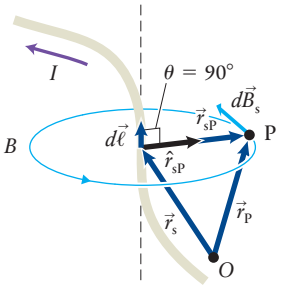
Let us first examine the direction of the magnetic field contribution $d\vec{B}_s$ due to a segment $d\vec{\ell}$ that is located such that $d\vec{\ell}$ is perpendicular to the vector $\vec{r}_{sP}$ pointing from $d\vec{\ell}$ to P ($\theta = 90°$, Figure 28.32*c*). The field lines of this segment are circles centered on the line of motion of the charge carriers causing the current through $d\vec{\ell}$ (see Figures 28.32*a* and *c*). Therefore the magnetic field at P due to $d\vec{\ell}$ is tangent to the circular field line through P. The direction of $d\vec{B}_s$ can be determined by associating the direction of $d\vec{B}_s$ with a vector product. To this end, we denote the unit vector pointing from the segment to P by $\hat{r}_{sP}$, as shown in Figure 28.32*c*. The direction of the vector product $d\vec{\ell} \times \hat{r}_{sP}$ is that of $d\vec{B}_s$: If you curl the fingers of your right hand from $d\vec{\ell}$ to $\hat{r}_{sP}$ in Figure 28.32*c*, your thumb points in the direction of $d\vec{B}_s$.

We expect the magnitude dB_s to be proportional to the current I through the segment and to the length $d\ell$ of the segment. The greater the current or the longer the segment, the stronger the magnetic field. We also expect dB_s to depend on the distance r_{sP} to the segment. The field line picture for magnetic fields suggests that the magnetic field should decrease with distance r_{sP} as $1/r_{sP}^2$, just like the electric field. Finally, for any other segment than the one shown in Figure 28.32*c* we expect the magnetic field to depend on the angle θ between $d\vec{\ell}$ and $\vec{r}_{sP}$: For $\theta = 0$ (which is along the direction of the current) the magnetic field is zero, and for $\theta = 90°$ the magnetic field is maximum. The trigonometric function that fits this behavior is $\sin\theta$. Putting all this information in mathematical form, we obtain



$$dB_s = \frac{\mu_0}{4\pi}\frac{I\,d\ell\sin\theta}{r_{sP}^2} \quad (0 \leq \theta \leq \pi). \tag{28.11}$$

Figure 28.32 The magnetic field at point P due to an arbitrarily shaped current-carrying wire cannot be obtained from Ampère's law. As shown in (*c*), the direction of $d\vec{B}_s$ can be found by taking the vector product of $d\vec{\ell}$, which has length $d\ell$ and direction given by the current through the wire, and $\hat{r}_{sP}$, which points from the segment to point P: $d\vec{\ell} \times \hat{r}_{sP}$.



(*a*) Arbitrarily shaped current-carrying wire

(*b*) Small segment $d\vec{\ell}$ contributes magnetic field $d\vec{B}_s$ at point P

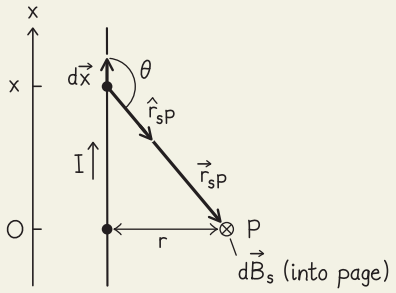
(*c*) Determining the direction of $d\vec{B}_s$

QUANTITATIVE TOOLS

The proportionality factor $\mu_0/4\pi$ is obtained by deriving this expression from Ampère's law, but the mathematics is beyond the scope of this book. Instead, we use the reverse approach and show in Example 28.6 that Eq. 28.11 yields the correct result for a long straight current-carrying wire.

Incorporating what we know about the direction of $d\vec{B}_s$, we can also write Eq. 28.11 in vector form:

$$d\vec{B}_s = \frac{\mu_0}{4\pi}\frac{I\,d\vec{\ell}\times\hat{r}_{sP}}{r_{sP}^2} \quad \text{(constant current)}, \tag{28.12}$$



where $\hat{r}_{sP}$ is the unit vector pointing along $\vec{r}_{sP}$ from s to P. Equation 28.12 is known as the **Biot-Savart law**. By substituting Eq. 28.12 into Eq. 28.10, we have a prescription for calculating the magnetic field produced by any constant current.

EXAMPLE 28.6 Another look at the magnetic field generated by a long straight current-carrying wire

A long straight wire carries a current of magnitude I. Use the Biot-Savart law to derive an expression for the magnetic field $\vec{B}$ produced at point P a radial distance r from the wire.

❶ **GETTING STARTED** I begin by making a sketch of the wire (**Figure 28.33**). I arbitrarily orient the wire vertically and then choose the positive x axis along the direction of the wire. Because the magnetic field produced by the current has cylindrical symmetry, I can set the origin anywhere along the axis without loss of generality. For simplicity, I let the origin be at the height of point P. I assume the wire is of infinite length.

Figure 28.33

❷ **DEVISE PLAN** To use the Biot-Savart law (Eq. 28.12), I need to divide the wire into segments, determine the magnetic fields due to all segments, and then take the sum of the fields. In the limit of infinitesimally small segments, this sum becomes the integral given by Eq. 28.10 with the wire serving as the current path along which the integration is carried out.

I indicate one such segment in my sketch, calling it $d\vec{x}$. The magnetic field $d\vec{B}_s$ at P generated by this segment is given by Eq. 28.12. The unit vector $\hat{r}_{sP}$ in this equation points from $d\vec{x}$ to P, and the direction of $d\vec{B}_s$ is given by the right-hand current rule: I point my right thumb along the direction of the current and curl my fingers around the wire to determine the direction of $d\vec{B}_s$ (into the page at P in my sketch). Alternatively, I can use the vector product $d\vec{x}\times\hat{r}_{sP}$ to determine the direction of $d\vec{B}_s$: I line up the fingers of my right hand along $d\vec{x}$ in Figure 28.33 and curl them toward $\hat{r}_{sP}$. When I do this, my thumb points in the direction of the magnetic field. Both methods yield the same result: $d\vec{B}_s$ points into the page.

Note that all the segments $d\vec{x}$ along the wire produce a magnetic field in the same direction. This means I can take the algebraic sum of the *magnitudes* of $d\vec{B}_s$ to determine the magnitude of the magnetic field at P. Then I can use Eq. 28.11 to express dB_s in terms of dx and integrate the resulting expression from $x = -\infty$ to $x = +\infty$ to determine the magnitude of the magnetic field at P.

❸ **EXECUTE PLAN** Because r_{sP} and θ in Eq. 28.11 both depend on x, I need to express them in terms of x before I can carry out the integration. By the Pythagorean theorem,

$$r_{sP}^2 = x^2 + r^2,$$

and remembering that $\sin\theta = \sin(180^\circ - \theta)$, I write

$$\sin\theta = \frac{r}{r_{sP}} = \frac{r}{\sqrt{x^2+r^2}}.$$

Substituting these last two results into Eq. 28.11 and using dx in place of $d\ell$, I get

$$dB_s = \frac{\mu_0 I}{4\pi}\frac{r}{\sqrt{x^2+r^2}}\frac{1}{x^2+r^2}\,dx = \frac{\mu_0 I r}{4\pi}\frac{dx}{[x^2+r^2]^{3/2}},$$

and integrating this result over the length of the wire gives me

$$B = \frac{\mu_0 I r}{4\pi}\int_{-\infty}^{+\infty}\frac{dx}{[x^2+r^2]^{3/2}} = \frac{\mu_0 I r}{4\pi}\left[\frac{1}{r^2}\frac{x}{[x^2+r^2]^{1/2}}\right]_{x=-\infty}^{x=+\infty}$$

$$B = \frac{\mu_0 I}{2\pi r}. \checkmark$$

❹ **EVALUATE RESULT** This is identical to the result I obtained using Ampère's law in Example 28.3, a strong indication that my result here is correct.

QUANTITATIVE TOOLS

28.15 Imagine a long straight wire of semi-infinite length, extending from $x = 0$ to $x = +\infty$, carrying a current of constant magnitude I. What is the magnitude of the magnetic field at a point P located a perpendicular distance d from the end of the wire that is at $x = 0$?

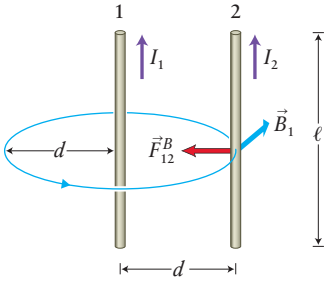
The expression for the magnitude of the magnetic field generated by a long straight wire obtained in Example 28.6 can lead us to an expression for the forces exerted by two current-carrying wires on each other. Consider the situation illustrated in **Figure 28.34**: Two parallel wires, of length ℓ and separated by a distance d, carry currents of magnitudes I_1 and I_2. To determine the magnetic force exerted by wire 1 on wire 2, we must first determine the magnitude and direction of the magnetic field generated by wire 1 at the location of wire 2 and then substitute this information into Eq. 27.8, which gives the magnetic force exerted on a straight current-carrying wire of length ℓ in a magnetic field $\vec{B}$:

$$\vec{F}^B = I\vec{\ell} \times \vec{B}, \tag{28.13}$$

where $\vec{\ell}$ is a vector whose magnitude is given by the length ℓ of the wire and whose direction is given by that of the current through the wire. Using the right-hand current rule, we see that the magnetic field $\vec{B}_1$ generated by wire 1 at the location of wire 2 points into the page (Figure 28.34). The result I obtained in Example 28.6 gives the magnitude of this field:

$$B_1 = \frac{\mu_0 I_1}{2\pi d}. \tag{28.14}$$

Because the magnetic field is perpendicular to $\vec{\ell}$, Eq. 28.13 yields for the magnitude of the magnetic force acting on wire 2



$$F_{12}^B = I_2 \ell B_1 \tag{28.15}$$

or, substituting Eq. 28.14,

$$F_{12}^B = \frac{\mu_0 \ell I_1 I_2}{2\pi d} \quad \text{(parallel straight wires carrying constant currents).} \tag{28.16}$$

The direction of this force follows from the vector product in Eq. 28.13: Using the right-hand force rule (place the fingers of your right hand along $\vec{\ell}$ in Figure 28.34, which points in the direction of I_2, and bend them toward $\vec{B}_1$), you can verify that the force points toward wire 1.

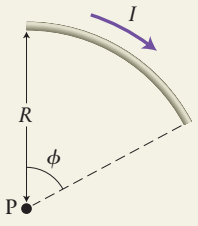


Figure 28.34 Calculating the magnetic force exerted by one current-carrying wire on another.

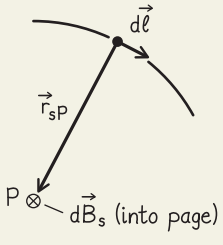
EXAMPLE 28.7 The magnetic field generated by a circular arc of current-carrying wire



A wire bent into a circular arc of radius R subtending an angle ϕ carries a current of magnitude I (**Figure 28.35**). Use the Biot-Savart law to derive an expression for the magnitude of the magnetic field $\vec{B}$ produced at point P, located at the center of the arc.

Figure 28.35 Example 28.7.

❶ **GETTING STARTED** I begin by evaluating what a small segment of length $d\ell$ along the arc contributes to the magnetic field. I therefore make a sketch showing one segment $d\vec{\ell}$ and the vector $\vec{r}_{sP}$ pointing from the segment to P (**Figure 28.36**). Using the right-hand vector product rule, I see that the direction of $d\vec{\ell} \times \vec{r}_{sP}$, and therefore the magnetic field $d\vec{B}_s$, are into the page at P.

Figure 28.36

(Continued)

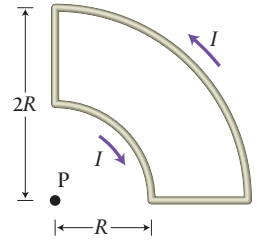
QUANTITATIVE TOOLS

2 DEVISE PLAN Because all segments contribute a magnetic field in the same direction, I can integrate Eq. 28.11 over the arc to obtain the magnitude of the magnetic field at P.

3 EXECUTE PLAN Because $d\vec{\ell}$ and $\vec{r}_{sP}$ are always perpendicular to each other, I can write for Eq. 28.11

$$dB_s = \frac{\mu_0}{4\pi}\frac{I\,d\ell\,\sin 90°}{R^2} = \frac{\mu_0}{4\pi}\frac{I\,d\ell}{R^2}, \qquad (1)$$

where I have substituted the radius R for the magnitude of $\vec{r}_{sP}$. To change the integration variable from $d\ell$ to the angular variable $d\phi$, I substitute $d\ell = R\,d\phi$ into Eq. 1:



$$dB_s = \frac{\mu_0 I}{4\pi R}\,d\phi$$

$$B = \int_{arc} dB_s = \frac{\mu_0 I}{4\pi R}\int_0^{\phi} d\phi$$

$$= \frac{\mu_0 I\phi}{4\pi R}. \checkmark$$

4 EVALUATE RESULT My expression for B shows that at P the magnetic field magnitude is proportional to the current through the arc, as I expect. It is also proportional to the angle ϕ of the arc (when measured in radians), also what I expect given that two such arcs should yield twice the magnetic field. Finally, B is inversely proportional to the arc radius R. That dependence on the radius makes sense because increasing the radius increases the distance between P and the arc, thus diminishing the magnetic field.

Figure 28.37 A current loop carrying a current of constant magnitude I (Checkpoint 28.16).

28.16 What is the magnitude of the magnetic field (*a*) at the center of a circular current loop of radius R and (*b*) at point P near the current loop in Figure 28.37? Both arcs carry a current of constant magnitude I.

28.8 Magnetic field of a moving charged particle

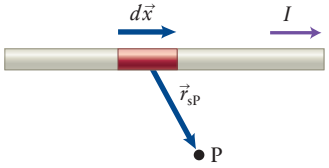
Let us now use the Biot-Savart law to obtain an expression for the magnetic field caused by charged particles moving at constant velocity.* Consider first a straight wire carrying a current of magnitude I and aligned with the x axis, as in Figure 28.38*a*. The magnetic field generated at point P by a small segment $d\vec{x}$ is given by Eq. 28.12:

$$d\vec{B}_s = \frac{\mu_0}{4\pi}\frac{I\,d\vec{x}\times\hat{r}_{sP}}{r_{sP}^2}, \qquad (28.17)$$

where $\hat{r}_{sP}$ is a unit vector pointing from the segment $d\vec{x}$ to the point at which we wish to determine the magnetic field, and r_{sP} is the distance between the segment and the point P. Suppose the segment contains an amount of charge dq. Let the charge carriers responsible for the current take a time interval dt to have displacement $d\vec{x}$ (Figure 28.38*b*). According to the definition of current (Eq. 27.2), we have

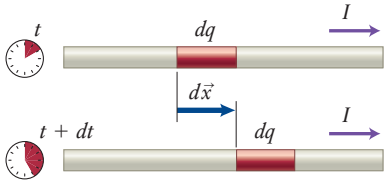
$$I \equiv \frac{dq}{dt}, \qquad (28.18)$$

and so



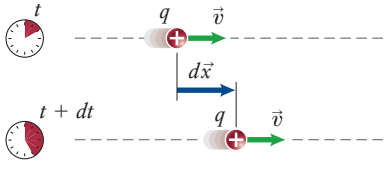
$$Id\vec{x} = \frac{dq}{dt}\,d\vec{x} = dq\,\frac{d\vec{x}}{dt} = dq\,\vec{v}, \qquad (28.19)$$

where $\vec{v}$ is the velocity at which the charge carriers move down the wire. In the limiting case where the segment $d\vec{x}$ contains just a single charge carrier carrying a charge q (Figure 28.38*c*), dq becomes q and



$$Id\vec{x} = q\vec{v}. \qquad (28.20)$$

Figure 28.38 We use the Biot-Savart law to obtain an expression for the magnetic field caused by charged particles moving at constant velocity.



(*a*) Small segment of current-carrying wire causes magnetic field at point P

(*b*) Displacement of charge dq in time interval dt

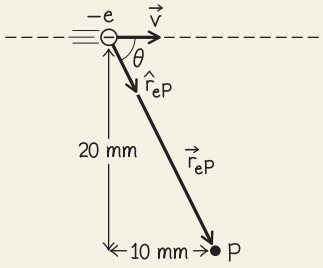
(*c*) Displacement of charged particle in time interval dt

*In the derivation that follows, we assume $v \ll c_0$ and ignore any relativistic effects as described in Sections 27.4 and 27.8.

QUANTITATIVE TOOLS

Substituting this result into Eq. 28.17, we obtain an expression for the magnetic field of a single moving charged particle:

$$\vec{B} = \frac{\mu_0}{4\pi}\frac{q\vec{v}\times\hat{r}_{\mathrm{pP}}}{r_{\mathrm{pP}}^2} \quad \text{(single particle)}, \tag{28.21}$$



where r_{pP} is the distance between the particle and P, and $\hat{r}_{\mathrm{pP}}$ is the unit vector pointing from the particle to P.

EXAMPLE 28.8 Magnetic field generated by a moving electron

An electron carrying a charge $-e = -1.60\times10^{-19}$ C moves in a straight line at a speed $v = 3.0\times10^{7}$ m/s. What are the magnitude and direction of the magnetic field caused by the electron at a point P 10 mm ahead of the electron and 20 mm away from its line of motion?

❶ **GETTING STARTED** I begin by drawing the moving electron and the point P at which I am to determine the magnetic field (**Figure 28.39**).

Figure 28.39

❷ **DEVISE PLAN** The magnetic field created by a moving charged particle is given by Eq. 28.21.

❸ **EXECUTE PLAN** The unit vector $\hat{r}_{\mathrm{eP}}$ points from the electron to P, and so $\vec{v}\times\hat{r}_{\mathrm{eP}}$ points into the page. Because the charge of the electron is negative, the magnetic field points in the opposite direction, out of the page. ✔

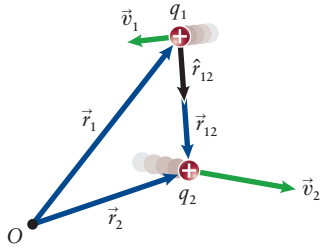
The magnitude of the vector $\vec{r}_{\mathrm{eP}}$ in Figure 28.39 is $r_{\mathrm{eP}} = \sqrt{(10\text{ mm})^2+(20\text{ mm})^2} = 22.36$ mm, and $\sin\theta = (20\text{ mm})/(22.36\text{ mm}) = 0.8944$. Substituting these values into Eq. 28.11 thus yields for the magnitude of the magnetic field

$$B = \frac{(4\pi\times10^{-7}\,\mathrm{T\cdot m/A})}{4\pi}\frac{(1.60\times10^{-19}\,\mathrm{C})(3.0\times10^{7}\,\mathrm{m/s})(0.8944)}{(22.36\times10^{-3}\,\mathrm{m})^2}$$

$$= 8.6\times10^{-16}\,\mathrm{T}. \checkmark$$

❹ **EVALUATE RESULT** The magnetic field magnitude I obtained is much too small to be detected, but that's what I expect for a single electron. I can verify the direction of the magnetic field by applying the right-hand current rule to the current caused by the electron. Because the electron carries a negative charge, its motion to the right in Figure 28.39 causes a current to the left. Pointing my right-hand thumb to the left in the figure, I observe that the fingers curl out of the page at P, in agreement with what I determined earlier for the direction of $\vec{B}$.

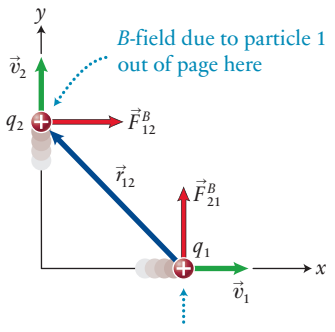
We can now combine the expression for the magnetic field caused by a moving charged particle (Eq. 28.21) with that for the magnetic force exerted on another moving charged particle (Eq. 27.19; $\vec{F}_{\mathrm{p}}^{B} = q\vec{v}\times\vec{B}$) to determine the magnetic interaction between two moving charged particles. Consider the situation illustrated in **Figure 28.40**. The magnetic field caused by particle 1 at the location of particle 2 is given by Eq. 28.21:



$$\vec{B}_1(\vec{r}_2) = \frac{\mu_0}{4\pi}\frac{q_1\vec{v}_1\times\hat{r}_{12}}{r_{12}^2}, \tag{28.22}$$

where r_{12} is the magnitude of the vector $\vec{r}_{12}$ pointing from particle 1 to particle 2 and $\hat{r}_{12}$ is a unit vector pointing along $\vec{r}_{12}$. Substituting this expression into Eq. 27.19, we obtain for the magnetic force exerted by particle 1 on particle 2

$$\vec{F}_{12}^{B} = q_2\vec{v}_2\times\vec{B}_1(\vec{r}_2) = \frac{\mu_0}{4\pi}\frac{q_1q_2}{r_{12}^2}\vec{v}_2\times(\vec{v}_1\times\hat{r}_{12}). \tag{28.23}$$



Notice the appearance of the double vector product: We must first take the vector product of $\vec{v}_1$ and $\hat{r}_{12}$ and then take the vector product of $\vec{v}_2$ and the result of the first vector product.

Figure 28.40 Magnetic interaction of two moving charged particles.

QUANTITATIVE TOOLS

Figure 28.41 The forces that moving charged particles exert on each other do not necessarily point in opposite directions.

Equation 28.23 also shows that we need a moving charged particle in order to generate a magnetic field ($\vec{v}_1 \neq 0$) and another moving charged particle to "feel" that magnetic field ($\vec{v}_2 \neq 0$), in agreement with our discussion in the first part of this chapter.

In contrast to the electric force, the magnetic force does not satisfy Eq. 8.15, $\vec{F}_{12} = -\vec{F}_{21}$. To see this, consider the two positively charged moving particles shown in **Figure 28.41**. Particle 1, carrying a charge q_1, travels in the positive x direction, while particle 2, carrying charge q_2, travels in the positive y direction. The force exerted by 1 on 2 is given by Eq. 28.23. Applying the right-hand vector product rule, we determine that the vector product $\vec{v}_1 \times \hat{r}_{12}$ on the right side of Eq. 28.23 points out of the page. Applying the right-hand vector product rule again to the vector product of $\vec{v}_2$ and $\vec{v}_1 \times \hat{r}_{12}$, we see that $\vec{F}_{12}^{B}$ points in the positive x direction.* The force exerted by 2 on 1 is obtained by switching the subscripts 1 and 2 in Eq. 28.23:

$$\vec{F}_{21}^{B} = \frac{\mu_0}{4\pi}\frac{q_1 q_2}{r_{12}^2}\vec{v}_1 \times (\vec{v}_2 \times \hat{r}_{21}), \tag{28.24}$$

where we have used that $q_1 q_2 = q_2 q_1$ and $r_{12}^2 = r_{21}^2$. Applying the right-hand vector product rule twice, we find that $\vec{F}_{21}^{B}$ points in the positive y direction, and so the magnetic forces that the two particles exert on each other, while equal in magnitude, do not point in opposite directions, as we would expect from Eq. 8.15.

We derived Eq. 8.15 from the fact that the momentum of an isolated system of two particles is constant, which in turn follows from conservation of momentum, one of the most fundamental laws of physics. The electric and magnetic fields of isolated moving charged particles, however, are not constant, and as we shall see in Chapter 30, we can associate a flow of both momentum and energy with changing electric and magnetic fields. Therefore we need to account not only for the momenta of the two charged particles in Figure 28.41, but also for the momentum carried by their fields—which goes beyond the scope of this book. Even though Eq. 8.15 is not satisfied by the magnetic force, the momentum of the system comprising the two particles and their fields is still constant.

Substituting Coulomb's law and Eq. 28.23 into Eq. 27.20, $\vec{F}_{\mathrm{p}}^{EB} = q(\vec{E} + \vec{v} \times \vec{B})$, we obtain an expression for the electromagnetic force that two moving charged particles exert on each other:

$$\vec{F}_{12}^{EB} = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r_{12}^2}[\hat{r}_{12} + \mu_0\epsilon_0\vec{v}_2 \times (\vec{v}_1 \times \hat{r}_{12})]. \tag{28.25}$$

By comparing the result obtained in Example 28.6 with Eq. 27.38 and substituting $k = 1/(4\pi\epsilon_0)$ (Eq. 24.7), we see that $\mu_0 = 1/(\epsilon_0 c_0^2)$ or

*Here is another way you can determine the direction of the magnetic force exerted by particle 1 on particle 2. The motion of particle 1 corresponds to a current directed in the positive x direction. Using the right-hand current rule, it follows that the magnetic field of 1 points out of the xy plane at any location above the x axis. The magnetic field due to 1 at the location of 2 thus points out of the plane. The motion of particle 2 corresponds to a current directed in the positive y direction. To determine the direction of the magnetic force exerted on this "current," we can use the right-hand force rule. When you curl the fingers of your right hand from the positive y axis to the direction of $\vec{B}_1$ at particle 2 (out of the page), your thumb points in the positive x direction, as we found before.

QUANTITATIVE TOOLS

$\mu_0\epsilon_0 = 1/c_0^2$, where c_0 is the speed of light. Using this information, we can write Eq. 28.25 as

$$\vec{F}_{12}^{EB} = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r_{12}^2}\left[\hat{r}_{12} + \frac{\vec{v}_2 \times (\vec{v}_1 \times \hat{r}_{12})}{c_0^2}\right] \quad (v \ll c_0). \qquad (28.26)$$

This equation is the most general expression for the electromagnetic interaction between moving charged particles. Because in most applications the speeds of charged particles are significantly smaller than the speed of light, the second term in the square brackets in Eq. 28.26 is much smaller than the first term, which represents the electric contribution to the electromagnetic force from Coulomb's law.

28.17 Consider two protons 1 and 2, each carrying a charge $+e = 1.6 \times 10^{-19}$ C, separated by 1.0 mm moving at 3×10^5 m/s parallel to each other and perpendicular to their separation. (*a*) What is the direction of the magnetic force that each proton exerts on the other? (*b*) Determine the ratio of the magnitudes of the magnetic and electric forces that the two exert on each other.

Chapter Summary

Current loops (Sections 28.1–28.3)

Concepts A magnetic field is produced by magnets, by current-carrying wires, and by moving charged particles.

The magnetic field pattern produced by a wire carrying a current and bent into a circular **current loop** is similar to the field pattern of a magnetic dipole.

A spinning charged particle has a magnetic field identical to that of an infinitesimally small magnetic dipole.

The **magnetic dipole moment** $\vec{\mu}$ is a vector that specifies the orientation and magnitude of a magnetic dipole. The direction of $\vec{\mu}$ is the same as the direction of the magnetic field at the dipole center. For a bar magnet, the direction of $\vec{\mu}$ is from south pole to north pole. For a current loop, the direction of $\vec{\mu}$ is the direction in which your thumb points when you curl the fingers of your right hand in the direction of the current.

A current loop placed in a magnetic field tends to rotate such that the direction of $\vec{\mu}$ aligns with the direction of the magnetic field.

Ampère's law (Sections 28.4, 28.5)

Concepts **Ampère's law** states that the line integral of the magnetic field along a closed path, called an **Ampèrian path,** is proportional to the current encircled by the path. See the Procedure box "Calculating the magnetic field using Ampère's law" on page 987 for how to apply Ampère's law.

Quantitative Tools If a constant current I_{enc} is encircled by an **Ampèrian path,** then by **Ampère's law,** the line integral of the magnetic field around the path is

$$\oint \vec{B} \cdot d\vec{\ell} = \mu_0 I_{\text{enc}}, \tag{28.1}$$

where $d\vec{\ell}$ is an infinitesimal segment of length of the Ampèrian path and μ_0, called the **permeability constant,** has the value

$$\mu_0 = 4\pi \times 10^{-7}\ \text{T} \cdot \text{m/A}.$$

If a long, straight wire carries a current I, the magnitude of the magnetic field it produces at a distance d from the wire is

$$B = \frac{\mu_0 I}{2\pi d}.$$

The magnitude of the magnetic field produced by a large sheet carrying a uniformly distributed current is

$$B = \tfrac{1}{2}\mu_0 K,$$

where K is the current magnitude per unit width of the sheet.

Solenoids and toroids (Section 28.6)

Concepts A **solenoid** is a long, tightly wound helical coil of wire. The diameter of the coil is much smaller than its length. Outside an infinitely long solenoid, the magnetic field approaches zero; inside the solenoid, the magnetic field is directed parallel to the solenoid length.

A **toroid** is a solenoid bent into a circle. The entire magnetic field is contained within the windings of the toroid, and the magnetic field lines form circles around the center of the toroid.

Quantitative Tools If an infinitely long **solenoid** that has n windings per unit length carries a current I, the magnetic field the solenoid produces in its interior has magnitude

$$B = \mu_0 n I. \tag{28.6}$$

If a **toroid** that has N windings carries a current I, the magnetic field the toroid produces inside the windings at a distance r from the toroid center has magnitude

$$B = \mu_0 \frac{NI}{2\pi r}. \tag{28.9}$$

Biot-Savart law (Section 28.7)

Quantitative Tools **Biot-Savart law:** If a small segment of wire $d\vec{\ell}$ carries a constant current I, the magnetic field produced by the segment at a point P a distance r_{sP} from the segment is

$$d\vec{B}_s = \frac{\mu_0}{4\pi} \frac{I\, d\vec{\ell} \times \hat{r}_{sP}}{r_{sP}^2}, \tag{28.12}$$

where $d\vec{\ell}$ points in the current direction and $\hat{r}_{sP}$ points from the segment to P. The magnetic field is

$$\vec{B} = \int_{\text{current path}} d\vec{B}_s. \tag{28.10}$$

A circular arc of radius R spanning an angle ϕ and carrying a current I produces a magnetic field at the center of the circle of magnitude

$$B = \frac{\mu_0 I \phi}{4\pi R}.$$

Magnetic field of a moving charged particle (Section 28.8)

Quantitative Tools A particle that has charge q and velocity $\vec{v}$ produces at a point P a magnetic field

$$\vec{B} = \frac{\mu_0}{4\pi} \frac{q\vec{v} \times \hat{r}_{pP}}{r_{pP}^2} \tag{28.21}$$

where $\hat{r}_{pP}$ points from the particle to P and r_{pP} is the distance from the particle to P. If charged particles 1 and 2 carrying charges q_1 and q_2 are a distance r_{12} apart and have velocities $\vec{v}_1$ and $\vec{v}_2$, the electromagnetic force exerted by particle 1 on particle 2 is

$$\vec{F}_{12}^{EB} = \frac{1}{4\pi\epsilon_0} \frac{q_1 q_2}{r_{12}^2} \left[\hat{r}_{12} + \frac{\vec{v}_2 \times (\vec{v}_1 \times \hat{r}_{12})}{c_0^2} \right], \tag{28.26}$$

where $\hat{r}_{12}$ points from particle 1 to particle 2 and

$$c_0 = \frac{1}{\sqrt{\mu_0 \epsilon_0}}$$

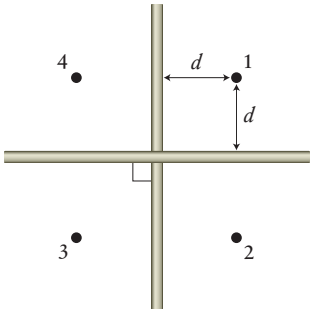
is the speed of light. Equations 28.21 and 28.26 are valid only if $v \ll c_0$.

Questions and Problems

For instructor-assigned homework, go to Mastering Physics

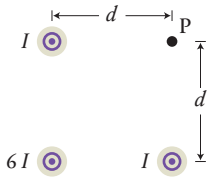
Dots indicate difficulty level of problems: • = easy, •• = intermediate, ••• = hard; CR = context-rich problem.

28.1 Source of the magnetic field



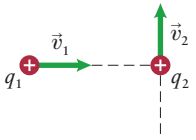
1. A negatively charged particle sits midway between the two magnets in Figure P28.1, at rest relative to the magnets. If the magnet on the left is twice as strong as the magnet on the right, what is the direction of the magnetic force exerted on the particle? •

Figure P28.1



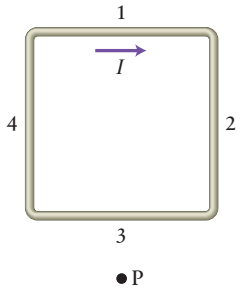
2. There are two parallel wires, each carrying a current I in such a way that in one wire the current flows along positive x-direction and in the other in the negative x-direction. What is the direction of magnetic field at any point at the midway between the two wires and the plane defined by them? •
3. Consider a conducting wire having a shape of a hexagon carries a current that flows in an anti-clockwise manner when viewed from the above. What is the direction of the magnetic field at the center of the hexagon due to each side of the loop? •
4. A negatively charged particle is at rest in a region where a uniform magnetic field points in the positive x direction and a uniform electric field points in the positive y direction. What is the direction of the vector sum of the forces exerted on the particle? ••
5. Suppose two electrons move on parallel, closely spaced paths in the $+z$ direction, each with velocity $\vec{v}$ in the Earth reference frame. Discuss all forces exerted on the electrons. ••
6. Two protons are fired toward each other on closely spaced paths, one moving in the $+z$ direction and one in the $-z$ direction. As they pass close to each other, is the magnetic force between them attractive, repulsive, or neither? ••
7. The two insulated, current-carrying wires in Figure P28.7 cross at right angles, and each carries a current I. The locations labeled 1–4 are all in the plane defined by the wires, with each location a perpendicular distance d from both wires. At how many of these four locations is the magnetic field (*a*) directed out of the page, (*b*) directed into the page, and (*c*) equal to zero? ••

Figure P28.7



8. Two of the three wires in Figure P28.8 carry current I, and the third wire carries current $6I$. The location labeled P is a distance d from each of the wires carrying current I. What is the direction of the magnetic field at P? ••

Figure P28.8



9. Two positively charged particles 1 and 2 are moving in the same plane, with the velocity of particle 1 perpendicular to the velocity of particle 2. At the instant shown in Figure P28.9, particle 2 is on the line that defines the velocity of particle 1. (Take their speeds to be much less than c_0.) For this instant, describe and sketch the direction of the magnetic force that each particle exerts on the other. •••

Figure P28.9

10. In Figure P28.10, (*a*) specify the direction of the magnetic field at the location labeled P due to each of the four sides 1–4 of the current loop. (*b*) Which side produces the strongest magnetic field at P? (*c*) What additional information is needed to determine the direction of the magnetic field at P due to the loop? •••

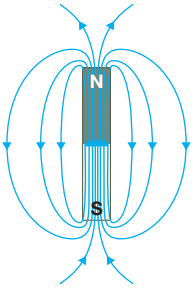


Figure P28.10

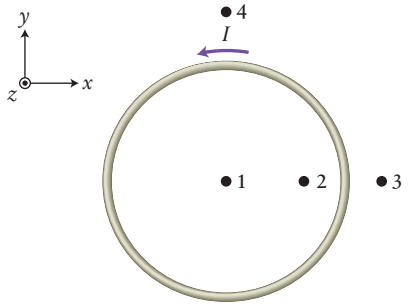
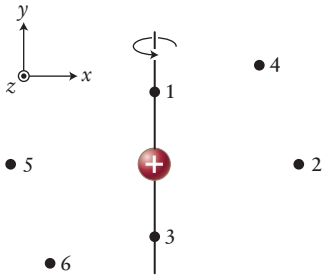
28.2 Current loops and spin magnetism



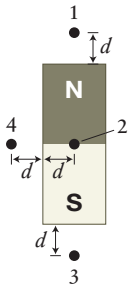
11. A hexagonal wire loop with side 5 cm carries a current 2 A in a clockwise direction when viewed from the top. Where you can predict the magnitude of the magnetic field inside the loop will be maximum by taking symmetry into consideration? •
12. Could Figure P28.12 represent the magnetic field due to a bar magnet that has a rectangular cross section rather than a circular cross section? •

Figure P28.12



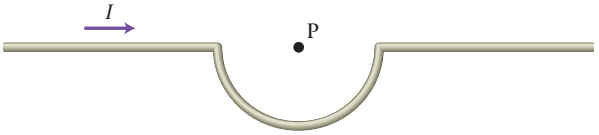
13. A loop of wire carries a current I as shown in Figure P28.13. Determine the direction of the magnetic field at the points labeled. •

Figure P28.13



14. Figure P28.14 shows a positively charged spherical object that is spinning. For each of the labeled points, state the direction of the magnetic field. Assume all points lie in the xy plane. ••

Figure P28.14

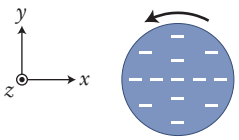


15. Consider four identical square current loops arranged in a square with four times the area of one loop. Use this arrangement to predict how the magnetic field far from a small current loop depends on the area of the loop if the current and orientation of the loop is held fixed. ••
16. Consider two charged particles 1 and 2, each of them able to translate (move from place to place) and to spin. In which of the following circumstances is there a magnetic interaction between the particles: (*a*) neither particle translating, neither particle spinning; (*b*) neither translating, only particle 1 spinning; (*c*) neither translating, both spinning; (*d*) 1 at rest and not spinning, 2 translating and not spinning; (*e*) 1 at rest and not spinning, 2 translating and spinning; (*f*) 1 spinning and not translating, 2 translating and not spinning; (*g*) 1 spinning and not translating, 2 translating and spinning; (*h*) both translating, neither spinning; (*i*) both translating, only 2 spinning; (*j*) both translating, both spinning. ••
17. A circular current-carrying wire loop produces a magnetic field. A spinning disk of uniformly distributed charge produces a similar magnetic field. How would you expect the field due to a spinning disk to compare to the field due to a current-carrying wire loop? ••
18. For the bar magnet in Figure P28.18, which of the four locations labeled 1, 2, 3, 4 has the greatest density of magnetic field lines? ••

Figure P28.18

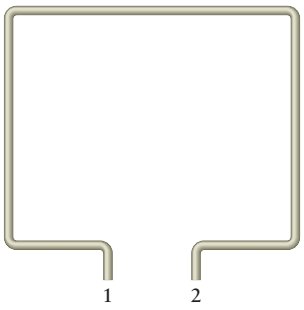
19. A negatively charged particle located at the origin of an xyz coordinate system is spinning clockwise about the x axis (that is, clockwise when you look at the particle while standing somewhere on the positive x axis). What is the direction of its magnetic field at all positions along (*a*) the x axis, (*b*) the y axis, and (*c*) the z axis? ••
20. Figure P28.20 shows a wire segment bent into a half-circle, with the center of curvature labeled P. If the wire of which this segment is a part is extremely long and carries a current I, what is the direction of the magnetic field at P? ••

Figure P28.20



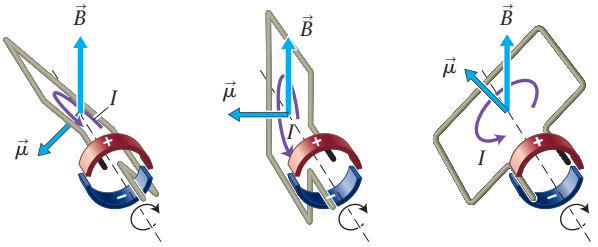
21. In the Bohr model of the hydrogen atom, an electron orbits a nucleus consisting of one proton. Given that the electron and proton are both spinning, describe the types of magnetic interactions you expect to be associated with the hydrogen atom. •••

28.3 Magnetic dipole moment and torque



22. In the space surrounding Earth, the main component of the planet's magnetic field is the field due to a magnetic dipole. In what direction is Earth's magnetic dipole moment? •
23. Earth's magnetic field is thought to be generated by currents in the planet's core. In what direction (clockwise or counterclockwise, when viewed along the rotation axis from north to south) does this current circulate? •
24. The disk shown in Figure P28.24 is charged with electrons and spins counterclockwise when viewed from above. From this perspective, what is the direction of the magnetic dipole moment of the disk? •

Figure P28.24

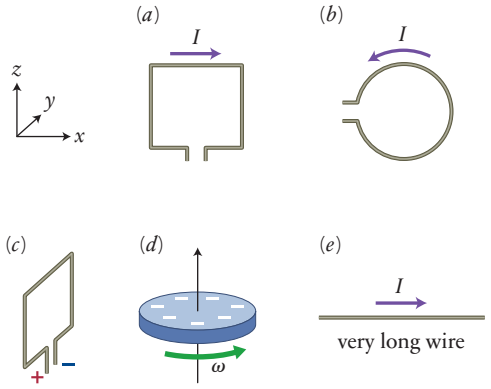


25. In the open wire loop of Figure P28.25, end 1 is held at a higher electric potential than end 2. (*a*) In which direction do electrons move through the loop? (*b*) What is the direction of the current? (*c*) What is the direction of the loop's magnetic dipole moment? ●●

Figure P28.25

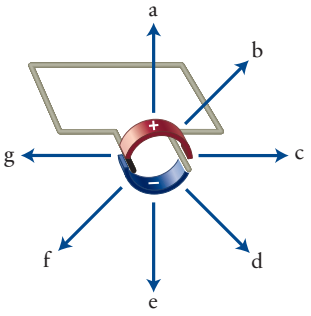
26. Figure P28.26 shows part of the rotation of an electric motor, during which the magnetic dipole moment of the loop points to the left or has some component to the left. If the entire rotation were shown, during what fraction of the rotation would the magnetic dipole moment have some component pointing to the right? ●●

Figure P28.26



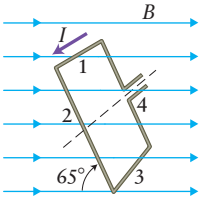
27. A current loop lying in the *xy* plane of an *xyz* coordinate system experiences a torque that is clockwise about the *y* axis when viewed looking down from the positive *y* axis toward the origin. This torque is due to a uniform external magnetic field that points in the positive *x* direction. What is the direction of the current in the loop? ●●

28. A circular current loop lies in the *xy* plane of an *xyz* coordinate system and is initially oriented so that it carries a clockwise current when viewed from the positive *z* axis. It is mounted in such a way that it can rotate about the *x*-axis, which passes through its centre, without affecting the magnitude or direction of the current it carries. How would the loop rotate if the magnetic field is rotated by a small angle about the *x*-axis? ●●



29. Determine the direction of the magnetic dipole moment in each current loop or charge distribution in Figure P28.29. In (*c*), the higher potential end of the loop is marked +, and in (*d*), the disk has a uniform negative charge. ●●

Figure P28.29



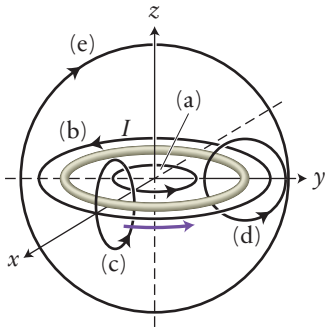
30. (*a*) As the electric motor shown schematically in Figure P28.30 operates, which of the arrows shown could represent the magnetic dipole moment at various instants? (*b*) If there are any arrows that are not possible magnetic dipole moment vectors, state why they are not allowed. ●●

Figure P28.30

31. Figure P28.31 shows a rectangular loop of current in an external magnetic field. Initially the plane of the loop makes a 65° angle with the magnetic field. (*a*) Determine the direction of the magnetic force exerted on each side of the loop. Treat side 4 as though it were one unbroken wire. (*b*) Determine the direction of the torque on the loop about the axis shown as a dashed line. (*c*) What is the orientation of the loop once the system reaches equilibrium? ●●

Figure P28.31

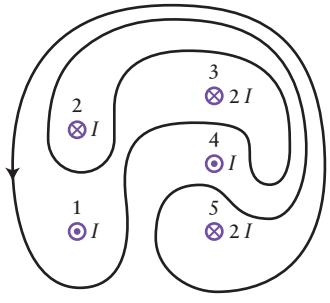
32. Figure 28.10 shows a current loop in an external magnetic field and the forces exerted on the different lengths of the wire. Assume that the loop is attached to a pivot



that allows it to spin (as between Figures 28.10 and 28.11). (*a*) Determine the directions of all the forces on the loop if the current were reversed. (*b*) Is this new situation any different from that shown in Figure 28.11? •••

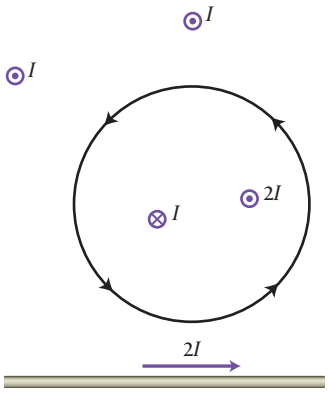
33. If a stationary electron experiences a torque when a proton passes near it, then by the principle of relativity, a moving electron also experiences a torque when passing by a stationary proton. The electron orbiting the proton in a hydrogen atom, therefore, experiences a torque due to its intrinsic magnetic dipole moment. If the electron orbits counterclockwise in the *xy* plane when viewed from the positive *z* axis, what is the direction with which this torque tends to align the electron's intrinsic magnetic dipole moment? •••

28.4 Ampèrian paths



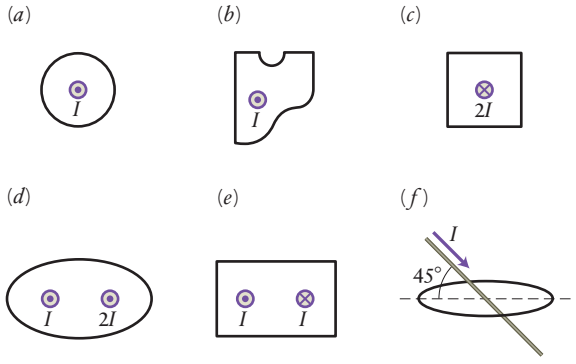
34. The current loop in Figure P28.34 lies in the *xy* plane. For each of the Ampèrian paths (a)–(e), is the line integral of the magnetic field positive, negative, or zero? •

Figure P28.34



35. Wires 1 to 5 in Figure P28.35 carry current either into or out of the page. What is the magnitude of the current enclosed by the Ampèrian path indicated? Is the line integral of the magnetic field around this path, in the direction indicated, positive, negative, or zero? •

Figure P28.35



36. Is the line integral of the magnetic field along the closed path in Figure P28.36 positive, negative, or zero? The direction of integration is shown with arrows on the path. •

Figure P28.36

37. Figure P28.37 shows a series of current-carrying wires, and in each case an Ampèrian path is shown (but without direction). Rank the six cases according to the magnitude of the line integral of the magnetic field calculated along the Ampèrian path shown in each case, smallest value of $\left|\oint \vec{B} \cdot d\vec{\ell}\right|$ first. ••

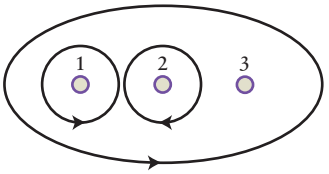


Figure P28.37

38. The line integral of the magnetic field around a certain closed path is initially *L*. The current that penetrates this path is then doubled. What can you say about the current through the path if the new integral of the magnetic field around the closed path is (*a*) *L* and (*b*) 2*L*? ••

39. Each of the wires 1 to 3 in Figure P28.39 carries a current perpendicular to the page. The line integrals of the magnetic field around the three Ampèrian paths shown all have the same positive value. How do the magnitudes and directions of the three currents compare? ••

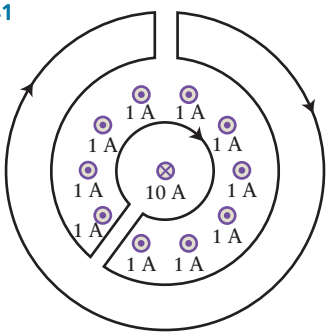

Figure P28.39

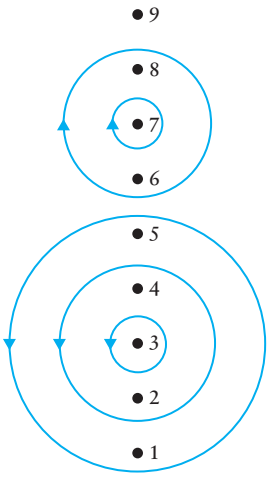
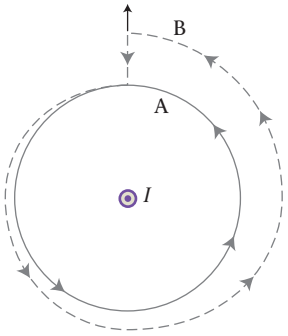
40. A positively charged particle located at the origin of an *xyz* coordinate system spins about the *z* axis, and the spin is counterclockwise when viewed looking down from the positive *z* axis toward the origin. Is the line integral of the magnetic field positive, negative, or zero for an Ampèrian path going (*a*) clockwise around the origin in the *xy* plane when viewed looking down from the positive *z* axis, (*b*) clockwise around the origin in the *yz* plane when viewed looking from the positive *x* axis, and (*c*) clockwise around the origin in the *xz* plane when viewed looking from the positive *y* axis? ●●



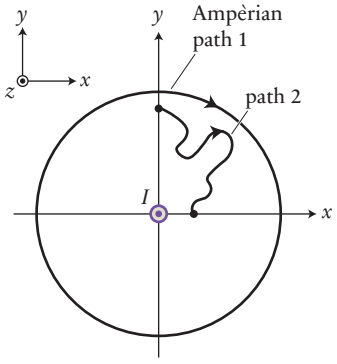
41. Eleven wires and one Ampèrian path are shown in Figure P28.41, with current values and directions as indicated. Is the line integral of the magnetic field along the Ampèrian path shown greater than, smaller than, or equal to zero? ●●

Figure P28.41



42. Figure P28.42 shows magnetic field lines in a certain region. Are there any locations where there must be a current directed into or out of the plane of the diagram? (Consider locations near the numbers on the vertical axis.) At which of the locations 1–9 does a current exist? What is the current direction in each case? ●●

Figure P28.42



43. Figure P28.43 shows two paths (A and B) around a wire that carries current *I*. (*a*) Along which path is the line integral of the magnetic field greater? (*b*) Along which path is the average magnetic field greater? (*c*) Explain how your answers to parts *a* and *b* are consistent. ●●●

Figure P28.43

44. Figure P28.44 shows a very long wire that carries a current *I* in the *z* direction and is centered in the *xy* plane at the position (0, 0). The line integral of the magnetic field along Ampèrian path 1 is $-5.50\ \mathrm{T \cdot m}$. Determine the line integral of the magnetic field along path 2. ●●●

Figure P28.44

28.5 Ampère's law

45. A long, straight, current-carrying wire carries a current of magnitude 3 A. Calculate the magnitude of the magnetic field at a location 35 mm away from the wire. ●

46. A long, straight wire carrying a current of 5 A flowing from left to right is placed above a large, flat sheet through which the current per unit width is 6.0 A/m flows from right to left. Calculate the magnitude and direction of the magnetic force per unit length exerted by the wire on the sheet. ●

47. The magnitude of magnetic field around a straight current carrying wire at a radial point 25 mm is 6 mT. (*a*) At what radial point will the magnitude of magnetic field be 10 mT? (*b*) Calculate the current in the wire. ●

48. Two infinitely long, straight, parallel wires are 6 cm apart, carrying currents 2 A and 4 A, respectively, in the same direction. A third infinitely long, straight wire, parallel to the other two, and carrying a current *I*, lies between the two wires. Find the equilibrium position(s) of this wire. ●●

49. An electron travels at a velocity of 3.0×10^6 m/s parallel to a sheet carrying a current to the right. When a uniform electric field of magnitude 200 V/m is applied, it travels at an angle of 45° to the current in the sheet, with no deflection. What is the magnitude of the current per unit width in the sheet? ●●

50. An electric current is uniformly distributed throughout a long, straight wire that has a diameter of 10 mm. If the current through the wire is 3.0 A, calculate the magnitude of the magnetic field (*a*) 4 mm radially away from the wire center and (*b*) 12 mm radially away from the wire center. (*c*) What must the current be to create a magnetic field of magnitude 10^{-2} T at a distance of 5 cm from the wire center? ••

51. Two large, flat current-carrying sheets are placed parallel to each other, one sheet above the other. The upper sheet carries a current 1.0 A per unit of width to the left, and the lower sheet carries a current 3.0 A per unit of width to the right. Calculate the magnitude of the magnetic field (*a*) between the sheets, (*b*) above the upper sheet, and (*c*) below the lower sheet. (*d*) Draw a diagram showing the direction of the magnetic field in each of these regions. ••

52. An electron travels to the right at 2.5×10^6 m/s between two large, flat sheets that are parallel to each other and to the electron's line of motion. A current per unit width of 8.0 A/m flows to the right through the top sheet. (*a*) What current should flow in the second sheet so that the electron does not deviate from its path? (*b*) If one generates a current of 10 A/m to the right on the second sheet, what is the magnitude and direction of the magnetic force on the electron? ••

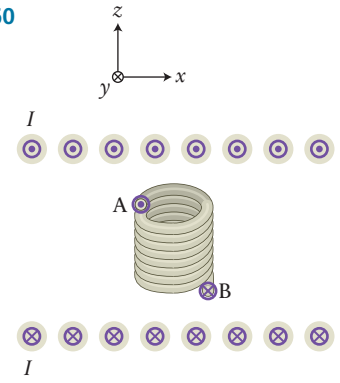
53. A certain wire has a circular cross section of radius R and carries a current I. Suppose that the charge carriers all move along the cylindrical surface of the wire, not through its cross-sectional area. (*a*) Derive an expression for the magnetic field magnitude $B(r)$ as a function of distance r from the center of the wire; check that your expression makes sense for $r < R$ and for $r > R$. (*b*) Make a graph showing the magnitude of the magnetic field in and around the wire as a function of the radial distance r from the center. Mark the wire radius R on your graph. ••

54. An electron travels at a constant velocity at a distance $d_1 = 4.0$ mm above a large sheet of metal that carries a current of 3 A, and at a distance $d_2 = 3.0$ mm below a very long wire that carries a current 0.5 A. The wire is parallel to the sheet, and both currents flow in the same direction. Compute the width of the metal sheet. ••

55. Two large, parallel, current-carrying plates are oriented horizontally and the vertical distance between them is 5.0 mm. The current per unit width in each plate is 100 A/m, and both currents are in the positive x direction. Determine the magnitude and direction of the magnetic force per unit area exerted by the lower plate on the upper plate. ••

56. A coaxial cable carries a current I_{wire} in its inner conducting wire and a current I_{shell} in its outer conducting shell. The radius of the wire is R_{wire}, the distance from the cable center to the inside of the shell is R_{shell}, and the distance from the center to the outer edge of the shell is $2R_{\text{shell}}$. Determine all locations (if any exist) at which the magnetic field magnitude is zero if (*a*) $I_{\text{wire}} = I_{\text{shell}}$, (*b*) $I_{\text{wire}} = -I_{\text{shell}}$, and (*c*) $I_{\text{wire}} = -I_{\text{shell}}/2$. •••

57. A particle is shot at a velocity of 3×10^4 m/s to the right and enters the magnetic field generated by a large, flat current-carrying sheet. The current in the sheet is parallel to the particle's initial line of motion. The particle exits the magnetic field 6.8 cm directly above the location where it enters. (*a*) Is the particle's charge positive or negative? (*b*) If the sheet carries a current of 4 A per unit width, what is the ratio of the charge on the particle to its mass? •••



28.6 Solenoids and toroids

58. A long solenoid having 16 windings per centimeter of length carries a current of 0.8 A. Calculate the magnitude of magnetic field inside the solenoid. •

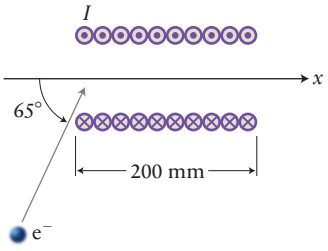
59. Considering the magnetic field produced at the center of solenoid is uniform, one need to produce a magnetic field of magnitude 0.06 T. If the available current that one can use to flow through the windings is 12 A, calculate the number of windings per centimeter the solenoid must have. •

60. A small solenoid is inserted into a larger solenoid (Figure P28.60). The current in the small solenoid is from A to B. (*a*) Determine the initial direction of the magnetic dipole moment of the small solenoid. (*b*) Assuming the large solenoid is fixed in place and the small solenoid is free to rotate, determine the equilibrium direction of the magnetic dipole moment of the small solenoid. •

Figure P28.60

61. A long solenoid with 1000 windings per meter is placed with its central axis parallel to the y axis and 20 mm above a sheet of metal that is 0.5 m wide in the y direction and carries a uniform current of 20 A in the positive x direction. What current must the solenoid carry in order that the magnetic field at its centre is zero? ••

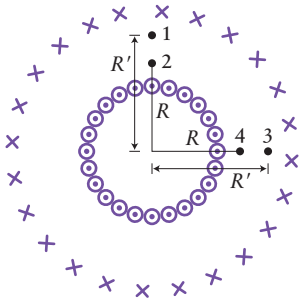
62. A small coil, of area 2 cm^2, carries a current of 1.5 A. The coil is suspended inside a solenoid at an angle of 45° with respect to the magnetic field. The solenoid has 500 turns per meter of length and carries a current of 4.0 A. Calculate the magnitude of the torque exerted on the coil. ••



63. A toroid has 250 square windings carrying a current of 3.0 mA. Each side of each square winding is 50 mm long, and the distance from the toroid center to the inner surface of the windings is 120 mm. What is the magnitude of the magnetic field (*a*) at the center of any square winding, (*b*) midway between the toroid center and the inner surface of the windings, and (*c*) 30 mm beyond the outer surface of the windings? ••

64. If the magnitude of magnetic field produced at a radial distance of 8.5×10^{-2} m from the center of a toroid of 300 windings is equal to the magnetic field produced inside a solenoid, then calculate the number of turns per unit length of the solenoid. Consider the same current flowing through both the solenoid and toroid. ••

65. A current of 10 A flows through a toroid that has 300 circular windings per meter measured along the interior edge of the windings. The radius of each circular winding is 20 cm, and the inner radius of the toroid is 40 cm. Find the magnitude of the magnetic field at 30 cm inside the circular winding. ••



66. An electron is fired into one end of the solenoid in Figure P28.66. Viewed along the positive x axis from a negative x coordinate, the electron enters from below at a 65° angle to the horizontal, just inside the bottom edge of the solenoid. From this viewpoint the solenoid carries a 10-A clockwise current. The solenoid is made from a 33.0-m length of wire, and it has 400 turns along the 200-mm length shown in the figure. (*a*) Ignoring end effects, what is the smallest time interval required for the electron to pass through the solenoid without striking the coils? (*b*) If the electron follows the quickest path through the solenoid as determined from the time interval you calculated in part *a*, how many revolutions does the electron's path make around the solenoid axis? •••

Figure P28.66

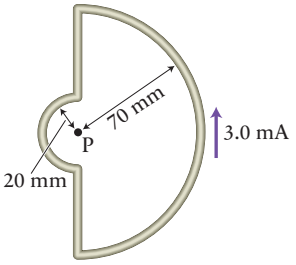
67. You are calibrating magnetic coils for a particle detector. One step involves checking the magnetic field at different positions inside a toroid, and you are asked to measure the field at the positions labeled 1, 2, 3, 4 in Figure P28.67. Your partner, knowing that the magnetic field inside a *solenoid* is uniform, asks why anyone would measure more than one position inside the toroid, which is a solenoid bent into a ring. How can you explain the need to compare the field magnitudes at positions 1 and 2? Why compare the magnitudes at positions 3 and 4? Can you explain to your partner why the magnetic field is not uniform in a toroid even though a toroid is nothing more than a solenoid bent into a donut shape? •••

Figure P28.67

28.7 Magnetic fields due to currents

68. Calculate the magnitude of the magnetic field at the center of a circular arc of radius 25 mm spanning an angle of $\pi/2$ and carrying a current of 3.0 A. •

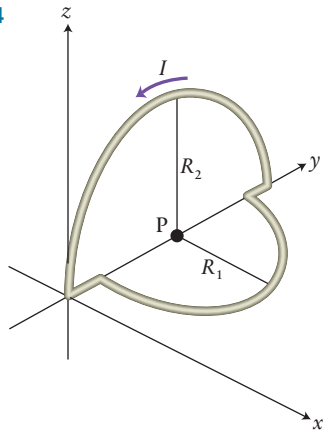
69. A 100-mm section of wire is bent into a circular arc. What must the radius of the arc be for a current of 6.0 A to produce a magnetic field of 7.5×10^{-5} T at the centre of the arc? •



70. Use the Biot-Savart law to determine the magnetic field 70 mm above the center of a loop of wire that has a radius of 0.22 m and carries 3.0 A of current. ••

71. Wire 1, 3.0 m long and of linear mass density 0.010 kg/m, is initially held in place and carries 10 A of current to the right. Very long wire 2 is placed parallel to and 5.0 mm directly above wire 1. When wire 1 is released, it stays in place. What are the magnitude and direction of the current in wire 2? ••

72. The magnetic field a distance z above the centre of a circular loop of radius r carrying current I in the xy plane is $\vec{B} = \frac{\mu_0 I r^2}{2(r^2+z^2)^{3/2}}\hat{k}$. [See problem 28.70] (*a*) Use this result to re-derive the formula for the magnetic field inside a very long solenoid of radius r with n windings per unit length, carrying a current I per winding. [Hint: you need to perform an identical integral to the one required to calculate the magnetic field of a straight wire using the Biot-Savart law.] (*b*) Now replace the very long solenoid with one of arbitrary length L, and find the magnetic field on its central axis, a distance D from its centre. ••



73. In Figure P28.73, point P is the common center of two circular arcs of wire, the larger of radius 70 mm and the smaller of radius 20 mm. What are the magnitude and direction of the magnetic field at P if the current through the wire is 3.0 mA? ••

Figure P28.73

74. A current-carrying wire has been bent into the form shown in Figure P28.74, with a half-circle of radius R_1 lying in the xy plane connected via two straight segments to a half-circle of radius R_2 lying in the yz plane. The current direction is as indicated. If $R_2 = 1.5R_1$, what is the direction of the magnetic field at P, which lies at the common center of the half-circles? ••

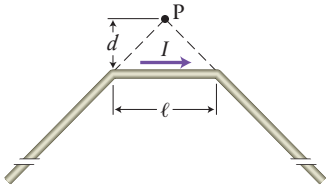


Figure P28.74

75. (*a*) Find the magnetic field produced by a 10-cm section of a wire carrying a 3 A current at a distance 5 cm above its centre. (*b*) Now, find the magnetic field at the centre of a square loop comprising four such sections. •••

76. The horizontal portion of the wire in Figure P28.76 has a length $\ell = 0.100$ m, and position P is a perpendicular distance $d = 30.0$ mm above the center of the horizontal portion. The wire carries a 45.0-A current, and the two slanted portions of the wire are extremely long. Calculate the magnitude of the magnetic field at P. •••

Figure P28.76

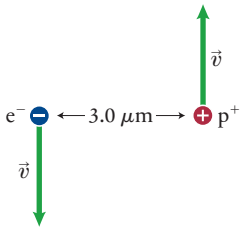
28.8 Magnetic field of a moving charged particle

77. An electron moves in a straight line at a speed of 6.0×10^7 m/s. Calculate the magnitude and direction of the magnetic field at a position 5.0 mm behind the electron and 15 mm below its line of motion. •

78. A proton moves in the positive x direction at 4.00×10^4 m/s. Calculate the magnitude of the magnetic field at the point $(x, y) = (+2.00 \text{ mm}, +1.00 \text{ mm})$ as the proton passes through the origin. •

79. Express the magnetic field due to a uniformly moving charged particle in terms of the electric field of the particle and its velocity. ••

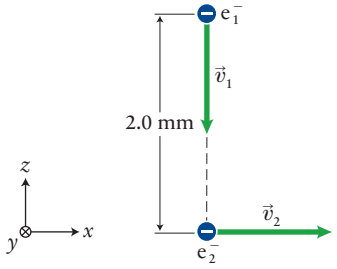
80. Two electrons 1 and 2 move along antiparallel paths separated by a distance of 10 nm, traveling at speeds $v_1 = 4.0 \times 10^7$ m/s and $v_2 = 7.0 \times 10^6$ m/s. What is the magnitude of the magnetic force exerted by electron 2 on electron 1? ••



81. Proton 1, traveling in the negative x direction at speed v_1, is directly below proton 2, which is traveling at speed v_2 at an angle of 45° above the positive x axis. If the protons are separated by a distance r, calculate the magnitude of the magnetic force each proton exerts on the other. ••

82. One runs into trouble when trying to apply Ampère's law to the magnetic field of a moving charge. For instance, what is the current enclosed by an Ampèrian path that encircles the path of the particle? Because of the discrete nature of the charge, any sensible denition is zero most of the time and very large for a brief instant. The magnetic field does not have a similarly abrupt time dependence. One way out is to integrate over time. Show that the magnetic field $\vec{B}$ produced by a charge q moving in a straight line at a constant velocity obeys $\int_{-\infty}^{\infty} \left(\oint \vec{B} \cdot d\vec{\ell} \right) dt = \mu_0 q$. Use a circular Ampèrian path in the plane perpendicular to and centred on the path of the charge. ••

83. The electromagnetic force between two particles, both of mass m, with one having charge $+q$ and the other having charge $-q$ can cause them to orbit in a circle around the centre of the line that connects them. (*a*) Relate their velocities to their separation distance d. (*b*) Without the magnetic contribution to the force, would the velocity at a given separation be larger or smaller? ••



84. An electron and a proton are fired in opposite directions, and at the instant they are nearest each other, their separation distance is 3.0 μm (Figure P28.84). At that instant, the two particles are both moving at 3.0×10^4 m/s but in opposite directions. (*a*) Determine the magnitude and direction of the magnetic force exerted by the proton on the electron at this instant. (*b*) Show that the ratio of the magnetic to electric forces at this instant equals v^2/c_0^2, where $v = 3.0 \times 10^4$ m/s and c_0 is the speed of light. ••

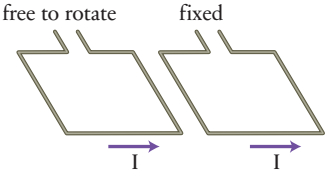
Figure P28.84

85. Two electrons move near each other and at the instant shown in Figure P28.85 are 2.0 mm apart. The speed of electron 1 is $v_1 = 300$ m/s, that of electron 2 is $v_2 = 500$ m/s, and the directions of motion are as shown in Figure P28.85. Determine the magnitude and direction of (*a*) the magnetic force exerted by electron 1 on electron 2 and (*b*) the magnetic force exerted by electron 2 on electron 1. ••

Figure P28.85

86. At $t = 0$, electron 1 is shot out of an accelerator at a speed of 2.0×10^3 m/s. At $t = 1.0$ μs, electron 2 is shot out of the accelerator and travels on a path that is parallel to and 10 mm below the path of electron 1. The speed of electron 2 is 5.0×10^3 m/s. (*a*) At $t = 3.0$ μs, what is the magnitude of the magnetic field at a point that is 3.0 mm ahead of electron 1 and 5.0 mm below it? Assume that the magnetic forces the electrons exert on each other for the 2.0 μs before you make your calculations do not alter the electrons' paths significantly. (*b*) Show whether or not it is valid to assume that the magnetic forces the electrons exert on each other during the interval from $t = 1.0$ μs to $t = 3.0$ μs do not alter the electrons' paths significantly. ●●●

Additional Problems



87. A current loop lies in the *xy* plane, with the current circulating counterclockwise when viewed from the positive *z* axis. Is there a torque on the loop, and if so, in what direction, if a uniform magnetic field is applied along the positive (*a*) *x* axis, (*b*) *y* axis, and (*c*) *z* axis? ●

88. The length of a straight solenoid is 50 cm. If a current of 12 A flows through the solenoid produces a magnetic field of magnitude 0.06 T inside it, calculate the number of windings. ●

89. Two parallel rods having length 12 cm and a separation of 50 cm carry current from left to right. If current through wire 1 is 10 A and through wire 2 is 12 A, calculate the magnitude and direction of the magnetic force per unit length exerted by wire 1 on wire 2. ●●

90. Figure P28.90 shows two square loops of wire. The loop on the right is fixed in place, and the one on the left is free to pivot in any direction. Both loops carry a current that is counterclockwise when viewed from above. (*a*) What is the direction of the magnetic field created by the right loop at the left loop? (*b*) What is the initial direction of the magnetic dipole moment of the left loop? (*c*) How does the left loop rotate? (*d*) After the left loop is allowed to rotate and the system reaches equilibrium, are the magnetic dipole moments of the two loops parallel, antiparallel, or neither? ●●

Figure P28.90

91. A wire segment of 1.0 m and carrying a current of 5.0 A is held in a plane in which it can rotate and translate with little friction. A long wire is fixed parallel to this plane, perpendicular to the 1.0 m wire and 50 mm above its centre. (*a*) Describe how the 1.0 m wire starts to move when a 10-A current is switched on in the long wire. (*b*) Calculate the magnetic force on the 1.0 m wire after static equilibrium is reached. ●●

92. You have a solenoid for which a current *I* per winding produces a magnetic field of magnitude B_1 inside the soleniod. You cut the solenoid open parallel to its symmetry axis. You then carefully bend it open to form a flat sheet of parallel wires and electrically connect the wire ends on the cut edges in a way that allows you to run the same current through every parallel wire. Now a current *I* per wire produces a magnetic field of magnitude B_2 just above the sheet. You have a friend who claims that B_1 must be many times bigger than B_2, because, by cutting the solenoid open, you have allowed the field lines trapped inside the solenoid to escape into an infinite volume. You have another friend who claims that $B_1 = B_2$, because in both setups, the magnetic field can be determined from Ampère's law using the same rectangular path that encloses the same current. Explain why both friends are wrong. ●●● CR

93. You need to design a square toroid such that the magnetic field in the centre of the square windings is 0.0020 T, and the side length of a square winding is 3 cm. The wire you are using can carry a current of at most 0.5 A. The magnetic field anywhere inside the windings must be at least 0.0016 T. What is the minimum number of windings you will need? ●●● CR

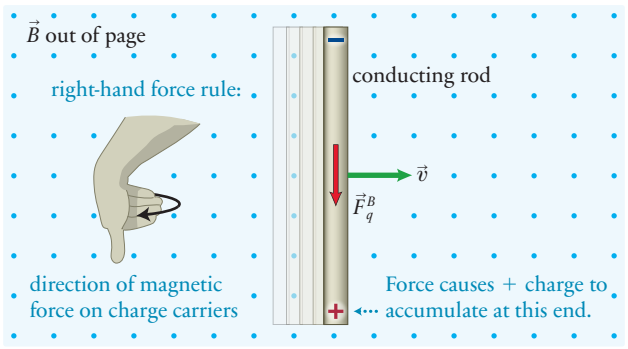
CONCEPTS

QUANTITATIVE TOOLS

Up to now, the only electric fields we have encountered are those that arise from the presence of electrical charges. In this chapter we explore electric fields that accompany changing magnetic fields. As we saw in Chapter 27, constant magnetic fields exert forces on moving charge carriers. Now we discover that there is no fundamental difference between the interaction of changing magnetic fields with stationary charge carriers and the interaction of constant magnetic fields with moving charge carriers. We shall also learn that energy can be stored in magnetic fields. These ideas are harnessed in a wide variety of important applications, from electric motors and electrical power generation to electronic appliances and other everyday devices.



29.1 Moving conductors in magnetic fields

Let's examine what happens when a conducting rod moves with velocity $\vec{v}$ through a magnetic field of constant magnitude B, where $\vec{v}$ is perpendicular to $\vec{B}$ (**Figure 29.1**). Recall from Chapter 27 that a magnetic field exerts a magnetic force on moving charge carriers. That force is proportional to the field magnitude, the amount of charge, and the velocity component perpendicular to the field. The right-hand force rule gives the direction of the resulting force exerted on positive charge carriers.

As the rod in Figure 29.1 moves to the right in the magnetic field, positive charge carriers in the rod experience a downward force. As a result, a positive charge accumulates at the lower end of the rod, leaving behind a negative charge at the other end. (If the charge carriers are negatively charged, they experience an upward force; the end result, however, is still as shown in Figure 29.1.)

Does charge continue to accumulate as the rod moves? No—as charge accumulates, the electric field between the oppositely charged ends of the rod resists further accumulation of charge. Once the opposing force due to the electric field is equal in magnitude to the force exerted by the magnetic field on the charge carriers, the vector sum of the forces exerted on the charge carriers is zero, and no further accumulation of charge takes place. The motion of the rod through the magnetic field thus establishes a charge separation, the amount of which is determined by the magnitude of the force exerted by the magnetic field on the charge carriers.

Figure 29.1 When a conducting rod moves in a magnetic field, positive charge carriers in the rod experience a magnetic force. In the configuration shown, the right-hand force rule tells us that a positive charge accumulates at the bottom of the rod.

CONCEPTS

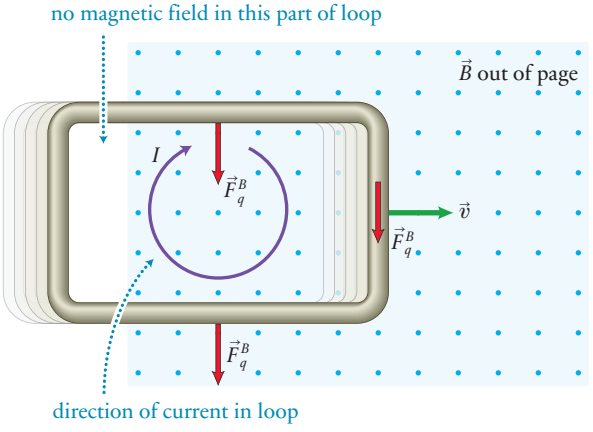
29.1 What happens if the rod in Figure 29.1 moves to the left?

Now consider what happens if, instead of a conducting rod, a conducting rectangular loop moves into a magnetic field (**Figure 29.2**). As the right side of the loop enters the field, its charge carriers move in response to the magnetic force exerted on them. Rather than just accumulating at the ends of the right side, however, the carriers now have a closed path along which to travel. Thus, the magnetic force exerted on the carriers creates a current in the loop. (The carriers in the top and bottom sides of the loop also feel magnetic forces, as shown in Figure 29.2, but because these carriers can't move very far in the vertical direction, we can ignore the effects of these forces.)

The current that arises from moving a conducting loop through a magnetic field can be verified experimentally. **Figure 29.3** shows a simple experiment using a bar magnet and a current meter, which shows both the magnitude and the direction of the current through the wire. When the wire is at rest in the field of the magnet (Figure 29.3*a*), the meter indicates no current. Moving part of the wire to the right causes a counterclockwise current (Figure 29.3*b*); moving the same part of the wire to the left causes a clockwise current (Figure 29.3*c*).

The current that arises from the motion of charged particles relative to a magnetic field is called an **induced current** (as opposed to a "regular" current caused by a potential difference between, for instance, the terminals of a battery).

Figure 29.2 Direction of current in a rectangular loop moving into a magnetic field. Magnetic forces exerted on the charge carriers in the loop cause them to move around the loop.



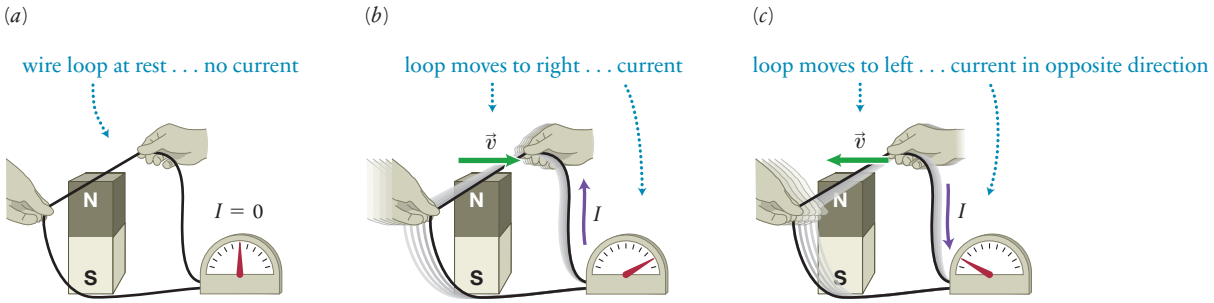


Figure 29.3 Experimental observation of induced current.

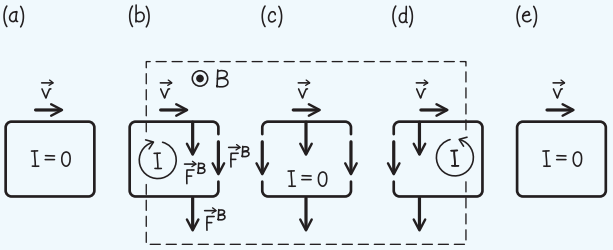
EXAMPLE 29.1 A rectangular loop passing through a magnetic field

Consider a rectangular conducting loop traveling from left to right through a magnetic field as shown in **Figure 29.4**. During this motion, at what positions *a*–*e* is a current induced in the loop, and what is the current direction at each position?



1 GETTING STARTED As the loop moves through the magnetic field, the charge carriers in the loop experience a magnetic force. For each of the five positions I need to determine whether or not the magnetic force causes the carriers to flow around the loop. To simplify the problem, I assume that only the positive charge carriers are free to move.

2 DEVISE PLAN The direction of the magnetic force exerted on the charge carriers is given by the right-hand force rule. To see if there is a current in the loop, I'll sketch the loop in each position and determine the direction of the magnetic force exerted on the charge carriers in each side of the loop.

3 EXECUTE PLAN No matter where along the loop perimeter the carriers are, they always move to the right with the loop, and so curling the fingers of my right hand from $\vec{v}$ to $\vec{B}$, I see that the magnetic force exerted on them is always toward the bottom of the page. I draw this force for each side of the loop that is inside the magnetic field (**Figure 29.5**). The magnetic forces exerted on the top and bottom sides of the loop cause no current through the loop because the charge carriers in these sides have essentially no mobility in the direction in which $\vec{F}^B$ is exerted.

In position (*a*), with no part of the loop in the magnetic field, no magnetic force is exerted on any of the carriers, and therefore no current is induced. When the right side of the loop passes into the magnetic field but the left edge has not yet entered (*b*), the magnetic force exerted on the charge carriers in the right side of the loop causes a clockwise current around the loop. Once the entire loop is in the magnetic field (*c*), the magnetic force exerted on the carriers in the left side drives a counterclockwise current equal in magnitude to the clockwise current driven by the magnetic force exerted on the carriers in the right side. The combined effect is that no current is induced. In position (*d*), only the left side of the loop is in the field, and the magnetic force exerted on those charge carriers induces a counterclockwise current around the loop. When the loop has passed out of the magnetic field (*e*), once again no magnetic forces are exerted on the carriers and therefore no current is induced. ✔

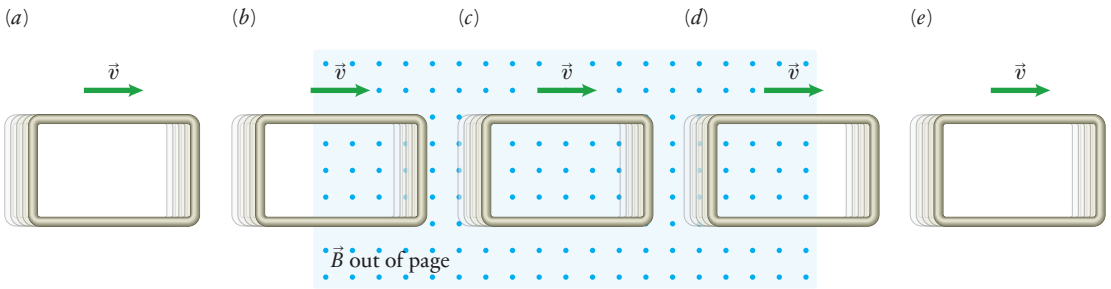


Figure 29.5

4 EVALUATE RESULT In position (*b*) I have the same situation as in Figure 29.2, so it is reassuring that my answer is the same. If I ignore any dissipation of energy, the initial and final states are the same. Therefore it makes sense that the effect of moving the loop through the field is zero: The charge carriers first move clockwise as the loop moves into the field, then move counterclockwise as the loop moves out of the field.

(Continued)

Figure 29.4 Example 29.1.

CONCEPTS

I assumed that only the positive charge carriers can move. Had I assumed that the negative charge carriers are free to move, my answer would not have changed. Even though the direction of motion of the negative charge carriers is opposite the direction of motion of the positive carriers, the current is still in the directions shown in Figure 29.5 because current direction is *defined* as the direction in which positive charge carriers move.

29.2 In Example 29.1, suppose the loop is stationary and the source of the magnetic field is moved to the left such that their relative motion is the same. Do you expect there to be a current through the loop?

29.2 Faraday's law

As Example 29.1 indicates, a current is induced through a conducting loop when the loop moves into or out of a uniform magnetic field, not when the loop is entirely in or entirely out of the field. In other words, a current is induced when the area of the loop inside the field changes—that is, when the magnetic flux passing through the loop is changing with time.

Experiments show that the rate at which the magnetic flux through the loop changes affects the magnitude of the induced current. As illustrated in Figure 29.6, moving the loop through the magnetic field faster, which causes a greater rate of change in the magnetic flux through the loop, produces a greater induced current.

As we learned in Chapters 6 and 14, physical phenomena do not depend on the reference frame in which we observe them. Indeed, if the change in magnetic flux through a conducting loop is responsible for inducing a current, it should not matter whether the loop is moving in a constant magnetic field or the source of the magnetic field is moving and the loop is stationary. Only the motion of one relative to the other matters. Experiments confirm that the same current is measured in the loop no matter whether the loop moves to the right with speed v or the source of the magnetic field moves to the left with speed v (Figure 29.7). In fact, current is induced in a stationary conducting loop in any region where a magnetic field is changing, even if the source of the magnetic field is stationary and the magnitude of the magnetic field is changing.

Figure 29.6 The speed at which a conducting loop is moved through a magnetic field affects the magnitude of the induced current.
